A body exposed in the environment represents a trophic resource for necrophagous organisms. Faunal succession and free access to the corpse are influenced by environmental factors and by the state of the body remains. Instead, in the case of buried corpses, few organisms are able to reach and process these remains. To study which insect species are responsible for underground degradation, we performed experiments by burying some boxes with meal at different soil depths. Two experimental areas in NE Italy were chosen: one in a hilly landscape without agricultural activities, the other in a zone with high human exploitation. In these sites both grassland and deciduous forest were tested. The buried boxes were collected at different times and insect specimens were identified. Diptera belonging to 8 families were found: Stratiomyidae, Phoridae, Sphaeroceridae, Piophilidae, Anthomyiidae, Muscidae, Sarcophagidae and Calliphoridae. The most abundant being the Phoridae, with *Diplonevra funebris* the most abundant species (80% of the total). Calliphoridae and Sarcophagidae were present only in the non-buried boxes. Several Coleoptera were also collected: Staphylinidae were found at all the depths, both as adults and larvae, while Silphidae and Dermestidae were collected only in the non-buried boxes.

Bionomic of *Anopheles stephensi* Liston in a malarious area, Hormozgan province, southern Iran, 2002

H Vatandoost, MA Oshaghi, MR Abaie, M Shahi, F Yaghoobi, M Baghaii, AA Hanafi-Bojd, G Zamain
School of Public Health & Institute of Public Health Research, Tehran University of Medical Science, P.O.Box: 6446-14155, Tehran, Iran. e-mail:hvatandoost@yahoo.com

A total of 25000 malaria cases has been reported from Iran. From which Hormozgan province has a higher API comprising 30% of total cases. *Anopheles stephensi* is an important malaria vector in Iran. This species has two activity peaks, one in spring and another in autumn in the region. Mosquitoes of this species prefer to rest and feed indoors. Larval habitats are quite different. All three known biological forms of this species; type, intermediate, and *Mysorensis* occur in the province. Insecticides susceptibility tests showed susceptibility to bendiocarb, propoxur, malathion, fenitrothion, deltamethrin, permethrin, cyfluthrin and lambdacyhalothrin, but resistant to DDT and low level of tolerance to dielin. Larvicidal activity of malathion, fenitrothion, temephos and chlorpyrifos at diagnostic dose exhibited susceptibility to all larvicides except to fenitrothion. The irritability tests to pyrethroid insecticides showed a high level of irritancy to permethrin and lambda-cyhalothrin, but low irritancy to cyfluthrin and deltamethrin.

Identification of Australian carrion-breeding blowflies using multiple gene regions

J Wallman, M Dowton, R Leys, L Nelson
Institute for Conservation Biology, School of Biological Sciences, University of Wollongong, NSW, 2522, Australia, jwallman@uow.edu.au

"Carrion-breeding blowflies have well recognised forensic importance. Their period of development on a corpse can help indicate the time elapsed since death. The applied importance of these flies makes their reliable identification a necessity. Mitochondrial DNA markers may help identify immature blowflies whose identity is difficult or impossible to confirm morphologically. DNA recognition of Australian blowflies poses a special challenge, because their relatively recent speciation makes it necessary to focus on highly variable gene regions for their molecular separation. Thirty-four blowfly species from southern and north-eastern Australia were included in our study, representing almost all species currently known or suspected to be carrion-breeders. Phylogenetic analyses of DNA sequences from the mitochondrial genes COI, COII and ND4 were conducted using parsimony, maximum likelihood and Bayesian methods. In general, these genes provide a powerful tool for the identification of the immature stages of Australian carrion-breeding blowflies. However, in some cases mtDNA sequence divergence is very low, even though statistical support for the separation of individual specimens may be high. Since this leaves open the potential for misidentifications, we have also investigated the applicability of variable nuclear gene markers, the ITS1 and ITS2 regions, to the molecular identification of very closely related species."

Emerging Vectors in Urban Wetland Ecosystems

WE Walton
Dept. of Entomology, Univ. Of California, Riverside, CA, 92521, USA, william.walton@ucr.edu

The use of constructed treatment wetlands for water quality improvement, water reclamation, wetland habitat supplementation, and other goals is increasing worldwide. Man-made wetlands can provide a cost-effective alternative to conventional water treatment facilities for municipal wastewater and are one of several technologies being used to improve the water quality of urban/suburban storm water runoff. A drawback of man-made wetlands used to treat municipal and storm water in areas of rapid human development is the juxtaposition of developmental sites for pathogen-transmitting and pestiferous mosquitoes with human development and peridomestic reservoirs of the causative agents of disease. Management practices and design features thought to be important for water quality improvement often enhance mosquito production. Vector control activities can be impeded by the management practices used to fulfill simultaneously the diverse goals for multipurpose constructed wetlands. The production of native mosquito species which are known to be vectors of the causative agents of disease remains a concern at man-made wetlands and at many best management practices for treating non-point pollutants in the urban environment. The introduction of novel pathogens and vectors into urban landscapes containing treatment wetlands creates new challenges for agencies charged with protecting public health.

The response of mosquito populations to conservation, rehabilitation and construction of urban wetlands at Sydney Olympic Park, NSW, Australia.

CE Webb, KJ Willems, PH Johnson, RC Russell.
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead NSW 2145, Australia;
cameronw@icpmr.wsahs.nsw.gov.au

Homebush Bay once contained diverse, yet degraded, estuarine and freshwater wetlands that were either removed or rehabilitated in conjunction with the Sydney Olympic Park urban redevelopment. In addition, extensive freshwater wetlands were constructed for water storage, waste-water treatment, wildlife conservation and aesthetic enhancement. Over 50 mosquito species belonging to 8 genera have been identified from the area, and the potential increases in nuisance biting and public health risks following redevelopment have been a major concern for local authorities. Poor tidal flushing of the estuarine wetlands resulted in unusually large populations of the saltmarsh mosquito, *Ochlerotatus vigilax*, a known virus vector and biting pest, but populations have declined following the commencement of pesticide application and wetland remediation programs. *Culex annulirostris* and *Coquillettidia linealis* are two freshwater pest/vector species that were abundant but declined with the redevelopment. Although the constructed freshwater wetlands were designed to minimise mosquito populations, they have become more productive with increasing vegetation density. Additionally, domestic species *Ochlerotatus notoscriptus* and *Culex quinquefasciatus* are expected to increase with the further residential development. This presentation will provide commentary on the response of mosquito fauna to changes in estuarine and freshwater habitats influenced by the Sydney Olympic Park urban development.

Using vector-borne disease outbreaks to guide ecosystem interventions.

A Cook, A Jardine, P Weinstein
M431, School of Population Health, The University of Western Australia, 35 Stirling Highway, Crawley, WA, 6009, Australia, philipw@sph.uwa.edu.au

There is close association between ecosystem health and human health, exemplified by disease outbreaks that result from ecosystem disruptions. Historical examples include the massive mortality from yellow fever and malaria during construction of the Panama Canal, and more recently the emergence of Lyme disease in ecosystems with decreased biodiversity. In order to decrease the burden from such vector-borne diseases, it is necessary to identify disrupted ecosystems for early remediation. Human health is generally subject to the most widespread and comprehensive surveillance compared to other proposed 'indicators of ecosystem health'. Thus we suggest that human disease outbreaks are one of the most useful and practical bioindicators of the health of an ecosystem. Indeed, many subtle ecosystem disruptions are often only identified as a result of detailed epidemiological investigations following an anomalous increase in human disease incidence detected by routine surveillance mechanisms. Outbreak data can act as a pivotal warning system for ecosystem disruption and can be used to identify interventions for preservation of ecological (and ultimately human) health. Using this approach, appropriate strategies for intervention and remediation can be introduced at an earlier stage than would be possible based solely on environmental monitoring, thereby improving ecosystem health and human health concurrently.

Genotyping human and other vertebrate DNA from maggot gut contents: practical considerations

JD Wells, JG Linville, J Hayes
Dept Biology, West Virginia U, Morgantown, WV 26506, USA, jdwells@mail.wvu.edu

Genetic analysis of maggot gut contents may aid a death investigator. We performed experiments aimed at defining procedures and conditions that will allow such an analysis to succeed. Calliphorid larvae were fed on beef, pork, rat, dog, cat, sheep, rabbit, deer, and human tissues. Larvae were then harvested at a range of developmental stages. Conventional forensic DNA typing procedures were performed on larval gut DNA extracts. The effects of maggot development, specimen preservation technique, larval starvation, and transfer of a feeding larva to a new food type, on recovery of the correct food genotype were examined. PCR amplification involved new cytochrome b primers specifically for vertebrate and not insect DNA, and a commercial STR kit. 20% bleach destroyed surface contamination without interfering with the analysis of internal tissues. Larvae manually removed from food or naturally postfeeding were unsuitable for this analysis after 24 hr off the food. For larvae transferred between food types, both the original and second food genotype could be recovered 46 hr following transfer if specific primers were used. Our methods failed with formalin-preserved specimens. However for all other preservation strategies STR and mtDNA types were obtained from at least some specimens after six months of storage.

Cellular and molecular immunology of the tick-host interface: implications for pathogen transmission

SK Wikel
"Center for Microbial Pathogenesis, School of Medicine, University of Connecticut Health Center, 263 Farmington Avenue, MC3710, Farmington, CT, 06030, USA; swikel@up.uchc.edu"

Complex immunologic interactions occur at the tick-host interface. Tick feeding stimulates host innate and specific acquired immune responses to limit blood meal acquisition. In response to host defenses, tick saliva contains molecules that counteract host immunity. Tick infestation suppresses lymphocyte proliferation, polarizes/modulates cytokine responses, reduces adhesion molecule/integrin expression, modifies antigen presentation, and inhibits cytokine action. The cellular and molecular bases for these phenomena are being defined and multiple diverse pathways for achieving the same end point of immunomodulation are being characterized. The earliest stages of specific T-lymphocyte responses are being analyzed. Genomic and proteomic approaches are used to identify the molecules responsible for modulation of host immune defenses. Tick salivary gland gene expression is being characterized during the first few hours of feeding, and salivary gland molecules of interest are being cloned, expressed and their biological activities identified. Emerging from these studies is a picture of a web of interactions essential for successful blood feeding and transmission of infectious agents that is far more complex than initially envisioned.

Genomics and the development of vaccines against ticks and tick borne disease

P Willadsen, M Hope
"CSIRO Livestock Industries, 306 Carmody Rd., St Lucia, Queensland, Australia, 4067; Peter.Willadsen@csiro.au"

Whole genome sequences of major tick borne disease organisms are available or in progress. Sequencing of the first tick genome will commence soon. Host microarrays allow the dissection of the response to tick or pathogen infestation in a novel way. However, analysis of this deluge of information remains problematic. The rate-limiting step in vaccine development typically remains the assessment of candidate antigens and delivery systems in animals. Genomic information to be useful must be filtered to select a small number of candidates from a plethora of choices. Experience with *Boophilus microplus,* other tick species as well as *Anaplasma marginale* suggests that few highly effective antigens have yet been discovered and the reason for the efficacy of those remains obscure. Other, often less efficacious antigens identified to date fall principally into a few biochemical classes while many other potential antigen classes remain unexplored. The effective use of genomic information will demand a greatly enhanced understanding of the biology of vaccination than is currently available.

Seasonal studies on the influence of clothing and wrapping on carcass decomposition and arthropod succession.

JA Kelly, TC van der Linde, GS Anderson.
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein, 9300, South Africa, kellyja@telkomsa.net

Six pig (*Sus scrofa* L.) carcasses, three wrapped and clothed carcass and three wrapped and naked, were sampled i) daily ii) after five days and iii) after ten days. Two more carcasses, one naked and not wrapped, and one clothed but not wrapped were sampled daily as controls. Differences in decomposition between the clothed or wrapped carcasses included the distribution and size of maggot masses and significant delay in ying out of the carcasses for all seasons. The maggot masses were primarily dominated by *Chrysomya marginalis* (Wiedemann) and *C. albiceps* (Weidemann), in autumn and summer. *Chrysomya chloropyga* (Weidemann) and *Calliphora vicina* Robineau-Devoidy in winter, with *C. chloropyga* and *C. albiceps* in spring. There was no delay in oviposition except in winter where a five day delay occurred on the wrapped carcasses. Extremely high internal temperatures in the warmer seasons caused significant maggot mortality on the wrapped carcasses. The predation of *C. marginalis* maggots by *C. albiceps* maggots was observed in autumn. In summer, maggot masses of these species were observed in separate groups. The coleopteran community was dominated by *Thanathopilus micans* L. larvae, succeeded by *Dermestes maculatus* De Geer, larvae. Adult *D. maculatus* and *Necrobia rufipes* De Geer, were present on the carcasses throughout all seasons.

Ectoparasites and arthropod-borne parasites of brown rat, *Rattus norvegicus*, in Ahvaz, southwest Iran

EB Kia, Z Telmadarraiy, H Vatandoost, A Farahnak, MM Homayouni, M Satvat, M Jedari, F Kasiri
School of Public Health & Institute of Health Research, Tehran University of Medical Sciences, P.O.Box: 6446-14155, Tehran, Iran, eshratkia@yahoo.com

Arthropods play an important role in the transmission of infectious agents to human and animals, such as rodents. Ahvaz, southwest Iran, is encountered with high density of rodents, especially *R. norvegicus*. In this study, 72 *R.norvegicus* were captured from different sites of Ahvaz, using live traps. Their ectoparasites were collected and identified. Thin and thick blood smears were prepared. After dissection of rats, their different organs were examined for any endoparasites, applying specific techniques. In general ectoparasites comprised 2 species of flea, *Xenopsylla astia* and *X. nubica*, 1 species of louse, *Polyplax spinula* and 1 species of mite *Laelaps nuttalli*. Among endoparasites, 9 species utilize arthropods as vector or intermediate host in their indirect life cycles. These included 1 species of protozoan parasite, *Trypanosoma lewisi* and 8 species of helminth parasites. The potential risk of each of these identified species to the health of human and animals will be discussed.

Applications of GIS and remote sensing for surveillance and control of mosquito borne diseases

U Kitron
University of Illinois, Urbana, IL 61801, USA, ukitron@uiuc.edu.

The risk of transmission of mosquito borne diseases depends on the spatial distribution of vector species in relation to the distribution of human hosts and, in case of mosquito-borne zoonoses, the distribution of vertebrate reservoir hosts. These distributions and temporal changes in these spatial patterns depend on environmental and climate/weather conditions. Satellite imagery provides means to gather vast amount of landscape/landcover and meteorological data that are proximate determinants of vector distribution and risk of disease transmission. Geographical information systems allow for the integration of environmental, entomological, epidemiological and demographic data and provide a framework for surveillance and control on scales ranging from local health departments and mosquito control districts to national and international programs. Products of applications of these tools and quantitative analysis of spatial data include data management tools, disease risk maps, and decision making tools for location and time of interventions. Examples from studies in the U.S. Israel, Trinidad and Kenya will be presented, including malaria cases in relation to *Anopheles* larval sites in Trinidad and Israel, dengue and dengue haemorrhagic fever in Trinidad, eastern equine encephalitis outbreaks in Michigan, USA, and La Crosse encephalitis transmission and the effect of introduction of *Aedes albopictus* in Illinois, USA.

Novel mosquito traps: can they control moquitoes

DL Kline
USDA-ARS, CMAVE,1600 SW 23rd , Gainesville, FL, USA, dkline@gainesville.usda.ufl.edu

A diversity of commercial traps for mosquito control have become available during the past five years. Most are marketed to homeowners. Many models have been evaluated in a large outdoor screened enclosure against two species (*Aedes aegypti* and *Ochlerotatus taeniorhynchus*) of laboratory reared mosquitoes to determine their relative efficacy. Several models were selected for field testing against natural populations. Ongoing research is trying to answer the question: Can mosquitoes be trapped out? Different management strategies are being evaluated, e.g. control potential on isolated islands versus urban/suburban residential settings. In urban/residential settings traps are being evaluated as a protective barrier around a city block and in individual yards. Preliminary results indicate that protective trap barriers provide excellent control (>90%) on isolated islands, but only moderate (50% reduction) control in urban/suburban areas. A single trap in a single yard provided no measurable mosquito control.

The mode of action of deet, SS220, and Bayrepel® arthropod repellents against *Aedes aegypti*, *Anopheles stephensi*, and *Phlebotomus papatasi*.

JA Klun, A Khrimian, M Debboun
USDA, ARS, 10300 Baltimore Ave. Beltsville, MD, 20705, USA, klunj@ba.ars.usda.gov

Laboratory bioassays were conducted with human subjects using six-celled K&D modules and the known arthropod repellents, N,N-diethyl-3-methylbenzamide (Deet), (1S, 2'S)-methylpiperidinyl-3-cyclohexene-1-carboxamide (SS220) and 2-(2-hydroxyethyl)-1-piperidine carboxylic acid 1-methylpropyl ester (Bayrepel) against *Aedes aegypti* (Linnaeus), *Anopheles stephensi* Liston mosquitoes and the sand fly, *Phlebotomus papatasi* which are vectors of human diseases. When five females of each species were simultaneously exposed to one half repellent-treated ($4.8 \times 10^{-2} \mu mol/cm^2$) and one half untreated skin beneath the opening of a 3x4 cm cell, they bit exclusively on untreated skin. When treated and untreated skin was covered with cloth to preclude tactile contact with skin surfaces, the insects bit only through cloth covering untreated skin. The tests proved that each species was exquisitely capable of avoiding the compounds in their close-range feeding behavior and this was accomplished by olfactory chemical sensing. When cloth, untreated and repellent treated, was placed over the skin all species avoided the compounds and fed through the cloth only where repellent was absent. In the presence of any the three repellents within a cell, biting responses were reduced by about 50% relative to controls. Thus, besides inhibiting feeding on repellent-treated skin, the compounds also exhibited spatial-repellent activity.

Key issues in advancing the sterile insect technique for African malaria vectors

BGJ Knols, B El-Sayed, MQ Benedict, C Malcolm, H Bossin, A Robinson
International Atomic Energy Agency (IAEA), A-2444, Seibersdorf, Austria; Tropical Medicine Research Institute, Khartoum, Sudan; CDC, Atlanta, USA; Queen Mary University, London, UK;

Pilot projects that assessed the feasibility of the sterile insect technique (SIT) against Anopheles mosquitoes were conducted in El Salvador in the 1970s. Though on a relatively small scale, these trials demonstrated that sterility could be induced in a wild mosquito population through releasing (chemo)sterilized males. Since then, major scientific advances merit a renewed look at SIT and its applicability in the African context. We describe the R&D phase currently underway in Sudan and Austria, to develop appropriate mass-rearing systems and sterilization procedures. The salient features of such releases, also in relation to the use of transgenic approaches, will be discussed. These include colonization and mass rearing, (genetic) sexing, mosquito fitness and release mechanisms.

The influence of burning on the decomposition and insect succession of pig carcasses.

JH Kolver, TC van der Linde, MW Mansell
Department of Zoology and Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300, South Africa, KolverJH.sci@mail.uovs.ac.za

Recent casework raised the question whether burning has an influence on the decomposition and insect succession of bodies. This was investigated by dousing three pig carcasses with different volumes of petrol and burning them to different degrees (Slight = 1.5L Medium =5L, Heavily = 10L). The insect succession onto these carcasses was compared to a control carcass. The control carcass decomposed at the fastest rate with the heavily burnt carcass at the slowest rate. Adult insects comprised the following: At the control carcass Diptera (60.8%), Coleoptera (29.9%) and Hymenoptera (8.8%). At the slightly burnt carcass Coleoptera (55.8%), Diptera (38.6%) and Hymenoptera (5.4%). The dominant orders at the medium burnt carcass were Coleoptera (38.5%), Diptera (33.3%) and Hymenoptera (28%). At the heavily burnt carcass Coleoptera (51.4%) and Diptera (28.6%) were dominant. Hymenoptera (18.7%) did not have a direct influence on decomposition, since they functioned as predators. *Chrysomya albiceps* was the dominant Calliphoridae species at the control and medium burnt carcasses and *Chrysomya marginalis* at the slightly and heavily burnt carcass. Representative samples of larvae collected during decomposition revealed that *C. albiceps* larvae preferred to feed underneath the carcasses, with *C. marginalis* larvae feeding mostly inside and at the top of the carcasses.

The study of excito-repellency phenomenon of *Anopheles stephensi* exposed to nets impregnated with cyfluthrin

H Laddoni, H Alipur, MR Abai,
Department of Medical Entomology, School of Public Health, Tehran University of Medical Sciences, ladani@tumssph.com

The excito-repellency phenomenon is occurred in the vector population following the application of definite insecticides. Based on the field observation, in relation to residual spraying operation, the excito-repellency phenomenon may led to behaviouristic changes of the mosquitoes as diversion either to new hosts or other unsprayed shelters. This occurrence may lead to failure in control program. At these conditions, the mosquitoes leave the sprayed houses to either unsprayed or outdoor shelters before picking up the lethal dose. The result of this investigation will be useful for planning of the control program in the country. For the first time, the standard design of excito-repellency (ER) test box was made of aluminum. The laboratory test was carried out with cyfluthrin treated nets against *An.stephensi* (Beech strain). The result showed that the tendency of the mosquitoes to long resting on the netting of exposure chamber was decreased at high dosage of insecticide, and tried to leave the exposure chamber toward the exit trap. The mean of the feeding rate was least at higher dosage in comparison of lower one.

Human behaviors and environmental factors elevating the risk of exposure to *Ixodes pacificus* nymphs in a hardwood forest

RS Lane, DB Steinlein, J Mun , M Peribañez-Lopez
Division of Insect Biology, 201 Wellman Hall, University of California, Berkeley, California 94720, U.S.A, blane@nature.berkeley.edu

The nymph of the western black-legged tick, *Ixodes pacificus*, has been implicated as the primary vector of the Lyme disease spirochete, *Borrelia burgdorferi*, in northwestern California. In 2002 and 2003, six human behaviors and environmental factors were evaluated as potential risk factors for acquiring nymphal ticks in a dense woodland in this region. The prevalence of *B. burgdorferi* and the causative agents of human anaplasmosis (*Anaplasma phagocytophilum*) and human monocytic ehrlichiosis (*Ehrlichia chaffeensis*) also were determined in nymphs that had been collected from subjects or by agging leaf litter. Time-adjusted tick-acquisition rates demonstrated that sitting on logs was the riskiest behavior followed, in descending rank, by gathering wood, sitting against trees, walking, stirring and sitting on leaf litter, and sitting on litter. The number of ticks acquired appeared to be unrelated to the type of footwear worn. Nymphal ticks were active throughout the daytime over a wide range of micrometeorologic conditions. Overall, about 3-4% of nymphs were infected with *A. phagocytophilum* and *B. burgdorferi*, regardless of the collection method, versus none with *E. chaffeensis*. Co-infection with *B. burgdorferi* and *A. phagocytophilum* was detected for the first time in this life stage of *I. pacificus*. The public health implications of these findings will be discussed briefly.

Genetically modified mosquitoes: a real world view

GC Lanzaro ADDRESS

The concept of controlling mosquito-borne diseases via the development and implementation of genetically modified strains has been under serious consideration since the early 1990's. Although this idea has been met with great enthusiasim in some quarters there remains substantial skepticism in others. The general concept and progress toward the development of such a strategy will be presented. Numerous roadblocks to the development of a GM mosquito plan remain, including (i) lack of gene drivers, (ii) lack of robust effector molecules and mechanisms to manipulate their expression, (iii) poor efficiency of transgenesis, (iv), and (v) no consideration of logistical problems associated with implementation in the field. These will be presented and prospects for overcoming them discussed. Aspects of the ecology and population genetics of targeted species will be discussed as they relate to the successful release and establishment of GM mosquitoes in nature.

Reverse chemical ecology: chemical prospecting of mosquito attractants and repellents

WS Leal, Y Ishida, A Cornel
Department of Entomology, University of California-Davis, Davis CA 95616, USA, wsleal@ucdavis.edu

For a few decades, chemical ecologists have been utilizing insect antennae as the sensing element or biodetector, in electroantennogram (EAG) and gas chromatography-electroantennographic detection (GC-EAD) assays for the identification of minute amounts of pheromones and other semiochemicals. The "molecular" equivalent of these electrophysiology-based "short cut bioassays" is the screening of attractants and repellents based on their binding affinities to odorant-binding proteins (OBPs). OBPs assist hydrophobic semiochemicals to cross an aqueous barrier in the insect sensilla (sensillar lymph) and reach odorant receptors (ORs). Both OBPs and ORs contribute to the high specificity of the insect olfactory system by forming two layers of filters. Although binding per se does not necessarily imply a physiological function, test compounds that do not bind to OBPs can be eliminated from further behavioral studies as they will never "see" the receptors. Reverse chemical ecology is a protein-based approach that requires the full identification of OBPs, cDNA cloning, functional expression of OBPs, and binding assays. In this presentation, we will discuss the latest development of a NIH-funded project* aimed at the development of better attractants and repellents for *Culex* species, the principal vectors of West Nile Virus.* NIH-National Institute of Allergy and Infectious Diseases (1U01AI058267-01).

Developing methodologies for a fungal biopesticide against *Boophilus* microplus, the cattle tick

DM Leemon, NN Jonsson, DJ Merritt
Animal Research Institute, Locked Mail Bag No 4, Moorooka, QLD, 4105, Australia, diana.leemon@dpi.qld.gov.au

The Queensland department of primary industries and fisheries has been investigating fungal biopesticides for livestock ectoparasites as part of a wider strategy to reduce the reliance upon chemicals in livestock industries. Fungal biopesticides have been available for the control of agricultural and horticultural pests for over thirty years and methodologies and accepted protocols for the development of these fungal biopesticides are now well established. Current work with the cattle tick has shown that livestock pests present additional challenges, some of which are due to the inability to conduct *in vitro* assays on obligate parasites, the cost of *in vivo* experiments using animals and the different environments the fungus must operate in when invading the parasitic and free-living phases. In addition, the development of formulation and application methods suitable for penetrating an animal's hair coat and delivering a lethal dose of spores to ticks present further challenges. Solutions to these problems have sometimes been obvious and straightforward but mostly have been arrived at slowly and painstakingly. We have concluded that the development of methodologies for fungal biopesticides of livestock ectoparasites is a multidisciplinary exercise requiring a thoughtful balance of appropriate *in vitro* bioassays with on-animal investigations.

Increased densities of vector mosquitoes in anthropogenic environments in the Kapiti region in New Zealand and potential ecological mechanisms as to why

PT Leisnham
Department of Public Health, Wellington School of Medicine & Health Sciences, PO Box 7343, Wellington South, New Zealand,
leipa321@student.otago.ac.nz

Landuse changes, including deforestation, agriculture and urbanisation, have coincided with increases in mosquito-borne diseases worldwide. Anthropogenic environmental changes can alter mosquito populations by modifying the characteristics of breeding habitats, but we still poorly understand the ecological mechanisms involved. Mosquito breeding habitats were sampled in native forest, pastureland and urbanland in the Kapiti region, New Zealand, and 17 environmental characteristics were measured of each. Higher immature mosquito densities were collected from mainly artificial containers in urbanland and pastureland compared to mainly ground pools in native forest. Nine environmental variables were significantly different between landuses but none of these were significantly related to mosquito density. Principal components analysis partitioned environmental data into seven ecological types. One ecological type was significantly related to both landuse and mosquito density, and positively associated with ammonia, bacteria and dissolved organic carbon (DOC), and negatively associated with nitrate and predatory damselfly larvae. The findings of this study support those from prior surveys in warmer climes of greater vector disease risk in anthropogenically-modified environments because of compromised ecosystem integrity. Unlike most previous field-based work, this study also suggests important mechanisms involved; pinpointing mainly bacteria, DOC, nitrate and damselfly larvae as acting in combination to regulate vector mosquito density.

The final word on the genetic, evolutionary and taxonomic relationship of *Pediculus humanus* and *P. capitis*.

NP Leo, JM Hughes, SC Barker
Department of Microbiology and Parasitology, University of Queensland, Brisbane 4072, Australia, N.Leo@imb.uq.edu.au

Body lice are thought to have diverged from head lice when humans began to wear clothes. This recent evolutionary divergence and incomplete lineage sorting has complicated assessments of whether head lice and body lice are separate species. We used microsatellite markers to test lice from hosts that were infested with head and body lice simultaneously, to see if the head and body lice had interbred. Our results showed that head and body lice had not interbred on a host. Assignment tests revealed that lice that had migrated among hosts always moved from head to head, and body to body, but never between heads and bodies. We conclude that head and body lice are separate species. We speculate that head lice are descended from the lice of neanderthals and modern humans, and that body lice are descended from the lice of modern humans that left Africa about 100,000 ya.

The search for natural repellents from human beings against mosquitoes

JG Logan, MA Birkett, LJ Wadhams, AJ Mordue (Luntz), JA Pickett
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire AL5 2JQ, james.logan@bbsrc.ac.uk

Blood sucking insects are differentially attracted to human beings. This is likely to be caused by differences in the semiochemical profiles of individual human hosts. Despite substantial research into insect-human interactions, the responsible semiochemicals have not yet been identified. An explanation for this difference is that unattractive individuals either lack attractant chemical compounds or may produce compounds that 'mask' the activity of attractants. A special air entrainment technique was developed and used to collect volatile chemicals from human volunteers, and the extracts analysed by gas chromatography (GC), coupled GC-electroantennography (GC-EAG) and GC-mass spectrometry (GC-MS). For the first time electrophysiological responses of female yellow fever mosquitoes, *Aedes aegypti* to volatiles from air entrainment extracts were recorded, and a number of electrophysiologically active compounds were identified. Previous behavioural studies have confirmed the differential attractiveness of volunteers to biting insects. A quantitative and qualitative analysis of compounds within the extracts, from individuals known to be differentially attractive to biting insects, has revealed significant differences in chemical profiles. The identification of behaviourally active compounds could lead to new and improved control technologies, whereby 'masking' compounds could potentially be incorporated into new, safe and natural repellents against biting insect pests.

Anopheles arabiensis at the edge of its distribution in Northern State, Sudan

CA Malcolm, BB El Sayed, ML Hickson, RS Azrag, AME Hassan, B Knols, MQ Benedict, AS Robinson
Biological Sciences, Queen Mary, University of London, London E1 4NS, UK, c.a.malcolm@qmul.ac.uk

Northern state, Sudan is mainly desert, rainfall is rare and most life is found close to the Nile. *Anopheles arabiensis* is the only anopheline and malaria vector found in the area in recent decades. It is present along the Nile downriver to about 200 km south of the Egyptian border, where poor terrain and control efforts prevent its spread further north. Initial results are presented from field and molecular studies to determine the population structure and dynamics of the species and related environmental factors. The receding Nile following the flood contributes most to sustaining *A. arabiensis*. Larval breeding sites can be found on low lying riverbank, ied-up inlets, or channels around islands, through most of the year. Land use is mainly associated with irrigation, but this does not appear to contribute greatly to anopheline numbers, however the extent of human presence and activities do increase the potential for anopheline breeding. Upriver from the fourth cataract and downriver from the third cataract, the terrain is rocky desert and less suitable for both humans and mosquitoes. The *An. arabiensis* population is thus semi-isolated within an approximately 700 km corridor a few kilometres wide and breaks down further into pockets depending on particular river features.

Control of biting midge (Ceratopogonidae) attack on residents of a marine canal estate in Redcliffe (Australia) by residual barrier treatment of Bistar 80SC® to ornamental garden plants in house yards

D McGinn, M Asnicar, C Perel, M Brown.
Griffith University, Brisbane 4111 Queensland Australia, mosquitosi@iprimus.com.au

Biting midge (Ceratopogonidae) breeding in marine sediments associated with engineered canals in a residential community in Redcliffe Australia have been responsible for considerable biting attack and nuisance. Limitations on approved applications of larvicides in breeding sites has historically restricted control to personal protection, midge screening and education of residents. In October 2003 – Feb 04, Redcliffe City Council funded a trial to test the efficacy of Bistar 80SC® (FMC Chemicals Pty Ltd) as a 0.1% AI (Bifenthrin) residual application to ornamental garden vegetation and dwelling external walls. Eight paired randomised treated and untreated premises were assessed for differences in biting midge exposure. The assessment was undertaken using CO_2 and Octenol baited light traps placed in treated and untreated yards. A self administered questionnaire scoring individual household daily experience of biting midge activity was also used. Untreated control premises received a placebo application of water alone to control bias in the resident questionnaire. Analysis of difference in light trap collections between treated and untreated showed a 76.4% reduction in midge (primarily *Culicoides molestus*) from treated premises. Resident survey results indicated occupants of treated premises experienced generally favourable biting midge conditions while residents from untreated homes experienced fluctuating exposure and discomfort corresponding to lunar emergence cycles.

Aerial efficacy assessment of Anvil 10+10 against *Anopheles quaimaculatus*

MV Meisch, DA Dame, JR Brown
319 Agri. Bldg. Fayetteville, AR, 72701, USA, meisch@uark.edu

Aerial ULV applications of Anvil 10+10 were conducted against caged, field-collected *Anopheles quaimaculatus* adults using Beecomist® 360A rotary atomizers. Standard and optimized applications were conducted at 0.62 fl oz (0.0036 lbs a.i.) per acre using stacked passes 3,500 ft and 5,000 ft upwind of the target site. Efficacy of Anvil 10+10 and impact of wind velocity at flight altitude (150 ft) were assessed by bioassay and analysis of collected droplets.

The potential role of aquatic insects in the transmission of Buruli ulcer disease in Africa

RW Merritt, ME Benbow, R Kimbirauskas
Dept. of Entomology, Michigan State University, East Lansing, MI, USA, merrittr@msu.edu

Buruli ulcer is the third most frequent mycobacterial disease in humans, next to tuberculosis and leprosy, often causing serious skin ulcerations, bone deformities, and disability. Unlike TB and leprosy, Buruli ulcer has emerged amatically since the 1980's, with increasing numbers of cases being reported from at least 31 countries, mostly in tropical and subtropical areas, including Africa. Although poorly understood, the epidemiology of Buruli ulcer associates the resurgence with people who live and/or work close to wetlands, especially slow flowing (riverine) or stagnant water bodies (marshes, swamps), often created as a result of some human environmental disturbance. The disease is not known to be contagious between humans, and epidemiological studies have not yet established natural reservoirs or modes of transmission. However, it was recently demonstrated experimentally that *M. ulcerans* could survive and multiply exclusively within salivary glands of aquatic bugs (Naucoridae: *Naucoris* sp.) and they were able to transmit *M. ulcerans* to mice by their bites, suggesting a possible mechanism for human infection. The organism has been found in samples of water, biofilm and detritus. A possible trophic scenario for the natural mode of transmission of *M. ulcerans* is presented based on preliminary work in Ghana by the authors.

Efficacy of a Spinosad suspension concentrate formulation for controlling chewing and sucking lice on cattle under field conditions

JA Meyer
2001 West Main Street, Greenfield, Indiana, 46140, USA, meyerje@lilly.com

Field studies were conducted with cattle in Wisconsin and Illinois between January and April, 2000, to determine the efficacy of 0.04% spray and 2 mg/kg pour-on treatments of a spinosad suspension concentrate formulation against chewing and sucking lice. Positive control substances included in the study were Co-Ral® EC (5.8% coumaphos) and CyLence™ Pour-on (1% cyfluthrin). Animals in the negative control group remained untreated. All lice species were visually sampled on each animal at weekly intervals after treatment, for eight weeks. Individual louse counts were summed over each examination site for each species. A repeated measures analysis using a mixed model (SAS PROC MIXED), was conducted for data pooled across both study sites. Both spinosad treatments and CyLence™ Pour-on provided excellent efficacy (98-100%) against *Bovicola bovis* over the entire study period; Co-Ral® EC efficacy opped below 90% from Weeks 6-8. The efficacy of the spinosad spray treatment against *Linognathus vituli* was >93% for the entire study and >88% for the spinosad pour-on treatment. Co-Ral® EC was >90% efficacious against *L. vituli* during Weeks 1-7, while CyLence™ Pour-on only exceeded 90% for Weeks 3-7. *Solenopotes capillatus* were found only at the Wisconsin site; all treatments were highly efficacious throughout the study period.

The effect of human age on Dengue seroconversion risk in Iquitos, Peru

SL Minnick, AC Morrison, TW Scott
Entomology Dept, University of California Davis, 1 Shields Ave, Davis, CA 95616, USA, slminnick@ucdavis.edu

Basic models of infectious disease often assume that force of infection is independent of host age. This assumption has been shown to be violated for many directly transmitted diseases, but has rarely been examined in vector-borne systems, such as dengue. Data from DNA fingerprinting studies of mosquito bloodmeals indicate that the biting rate of *Aedes aegypti* increases with human age. If risk for dengue infection increases with human age, models assuming an age-independent risk will underestimate the proportion of the population that needs to be vaccinated in order to eliminate disease transmission. A cohort of approximately 3,000 schoolchilen and their families in Iquitos, Peru were followed for up to 5 years (1999-2003) with blood samples collected at 6-month intervals. Sera were tested for dengue virus antibodies by the plaque reduction neutralization test. The effect of human age on risk for dengue seroconversion was evaluated using a multiple logistic regression model, which also included area of residence within the city. Preliminary analysis suggests that risk increased with age and was highest in the southern region of the city. Estimates of age-specific forces of infection can be used to design an optimal immunization program.

Oviposition site selection by mosquitoes in response to drought

A Mokany
School Of Botany And Zoology, Anu, Canberra, Act, 0200, Australia, allie.mokany@anu.edu.au.

Mosquitoes are vectors of many important medical and veterinary diseases. Although outbreaks of mosquito borne disease can be correlated to changes in precipitation in the very short term, precipitation rarely corresponds to mosquito abundance in the long term. Here, I present the results of a field based mesocosm experiment designed to test how water level and drought influence the oviposition behaviour of two species of mosquitoes. I used two water levels (high and low) and two drought treatments (normal and drought). Water for the drought treatments was obtained from ponds that had experienced drying for a period of a month prior to experimentation. The two mosquito species differed markedly in their oviposition response. The egg laying behavior of *Ochlerlatatus notoscriptus* was significantly greater in the drought treatments regardless of water level. However, the egg laying behavior *Anopheles annulipes* showed the opposite response with significantly more larvae present in the high water treatments regardless of whether the treatment water was normal or in drought. My results provide supportive evidence that mosquitoes may show population outbreaks following drought years and that this framework may provide a reliable way of predicting year-to–year variation in mosquito abundances based on individual species oviposition response.

Tests on a new bait for strike flies (Diptera: Calliphoridae)

MC Morris
57 Cornford St, Karori, Wellington, New Zealand; nezumi1@ihug.co.nz.

A bait consisting of sulphur-containing volatile compounds encapsulated in a caesin-based slow release matrix was tested for its efficacy in catching sheep strike flies (Diptera, Calliphoridae). The fresh bait was significantly more effective than a liver/sodium sulphide mixture in trapping a major strike fly (*Lucilia sericata*) and a minor strike fly (*Chrysomya rufifacies*) on a sticky trap. The bait also trapped significantly more gravid flies of these species. The bait efficacy wore off after 17 days under ambient conditions. The bait was also less effective than the liver mixture when used in Western Australia traps. This may be due either to its loss of effectiveness with age, or to differences in the responses of flies when landing close to the bait on a sticky trap and when searching for the exact location of an odour source in a Western Australia trap. Ways of improving the bait efficacy are discussed.

Aedes aegypti surveillance in Iquitos, Peru: a 4- year test of the pupal/demographic survey

AC Morrison, H Astete, A Getis, K Gray, M Sihuincha, J Stancil, J Olson, P Blair, TW Scott
Proyecto Dengue, University of California, Davis, Department of Entomology, Calle Nauta 898, Iquitos, Peru; aegypti@terra.com.pe

We present results from 4 years of pupal/demographic surveys of a circuit of ≈ 6,000 houses surveyed >10 times in the Amazonian city of Iquitos, Peru. We compare traditional larval indices with pupal and adult mosquito indices. We evaluated *Aedes aegypti* production from different container classes, including those based on water management practices overtime and space. A total of 289,941 water-holding containers were characterized, of which 7.3% were positive for *Ae. aegypti*. Although, temporal and geographic variations were detected for all variables examined, consistent production patterns were observed for the lid status (lids: 32% wet containers, 2% pupal production), container location (outdoor: 43% wet containers; 85% pupal production) and method by which the container was filled with water (rain filled: 15% wet containers; 88.3% pupal production). Based on these patterns and additional targeting of containers with highly variable pupal counts we propose a targeted control strategy for Iquitos that would reduce *Ae. aegypti* populations below published but untested threshold values for Iquitos.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera: Culicidae) & toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand; grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis*, *Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis*. These extracts delayed larval development and inhibited adult emergence.

The mosquito burden in Kenya

HN Njiru
HEADS Alliance P. O. Box 1905, 60100-Embu Kenya; hndwiga@yahoo.com

Kenya is a tropical country with a climate favourable for diverse insect life – both the harmful and the useful alike. Embu District experienced a malaria outbreak between January and February 2001 where more than 300 people were admitted at the main health facility in the District, 70 lives were lost. Malaria is endemic in Embu district with a morbidity of 60% and mortality of 25%. Expectant mothers and chilen are affected most with slide positivity of 30% and 45% respectively. Annually, each household spends around US$ 65 on malaria control and funeral expenses. Larval densities range from 30-40% with peak densities in March, April and May. Despite this, 25% of the community cannot positively identify mosquito as the malaria vector. Only 12% can correctly name the five main symptoms of malaria (fever, chill, sweating, anorexia, joint pains). The ministry of health has issued guidelines on uniform treatment and community sensitisation. Consistent use of bednets, chemoprophylaxis and indoor residual spraying are being encouraged. Plans are underway to start biological adult and larval control. This paper discusses the mosquito burden from the perspectives of larval density, host prevalence index, mortalities and morbidities, bed occupancy and the economics of vector control

Tick vector-pathogen interrelationships

PA Nuttall, M Labuda
NERC Centre for Ecology & Hydrology, Polaris House, North Star Avenue, Swindon SN2 1EU, U.K; pan@ceh.ac.uk

The interrelationships between tick-borne pathogens, their tick vectors and diverse vertebrate hosts, are represented by a triangle of parasitic interactions. The interactions are between (i) tick-pathogen, (ii) pathogen-host, and (iii) tick-host. In (i) the pathogen interacts with its vector, infecting and replicating within tick cells or extracellular spaces. The ability of a particular tick species to act as a vector depends on whether the pathogen can survive and overcome several 'barriers' within the tick. However, this is a simplistic view of the tick vector-pathogen interrelationship as both (ii) and (iii) influence the success of (i). This triangle of interactions is focused at the skin site of tick feeding - the initial site at which pathogens gain access to either their host or vector. For pathogens, the skin-feeding site is an ecologically privileged niche, profoundly modified by the pharmacological activities of bioactive tick saliva molecules. Exploitation of this niche is known as saliva-activated transmission (SAT). Tick saliva molecules that promote SAT have not been identified but appear to differ for different tick vector-pathogen interrelationships. Identifying the SAT factors and their mode of action offers new insights for controlling ticks and tick-borne diseases.

Argentina: veterinary forensic entomology as a potential tool against rustling

A Oliva
Av. A. Gallardo 470, C1405DJR, Buenos Aires, Argentina; aoliva@macn.gov.ar

Cattle rustling entails economic loss to cattle owners and danger to their safety, marketing of uninspected meat and hides and loss to the State from unpaid taxes. In 2003, the Faculty of Veterinary Medicine (Tandil, Buenos Aires province, Argentina) incorporated forensic entomology to a course of legal veterinary medicine aimed at fighting rustling. Preliminary field experiments showed a large proportion of hemisynanthropic insects, most of them Neotropical, which may represent the autochthonous necrophagous fauna, now displaced by synanthropic introduced species in urban environments. Colonization and development times proved longer in the arid climate of Tandil than at Buenos Aires city, where most published data were gathered. Field experiments with bovine bodies and parts are required. Hitherto, bovines have been avoided as a model because of the added complication of the ruminant digestive tract. Since most countries with rustling problems also have a pattern of introduced species displacing the original necrophagous fauna in city environments, they might benefit from knowledge obtained through these studies.

Arboviruses, mosquitoes & rNA interference

KE Olson, EA Travanty, I Sanchez-Vargas, KM Keene, BD Foy, BJ Beaty, CD Blair
Arthropod-borne and Infectious Diseases Laboratory, Department of Microbiology, Immunology and Pathology, Colorado State University, Fort Collins, Colorado 80523 USA; kolson@colostate.edu

The identification of critical arbovirus-vector interactions reveals new insights into vector competence. For instance, flavivirus and alphavirus replication in mosquitoes triggers a natural RNA interference (RNAi) response; however, viral counterdefenses probably allow RNAi evasion and establishment of persistent infections. We can enhance RNAi to dengue virus type 2 (DENV2) in *Aedes* species by administration of double-stranded (ds) RNA derived from the DENV2 genome, either by direct transfection of dsRNA, transient expression from a Sindbis virus (SINV) transducing system, or stable transformation with a plasmid that expresses a hairpin-forming transcript. RNAi is sequence-specific, is maintained by low concentrations of effector RNA, blocks accumulation of intracellular viral RNA, and results in the appearance of 21-25 nt siRNA homologous to the mRNA target. We have identified genes from the Dicer and Argonaute families in 2 mosquito genera and have used RNAi to knock down their expression to determine which genes have a role in virus resistance. We have evidence that DENV2 and some strains of SINV establish persistent infections in mosquitoes by suppression of RNAi, and are investigating mechanisms. We are identifying viral-encoded suppressors by site-specific mutations in infectious cDNA clones. Our work suggests that persistent infections in mosquitoes result from a balance between host RNA silencing and viral counterdefenses and provides new strategies for tipping the balance in favor of the vector host.

Endosymbionts & sex ratios in the human head louse

MA Perotti, HR Braig
School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK, bssc13@bangor.ac.uk

At the turn of the 19th century the first observations of a female-biased sex ratio in broods and populations of head lice had been reported. A study by Buxton in 1938 on the sex ratio of lice on prisoners in Ceylon is still today the subject of reanalyses. However, in the last sixty years no data have been collected, especially on more normal levels of infestations. Here we report a female bias of head lice in a survey of 480 school children in Argentina. This bias is independent of lice intensity. These lice as well as lice from pupils in Britain were carrying several, related strains of the endosymbiotic bacterium *Wolbachia*, one of the increasing number of intracellular sex ratio distorters. No lice without *Wolbachia* were detected. Similar *Wolbachia* strains are also present in the pig louse suggesting that this endosymbiont might have marked influence on the biology of the whole order. The sex ratio distortion in head lice that has been reported world wide is stable over time; that is a remarkable deviation from the stability of frequency-dependent selection of Fisher's sex ratio.

Blood feeding in *Cnephia* (Diptera: Simuliidae): molecular phylogeny

KP Pruess
University Of Nebraska, Lincoln, NE 68583-0816, USA; kpruess@unlnotes.unl.edu

Five species of *Cnephia* were studied, three non-biting, one a mammal feeder, and one a bird feeder. Of the non-feeding species, *C. eremite* is Holarctic in distribution and specimens were examined from both Canada and Sweden. *Cnephia pallipes* is a Palearctic non-feeder and *C. dacotensis* a temperate Nearctic non-feeder. *Cnephia pecuarum* is an economically important large mammal feeder in south-central U.S. and *C. ornithophilia* a widely distributed bird feeder in southern and eastern North America. Sequence was obtained from the complete mitochondrial CO-II gene (687 bp) and partial EF1-alpha nuclear gene (1030 bp). Molecular data is discussed in relation to conventional wisdom about relationships among species based on cytological and biological information, geographic distribution and genetic diversity within species. Molecular data strongly support *Cnephia* as a monophyletic clade in the tribe Simuliini. Speciation hypotheses were not fully concordant between molecular and conventional data.

Onchocerciasis in Central America: ecology & control

MA Roíguez-Pérez
Centro de Biotecnología Genómica-IPN, PO Box 152, Reynosa 87710, Tamaulipas, México; mroiguez@ipn.mx

Detection of O. volvulus larvae in vector populations of black flies is of prime importance in the assessment of the effectiveness of ivermectin control programs. Detection of larvae is attained by dissection of individual flies or by PCR (amplification of an Onchocerca 150 bp repeated sequence, followed by hybridization of the PCR products with a species-specific DNA probe) from pools of flies. The PCR was compared with dissection method to estimate the infection rate (p) and the mean larval load (any larval stage) per parous fly (m) in a local vector population. Both methods produced statistically similar estimates, thus PCR is an alternative and efficient method for entomological surveillance. Sample sizes required to estimate m from p for fixed levels of precision were calculated using Mexican and Guatemalan data, assuming that k (an aggregation parameter from the larval distribution among parous flies) is known. Optimal sampling and PCR was used to evaluate the impact of ivermectin on m, p and transmission potentials in Mexico. The data suggest that substantial progress towards the goal of suppressing transmission has been accomplished. In southern Chiapas, entomological estimates decreased in comparison with the baseline data, but PCR positivity was still detectable. In northern Chiapas and Oaxaca, with no baseline data, there was an absence or near absence of infected and infective flies.

Malaria vectors, *Anopheles hyrcanus* group (Culicidae, Diptera): morphological comparisons & molecular analysis

LM Rueda, RC Wilkerson, C Li, HC Kim, TA Klein, GH Song, D Strickman
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu

Anopheles hyrcanus group consists of at least 30 species, with several species including *Anopheles sinensis, lesteri, pullus*, that are known or potential malaria vectors. The morphological diagnostic features and molecular identities of malaria vector *hyrcanus* group species are determined. Larvae, pupae and adults of selected species were described morphologically, and their ITS2 and DNA sequences from our laboratory and GenBank were compared.

Distribution & bionomics of malaria mosquito vectors, *Anopheles (Anopheles)* in Japan, Korea & other parts of Asia

LM Rueda, TA Klein, HC Kim, J Pecor, M Iwakami, M O'Guinn, B Prendergast, M Mogi, T Toma, I Miyagi, RC Wilkerson
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu.

Mosquito specimens of *Anopheles (Anopheles)* from collections conducted in Japan (2002-03), Korea (1999-2003), Philippines (2002), HongKong (2001), mainland China (2001-03) were identified using morphological and molecular techniques, and recorded. Larval, pupal and adult rearings of field collected samples were conducted for morphological and molecular analysis. Detailed locations of various collection sites and habitats were characterized for known and potential malaria vectors of different countries. Habitats of vectors include ricefields, irrigated ditches, temporary and permanent pools, ponds, streams, others.

Dengue mosquito vectors, *Aedes* and *Ochlerotatus*: morphological identifications & distribution

LM Rueda
Walter Reed Biosystematics Unit, Department of Entomology-WRAIR, MSC MRC 534, Smithsonian Institution, 4210 Silver Hill Road, Suitland, Maryland 20746 USA; ruedapol@msc.si.edu.

The diagnostic morphological features of mosquito vectors of dengue viruses are compared for various *Aedes (Diceromyia, Stegomyia)* and *Ochlerotatus (Finlaya, Gymnometopa)* species found in four regions of the world, namely Oriental Region, Pacific and Australian Region, Afrotropical Region, and the Americas. Morphological characters are indicated to separate both larvae and adults of the vector species of each region. The distribution and bionomics of *Aedes* and *Ochlerotatus* vector species are included.

New & resurgent arboviral disease threatening humans in Australia

RC Russell
Department of Medical Entomology, University of Sydney and ICPMR, Westmead Hospital, Westmead, NSW 2145, Australia; rrussell@usyd.edu.au

Australia has a range of indigenous arboviruses and an introduced few that are of public health concern; all are mosquito-borne. Endemic encephalitogenic viruses (Murray Valley Encephalitis, Kunjin) are annually active and responsible for occasional cases in the northwest but, despite widespread vector distribution, only rare activity and no epidemics in the southeast since 1974. The most common arboviruses, Ross River annually infecting many thousands nation-wide causing polyarthritis, and Barmah Forest (a similar syndrome) on the increase and responsible for outbreaks of hundreds regionally, have a spectrum of coastal saline and inland freshwater vectors. The most important exotics are the returning dengue viruses with outbreaks of hundreds confined to Queensland by vector distribution but with virus endemicity and vector spread threatening, and the recently introduced Japanese Encephalitis virus causing only a few deaths in northern Queensland but with virus persistence and its affinity for a local vector threatening. Environmental factors drive arbovirus activity by influencing vector populations, which vary with virus and circumstance, although little is known of the role of reservoir hosts. Tourism and development activities that increase human/vector/virus contact, and climate changes that promote vector and virus proliferation, threaten to exacerbate the disease threat to the public health.

Repellents for integrated tsetse management

RK Saini, A Hassanali
International Center of Insect Physiology and Ecology (ICIPE), PO Box 30772 Nairobi, Kenya; rsaini@icipe.org

ICIPE is in the forefront in identifying potent repellents, both synthetic analogues of natural tsetse repellents and natural repellent blends from un-preferred animals like waterbuck and zebras. One potent synthetic repellent for savannah tsetse species, developed by molecular optimization studies, acts as an olfactory antagonist of a key phenolic kairomone, which flies use to locate the host for feeding (Saini & Hassanali; patent application). This repellent substantially reduce tsetse challenge (> 80%) and feeding efficiency (>80%) on cattle. A prototype dispenser which is placed around the neck of an animal has been developed. Field trials indicate that the repellent can provide effective protection to cattle but all animals in a herd need to be protected or else significantly higher infection occurs in unprotected animals. Experiments are ongoing to evaluate how repellents can be integrated with other existing tsetse control techniques. A 'push-pull' strategy that deploys repellents (to 'push') and baited traps / targets (to 'pull') to enhance suppression rates is being evaluated. A variant of this may involve the use of a proportion of cattle with 'pour on' insecticides as live baits. A business plan for commercial production and distribution of repellent products is also being developed.

Mitochondrial genome organization of lice is highly variable

R Shao, C Covacin, SC Barker
Department of Microbiology and Parasitology, The University of Queensland, QLD, 4072, Australia; r.shao@uq.edu.au

Mitochondrial (mt) genome organization is extremely conserved in mammals, vertebrates and most arthropods, e.g., humans and frogs have the same mt genome organization; so have fruit flies and water fleas. We have sequenced the entire mt genomes of the wallaby louse (Phthiraptera: Amblycera) and the pigeon louse (Ischnocera), and part of the mt genomes of the human louse (Anoplura) and four other amblyceran lice. Unlike most arthropods, the mt genome organization of these lice is highly variable. Lice share only 1-2 gene boundaries with fruit flies. No gene boundaries were shared among lice of the three suborders. Mt genome organization differs even among three genera within the suborder Amblycera. Changes in the mt genome organization of lice include gene translocation, inversion, separation of rRNA genes and loss or multiplication of non-coding regions. In addition to lice, we found mt genome organization was variable or highly variable in other two hemipteroid orders, Psocoptera (psocids) and Thysanoptera (thrips), but is strictly conserved in the order Hemiptera (bugs). We speculate that the changes in the mt genome organization in lice, psocids and thrips may be related to their life-history traits such as small body size, small colony size, and high degree of inbreeding.

Impact analysis of certain phyto-extracts on the life cycle of malaria vector

P Sharma, L Mohan, CN Srivastava
Dept. Of Zoology, Dayalbagh Educational Instt. Dayalbagh, Agra-282 005 (India); chandnarayan_dei@rediffmail.com

The petroleum ether extract (Pe. E.) of *Artemisia annua* and *Azardirachta indica* have remarkable influence on the lifecycle of malaria vector, *Anopheles stephensi* by arresting larval and pupal period. These phyto-extracts hamper the hatching of larvae and further deform the larvae. The retarded emergence of adults was observed due to percentage decrease in transformation of eggs into larvae from 100 to 75% and pupal from 80 to 45% at concentration variable from 7.50 to 240 ppm of Pe. E. of *A. annua* and 80 to 45% and 79 to 66% at concentration range from 6.25 to 100 ppm of Met. E. of *Az. indica.* The percent larval & pupal mortality range was observed from 20 to 55 and 19 to 83.50% on exposure to *A. annua* extract and 21 to 34% and 27 to 84% on treating with *Az. Indica* extract. The decreasing trend in the growth index was observed in both the extracts. These phyto-extracts have great potency and may be recommended as economical, ecofriendly and effective tool of bio-control of this highly nuisance vector.

Bidirectional signalling and synaptogenesis: semaphorin1a and the transition from growth cone to synapse.

RK Murphey, TA Godenschwege
"Department of Biology, University of Massachusetts, Amherst, MA 01003; rmurphey@bio.umass.edu"

Target recognition during which a motile growth cone is transformed to a sedentary synapse is poorly characterized at the molecular level. We have demonstrated in the *Drosophila* giant fiber system that this transition is regulated in part by semaphorin1a (Godenschwege et al., 2003). Sema1a is a trans-membrane member of a family of proteins typically thought of as repulsive ligands that guide growth cone path finding. We have shown that Sema1a is required in both the pre- and postsynaptic cells for normal synapse formation and are using Sema1a as a point of entry to discover the signaling systems that regulate the transition from growth cone to synapse. In the pre-synaptic giant fiber Sema1a functions as a repulsive receptor and when Sema1a is over-expressed in the giant fiber synapse formation is disrupted. This gain-of-function defect can be enhanced by over expression of rac1 and suppressed by expression of the dominant negative rac1 suggesting that the repulsive function of sema1a is dependent on the small GTPases. We will elaborate on the role of rac1 as well other signaling systems that interact with semaphorin1a and are required for synaptogenesis . Finally, a model for the assembly of this giant synapse will be presented.

Adult survival and reproductive effects of forced egg-retention time in *Aedes albopictus* after application of deet as an oviposition deterrent

A Ali, R Xue, DR Barnard
University of Florida, IFAS, MREC 2725 Binion Road, Apopka, FL 32703-8504, USA; aali@mail.ifas.ufl.edu

The insect repellent deet (0.1% concentration) used as mosquito oviposition deterrent in the laboratory could influence the gravid female *Aedes albopictus* Skuse to retain and maintain mature eggs in her body. The egg-retention in female mosquitoes could benefit survival of the gravid females. The gravid females can lay the maintained eggs on availability of water or another liquid medium in the cage, but the length of forced egg-retention time could reduce the mean number of eggs laid per female. The gravid females that retained eggs also laid a higher percentage of non-tanning eggs, which increased with the egg-retention time. The rate (%) of egg hatch was not affected by deet used as oviposition deterrent. It was however, affected by egg-retention time in both treated (exposed to deet) and untreated (control) gravid females. The rate of egg hatch reduced after 3 weeks of retention, and after 6 weeks of retention the eggs of both treated and control gravid females could not hatch. The fecundity and fertility of gravid female *Ae. albopictus* was affected by the time duration of forced egg-retention.

Haematobia irritans (Diptera: Muscidae) mitochondrial genome amplification and sequencing: potential of the long-PCR approach for calyptratae mitogenomics

JG Barau, AML Azeredo Espin, AC Lessinger
Laboratório de Genética Animal, Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade Estadual de Campinas (UNICAMP), Campinas, S.P. and Depto. Genética e Evolução, Instituto de Biologia, Universidade Estadual de Campinas (UNICAMP), Campinas, S.P.; barau@unicamp.br

Long-PCR strategies have significantly improved the sequencing and characterization of insect mitogenomes essentially by providing an alternative way to purify sufficient mtDNA from limited amounts of individual template and thus stimulating a wide range of otherwise limited techniques on insect molecular and evolutionary biology. We optimized Long-PCR reactions for the amplification and sequencing of the complete mitogenome of the horn-fly, *Haematobia irritans* (Diptera: Muscidae), a key parasitic fly of cattle. *H. irritans* mitogenome was amplified using four conserved Long-PCR primers designed on Dipteran 16S lrDNA gene combined with two previously described 'universal' primers. Amplified products ranged from 8.5 to 9.3Kb depending on primer combination, with a 1.5Kb overlap. We obtained specific products on a microgram range providing sufficient mtDNA for several techniques, including RFLP analysis and the sequencing of the *Haematobia irritans* mitogenome from a shot-gun library approach. Using H16S primers, we also amplified long-PCR products from seven other Calyptratae key species of medical-veterinary importance: the screw-worm fly, *Cochlyomyia hominivorax*, the blowflies *Chrysomya albiceps*, *Chrysomya megacephala*, *Chrysomya putoria*, *Lucilia cuprina*, the botfly, *Dermatobia hominis* and another muscid, *Musca domestica*. These results contribute not only to achieve complete *Haematobia irritans* mitogenome but also stimulate Calyptratae mitogenomics.

The complete mitochondrial genome of the human botfly *Dermatobia hominis* (Diptera: Oestridae)

AML Azeredo-Espin, ACM Junqueira, AC Lessinger, TT Torres, ML Lyra, FR da Silva, AAM Maia
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; azeredo@unicamp.br
"

The botfly *Dermatobia hominis* is a parasite of humans and livestock, producing a furuncular myiasis. The larvae of *D. hominis* develops in the subcutaneous tissue causing economic loss and health problems, being one of the most important livestock pests in Latin America. The complete mitochondrial DNA (mtDNA) sequence of *D. hominis* was determined and has 16360 bp. The nucleotide composition is biased towards adenine and thymine, which accounted for 77.8% of the whole genome. The *cox1* gene has a Serine as the start codon, while incomplete termination codons were found for *cox1*, *cox2* and *nd5*. The control region, protein-coding genes, rRNA and tRNA genes are in the same order and orientation when compared to other dipteran mitochondrial genomes, except for a duplication of $tRNA^{Val}$ located approximately in the same position of the $tRNA^{Asp}$, but in the opposite strand. The identification of restriction sites on the sequenced mtDNA and the correlation with previous RFLP analyses provided insights for an overall scenario of the genetic variability and population structure of *D. hominis*, being helpful for monitoring the variation and dynamics of this species. The availability of complete mitochondrial sequences is an important source of sequence information for Diptera molecular and evolutionary approaches.

Are *Pediculus humanus* infected with *Wolbachia* spp.?

C Covacin, S Barker
Department of Microbiology and Parasitology, & Institute for Molecular Biosciences University of Queensland, Brisbane 4072, Australia; S.Barker@imb.uq.edu.au

Wolbachia spp. belong to the alpha-subdivision of the Protobacteria and are closely related to the Rickettsia and their relatives (Class Alphaproteobacteria, Order Rickettsiales). *Wolbachia* spp. are obligate intracellular bacteria and have been recorded in approximately 76% of insects studied. *Wolbachia* spp. are transmitted from mother to offspring through the cytoplasm of the egg. Horizontal and accidental transmission have also been recorded. The impact of a *Wolbachia* sp. on its host may vary. Enhanced fertility or fecundity, pathenogenicity, parthenogensis, feminisation, male-killing as well as cytoplasmic incapability (unidirection and/or bidirectional) may be caused by *Wolbachia* spp. infections. Cytoplasmic incapability has been linked to the transmission and inheritance of mitochondrial DNA in that it may provide the impetus for selective sweeps. The sweep of a mitochondrial-type through a population and from generation to generation may be enhanced in lice due to the short generation time, small population size and the founder effect that occurs as a result of dispersal of lice. Here we present our data on whether or not *Pediculus humanus* (body/cloths louse) and *Pediculus capitis* (head lice) may be infected with *Wolbachia* spp.

Triatoma mexicana in the state of Guanajuato, Mexico: preliminary results.

M Cabrera, G Rojas, Y Guevara, S Rosales, H Aguilar, M Vences, PM Salazar.
Lab Biol Parasitos, Fac Med, UNAM. Edif A 2º. Piso CP 04510; imay@servidor.unam.mx

Mexico have 7 genera and 24 species of Triatoma genus which are *Trypanosoma cruzi* vector's, some with habits intradomicile. In Guanajuato state have been reported 5 triatomines species, among them *Triatoma mexicana*, which is little studied. With the purpose of know their ecotopes, distribution, infection for *T. cruzi*, morfometric, citogenetic and of life cycle in the laboratory, 9 localities of three municipalities were studied in the northeast of the State. We collected 110 triatomines, adults 91(83%), nymphs 19 (17%), males 80 (73 %) and females 11 (10 %). Positive to *T. cruzi*. 5 (4.54%). Capture sites, 6 (4%) were captured indoors and 104 (96%) in the outdoors. The main ecotopes in the intradomicile were: bed, wall, kitchen light bulb and in the peridomicile were: external wall, courtyard light bulbs, stone wall and farmyard. This specie is attracted by the artificial light (tungsten). The season with more triatomines was spring. Studies of morfometric , citogenetic and biological cycle are not concluding. This vector doesn't present intradomiciliated habits like initially it had been reported, their biological cycle performance in the peridomicile is in the stone wall and farmyard in these sites we captured the biggest number of triatomines in the nymphs phase

Vertebrate integumentary chemicals: endogenously produced and acquired chemicals use to deter arthropods

JF Carroll, PJ Weldon, M Kramer
"USDA, ARS, APDL, BARC-East, Bldg. 1040, Beltsville, MD 20705, USA; jcarroll@anri.barc.usda.gov "

Ectoparasitic arthropods may be deterred from feeding on certain vertebrates by substances endogenously produced in the skin, pelage or plumage. Deterrent chemicals may also be acquired by them by rubbing against exogenous sources, i. e. anointing. Monkeys and birds rub themselves with millipedes that defensively discharge benzoquinones. Laboratory bioassays showed that three benzoquinones in millipede secretions deterred ticks and mosquitoes by repellency, toxicity and behavior alteration.

Spatio-temporal analysis of reinfestation by *Triatoma infestans* (Hemiptera: Reduviidae) following insecticide spraying in a rural community in northwestern Argentina.

MC Cecere, GM Vazquez-Prokopec, RE Gürtler, U Kitron.
Lab. Eco-Epidemiology, Depto. EGE, FCEN, University of Buenos Aires, Pab. II, Ciudad Universitaria, C1428EHA, Buenos Aires , Argentina; carla@bg.fcen.uba.ar

The spatio-temporal reinfestation patterns by *Triatoma infestans* following a blanket insecticide spraying in a rural community (Amamá) was analyzed using geographic information system (GIS), satellite imagery, and spatial statistics. Domestic and peridomestic reinfestation by triatomine bugs was monitored from 1993 to 1997 after the apparent elimination of *T. infestans* in 1992. In addition to domiciles, *T. infestans* occupied pig and goat corrals, wood piles, trees, and additional sites associated with chickens. *T. infestans* was detected at least once in 75% of 2110 sites evaluated. The prevalence of sites positive at least once for *T. infestans* during the study period increased sharply from 1993-1995 (0.6-2.9%) to November 1997 (32%). The initial source of *T. infestans* was a pig corral in southern Amamá one year post-spraying. Subsequent infestations were clustered around this initial focus at a distance of ~400 m starting in 1995. In 1996, clustering was maximized in sites within the same compound or in neighboring compounds at distances of 25-175 m. These results indicate that an effective control program on the community level will be based on the spraying of actual epicenters as well as sites within a 450 m of these epicenters to prevent the propagation of *T. infestans*.

Vector biology and control research in southern Africa

M Coetzee, L Manga
"Vector Control Reference Unit, National Institute for Communicable Diseases, P.O. Box 1038, Johannesburg 2000, South Africa; maureen.coetzee@nhls.ac.za"

In collaboration with the World Health Organization Regional Office for Africa in Harare, Zimbabwe, a multicentre study for the characterization of vector populations and capacity building for vector control in seasonal, epidemic-prone malaria transmission areas of southern Africa, was initiated. Namibia, Botswana, Zimbabwe, Swaziland and South Africa participated in mosquito collections, insecticide susceptibility testing and involvement in malaria transmission. *Anopheles arabiensis* was the major malaria vector in all five countries. Only Zimbabwe and South Africa gave indications of insecticide resistance in *An. arabiensis. Anopheles merus* was implicated in malaria transmission at one locality in central Zimbabwe. A further study on insecticide resistance in northern Kwazulu/Natal Province of South Africa was undertaken. The efficacy of spraying houses with both DDT and pyrethroids, either together as a single mix or one on top of the other was investigated as a possible resistance management tool. Capacity building was a major component of both these projects. Collaborators processed their own samples in the laboratory in Johannesburg, and two were registered for Masters degrees at the University of the Witwatersrand.

Identification of gene candidates for age determination in *Aedes aegypti* (Diptera: Culicidae)

PE Cook, I Iturbe-Ormaetxe, SL O'Neill
"Department of Zoology and Entomology, School of Life Sciences, The University of Queensland, Brisbane, Qld 4072 Australia; p.cook1@uq.edu.au"

Aedes aegypti is the principal vector of dengue, a disease of increasing global significance. Vector population age structure is a critical determinant of a vector population's capacity to transmit disease. Current age-grading methods are of limited value as age estimates are restricted to 15 days, while only females older than approximately 14 days can potentially transmit dengue. Development of an age-grading method that predicts mosquito age over the entire lifespan of *Ae. aegypti* would be a valuable tool for disease transmission studies and evaluating vector control strategies. Here, we describe gene candidates that show age related expression profiles, for a rapid PCR-based method of age determination. Candidate genes have been identified from published *Drosophila* microarray data of gene expression across adult age. *Drosophila* candidate gene expression was confirmed using Northern blots of pooled RNA samples across a range of age groups (adults 1-29 d, with 4 d interval). Gene orthologues from *Ae. aegypti* were isolated by PCR using degenerate primers and gene expression profiles were validated by Northern blots analysis as for *Drosophila*. The application of real-time reverse transcriptase PCR techniques to determine gene expression levels in individual female mosquitoes and the statistical tools to predict age will be presented.

Detection and characterization of the tRNA^{Ile} in the mtDNA control region of myiasis-causing flies (Diptera: Calliphoridae).

G Turqueto Duarte, ACM. Junqueira, TT Torres and AML Azeredo-Espin
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; anacmj@unicamp.br"

The family Calliphoridae is formed by myiasis-causing flies, being known for its economic, medical, sanitary and forensic importance. Ecological similarities and the lack of morphological diagnostic traits may cause problems in the identification of species, especially for larvae. The mitochondrial DNA (mtDNA) is providing important clues for species identification and variability characterization. The control region (CR) represents the major noncoding region of the mitochondrial genome, with a bias towards A+T content. The CR has been divided in two different subregions, including the A domain with conserved sequence blocks and a hipervariable B domain. The entire CR could be recovered in two separated PCR reactions using a specific and universal primers combination. The efficient PCR amplification, sequencing and analysis of nine Calliphoridae species has shown a complete tRNA^{Ile} duplication into the B domain of four *Chrysomya* species: *C. albiceps*, *C. bezziana*, *C. chloropyga* and *C. megacephala*. The tRNA^{Ile} duplication could be used as a diagnostic marker for *Chrysomya* genus identification, since the duplication has not been reported for other related Calliphoridae genus. The characterization of the A domain for Calliphoridae species will allow the evaluation of this region as a molecular marker for evolutionary studies and for identification of Calliphoridae species.

Parasitoids of nuisance flies on Australian cattle feedlots

MM Elson-Harris, PE Green, RL Bright, R Urech, GW Brown, JA Hogsette, AG Skerman
Department Of Primary Industries And Fisheries, Lmb No 4, Moorooka, QLD, 4105, AUSTRALIA; marlene.elson-harris@dpi.qld.gov.au

Populations of adult and immature nuisance flies and associated parasitoids were monitored on three Australian feedlots with one southern Queensland (SQ) feedlot being continuously monitored over two years. In the SQ feedlot both sentinel pupae (cultured *Musca domestica* exposed for 1-2 weeks at various sites) and feedlot pupae, consisting largely of *M.domestica* (85%) and *Stomoxys calcitrans* (12%), were examined for parasitoids. The 4.2% of the sentinel pupae parasitised produced 7 species of parasitoids, with *Muscidifurax raptor* (52%) and *Spalangia cameroni* (39%), predominating. Parasitoids emerged from 10.3% and 11% of the *M.domestica* and *S.calcitrans* feedlot pupae respectively, with the emergence pattern indicating that both species were equally parasitised. Unlike the parasitised sentinel pupae, for feedlot pupae *Spalangia* spp. constituted 90% of the parasitoids with *S.endius*, *S.nigroaenea* and *S.cameroni* comprising 50%, 22% and 18% respectively. *M.raptor*, *Trichomalopsis* sp and Diapriids made up the remaining 10%. Some parasitoid preferences for various feedlot sites were evident but *S.endius* was the most common species found at all sites. Parasitoids, largely *S.endius* and *S.cameroni* were seen in 9% and 12% of pupae from feedlots in central NSW and central Qld respectively. Parasitoids appear to be one of the more important biological control agents on Australian feedlots.

Successional aspects of the sarcosaprophagous arthropods fauna associated to rabbit corpses in the nearing areas to Tenjo (Cundinamarca)

A Ordoñes, G Fagua, MA Dolores García García
Carrera 7ª No 43-82, Universidad Javeriana, Edificio 53; Bogotá, Colombia; fagua@javeriana.edu.co

The succession of adult sarcosaprophagous arthropods was studied using baited Schoenly traps and rabbits as model. The efficiency of the traditional methodology (Ptrad) against the use of baited Schoenly traps (PTC) was comparated. Modifications to the Schoenly trap were made in the material of the trap, a communication with the substrate, interchangeable collector bottles and the collector funnels. During the 42 days of sampling 11.847 individuals were collected included in 99 species (97 in PTC and 63 in Ptrad); this includes 43 families (43 in PTC, and 32 Ptrad) belonging to five troffic rolls: necrophagous, opportunists, parasites, prayers and accidental. Also significant differences in the species abundance, richness, diversity and dominance were found between PTC and PTrad. By multivaried analysis techniques five stages were determined: Fresh (72 hours), Active decomposition (78h), Advanced Decomposition (330h), dry Remains (288h) and Bones (144h). These stages deferred in duration with those found in other works as a result of the sampling efficiency. Significant differences between the five stages were found in the abundance of individuals, species richness, diversity, dominance and community composition. In conclusion the PTC showed to be more effective in collecting arthropod fauna and superior to Ptrad for evaluating the adult sarcosaprophagous succession process.

Altered colonization of dung from cattle treated with doramectin, eprinomectin, ivermectin or moxidectin

KD Floate
"PO Box 3000, 5401-1st Ave. S., Lethbridge Research Centre, Lethbridge, AB, T1J 4B1, Canada; floatek@agr.gc.ca"

Endectocides (e.g., abamectin, doramectin, eprinomectin, ivermectin, moxidectin) are used worldwide to control internal and external parasites affecting cattle. After application, most of the dose is excreted in the faeces of the treated animal where residues can either enhance or reduce the attractiveness of dung to coprophilous insects. By influencing the number of colonizing insects, residues may indirectly alter the rate of dung pat degradation. The current study compared collections of insects from pitfall traps baited with dung of untreated cattle versus dung of cattle treated 1 wk earlier with topical applications of ivermectin, doramectin, eprinomectin or moxidectin. The effect of residues on colonization previously has not been reported for the latter three compounds. In addition, these results are the first to compare directly the effects of faecal residues on colonization, when potential confounding factors of drug formulation, cattle diet, insect species, and time are held constant.

On the ubiquity and phylogeny of *Wolbachia* in lice

GK Kyei-Poku, DD Colwell, P Coghlin, KD Floate
"PO Box 3000, 5401-1st Ave. S., Lethbridge Research Centre, Lethbridge, AB, T1J 4B1, Canada; floatek@agr.gc.ca"

Wolbachia are intracellular bacteria of interest, because they profoundly affect the reproductive fitness of their insect hosts. Here, we provide the first report of *Wolbachia* in the two insect Orders Anoplura (sucking lice) and Mallophaga (chewing lice). We document the apparent ubiquity and diversity of *Wolbachia* in these orders with infections detected in each of 25 tested populations of lice, representing 19 species from 15 genera spanning eight taxonomic families. Phylogenetic analyses indicate a high diversity of *Wolbachia* in lice, as evidenced by the identification of 39 unique strains. Some of these strains are apparently unique to lice, whereas others are similar to strains infecting other insect taxa. *Wolbachia* are transmitted from infected females to their offspring via egg cytoplasm. Hence, the evolutionary radiation of *Wolbachia* strains is predicted to correspond with their host taxa. This prediction is met with strains in the *Wolbachia* taxon Supergroup B, which form a monophyletic clade. In contrast, strains in Supergroup A exhibit phylogenetic discrepancies that previously have been attributed to horizontal transmission between host species, possibly via a parasitoid vector. We interpret such discrepancies in the current study as evidence of genetic recombination between *Wolbachia* strains or between *Wolbachia* and non-*Wolbachia* bacteria.

Host preference in *Anopheles gambiae*: decision between plant and human volatiles in a wind tunnel

WA Foster, W Takken
Department of Entomology, 400 Aronoff Laboratory, 318 West 12th Ave., Columbus, OH 43210-1242, U.S.A.; foster.13@osu.edu

Both sexes of *An. gambiae* have small energy reserves at emergence, and at 27°C they begin to die within 2 days. Thus, 1 night after emergence is a critical time to obtain food. In a 2-choice wind-tunnel olfactometer, they oriented in significantly greater numbers toward honey, a source of nectar-related volatiles, than to human-foot volatiles. This was true both when the volatiles were paired with blanks and when they were presented simultaneously. In the latter case, the difference in response was greater, indicating direct competition between the two kinds of volatiles. After 5 days of sugar feeding and mating, males still strongly preferred honey volatiles, but females responded almost exclusively to human volatiles. These results suggest that under some conditions in the field, females take their first meal preferentially from plants. Females given sugar on the night of emergence exhibited stronger responses to human volatiles the following night, indicating that energy status itself promotes blood feeding, independent of maturation.

Phylogenetic relationships of midges of the *Culicoides obsoletus* species complex (Diptera: Ceratopogonidae) based on ITS2 rDNA sequences

LM Gomulski, R Meiswinkel, JC Delécolle, M Goffredo, G Gasperi
"Dept. of Animal Biology, University of Pavia, Piazza Botta 9, 27100 Pavia, Italy; gasperi@unipv.it"

The midges of the genus *Culicoides* Latreille, 1809 include species that are vectors of orbiviral diseases of bluetongue and African horse sickness that cyclically decimate livestock in the Mediterranean Basin. Recent outbreaks of these diseases in regions where the known Afro-Asiatic vector, *C. imicola,* is absent has incriminated other *Culicoides* species belonging, amongst others, to the Obsoletus Complex of the subgenus *Avaritia* Fox, 1955. The lack of taxonomic clarity concerning these potential vectors stimulated the molecular analysis of 21 *Culicoides* population samples from 18 localities spread throughout mainland Italy. Nuclear ribosomal DNA ITS2 sequence variation was used to determine the genetic differentiation within and between the members of the Obsoletus Complex and related species, by means of AMOVA and phylogenetic analyses. Although morphological discrimination of the members of these complexes is extremely difficult, the molecular analysis clearly demonstrated a high degree of divergence between most of the species. Also evident is that the subgenus *Avaritia* comprises at least three species complexes, all of which are separate from the Imicola Complex which was represented by *C. imicola* as the outgroup. Furthermore, a simple PCR assay was developed which rapidly discriminates between the species of the complex, a prerequisite for vector identification.

"Differences in sensitivity to action of insect hormones analogues and agonists in several populations of *Culex pipiens* s.l. caused by insect pheromones"

'*I Gelbic, J Olejnicek*"
"Institute of Entomology, Institute Of Parasitology As Cr, Ceske Budejovice, Czech Republic; gelbic@entu.cas.cz"

"Increasing interest for effective insect control, especially of hematophagous insects is provoked by number of diseases transmitted by some species from these insect groups. One of many ways how to control these species is the use of analogues and agonists of insect hormones. These analogues were tested against larvae of different strains of *Culex pipiens*. Larvae of *C. pipiens molestus* and *C. pipiens quinquefasciatus* originated from different countries were used in experiments. *Culex quinquefasciatus* is serious hygienic problem - vector of filariosis. Larvicidal activity of the methoprene, 20-hydroxyecdysone RH-5992 and RH-2484 were tested. All used compounds show different activity among experimental strains. In our laboratory strains - originated from Cuba, Iraq, India (two strains), Taiwan all tested compounds had dose depended activity. Toxic effect, morphological effects - inhibition of larval pupal or pupal-adult transformation and delayed pupation were observed. Very high activity of methoprene and 20-hydroxyecdysone were found in Cuban strain. On the other hand RH compounds were very active in Taiwanian strain. For example 20-hydroxyecdysone was still very toxic at 5 ppm concentration in Cuban strain, while in the Indian strain same toxic effect was caused at concentration 100 ppm. Similar results were obtained with methoprene RH-5992 and RH-2485.
"

Gene expression in ticks induced by blood meal and lyme borreliosis spirochetes

N Rudenko, M Edwards, L Grubhoffer
Institute of Parasitology, Academy of Sciences and Faculty of Biological Sciences, University of South Bohemia, 370 05 České Budějovice, Czech Republic; liborex@paru.cas.cz

The castor bean tick, *Ixodes ricinus,* is the principal European vector of *Borrelia burgdorferi* sensu lato, the causative agent of Lyme borreliosis (LB). Differentially expressed genes that underlie the host response of *I. ricinus* to *B. burgdorferi* have not been investigated prior to this study. The characterization of genes that are induced following an infected blood meal is essential for gaining an understanding of the molecular mechanisms that underlie vector-pathogen interactions. Subtractive hybridization was used to isolate tick genes that were induced in whole ticks following a blood meal and a blood meal on a *B. burgdorferi* infected guinea pig. Novel cDNA clones with similarity to cytochrome c oxidase, salivary secreted protein, actin, glutenin and a cysteine protease pro-peptide were induced following a blood meal. Novel cDNA clones with similarity to thioredoxin peroxidase(s), dolichyl-phosphate glucosyltransferase, glutathione-S-transferase, defensin, ML domain containing protein and von Willebrand factor were induced following *B. burgdorferi* infection. Northern analysis and RT-PCR were used to verify that these genes were differentially expressed in ticks and to determine the site of their expression. (Supported by the Grant Agency AS CR No. A6022306.)

Immune proteins in the soft tick *Ornithodoros moubata*

P Kopáček, V Kovář, L Grunclová, T Saravanan, I Šauman, C Weise, L Grubhoffer
Institute of Parasitology, Academy of Sciences and Faculty of Biological Sciences, University of South Bohemia, 370 05 České Budějovice, Czech Republic.

Three proteins playing a role in the immune system and/or pathogen transmission were isolated from the soft tick *Ornithodoros moubata*.:1. An abundant tick plasma protein was isolated and identified as a protease inhibitor of a_2-macroglobulin (a_2M) family. Tick a_2M - **TAM** has an atypical structure in that it is composed of two noncovalently bound subunits of about 180 kDa. Each subunit is post-translationally processed in two disulfidically bound chains in a manner similar to the C3 and C4 components of complement. TAM sequence is closely related to the *Limulus* a_2M. TAM possesses at least 4 variants of bait region domain created likely by alternative splicing. 2. A sialic-acid binding lectin named **Dorin M,** apparently produced by tick hemocytes has been purified from tick plasma. Cloning and sequencing of the DorinM gene revealed that the protein shares significant similarity with the family of fibrinogen-related proteins (especially tachylectin 5A, B from the horseshoe crab and ficolins of vertebrates) which function as pattern-recognition molecules. 3. An anti-bacterial protein **lysozyme** was isolated from gut contents of engorged ticks. The enzyme is apparently upregulated upon bloodmeal. The features of lysozymes with anti-bacterial as well as digestive function seem to be combined in the tick gut lysozyme sequence.

Characterization of hemolipoproteins from ticks.

NP Gudderra, CS Apperson, RM Roe, DE Sonenshine, JF Andersen.
"National Institutes of Health, NIAID, Lab of Malaria and Vector Research, Medical Entomology Section 12735 Twinbrook Parkway, Room 2E-32C, Rockville, MD 20852, USA; ngudderra@niaid.nih.gov."

Hemolymph proteins in ticks have not been completely studied. The hemolymph protein most studied in ticks has been vitellogenin (Vg). Besides Vg, another major hemolymph storage protein, a carrier protein (DvCP) and heme-binding lipoprotein (HeLp, for Heme LipoProtein) has recently been studied in two hard tick species but not in soft ticks. DvCP from *Dermacentor variabilis* is identical to a heme-lipoprotein (HeLp) from *Boophilus microplus*. An analogous protein to DvCP was reported in the soft tick, *Ornithodoros parkeri* (OpCP) but its tissue distribution and biochemical properties have not been fully understood. Further characterization of OpCP and biochemical characterization of major hemolipoproteins from other important tick species is in progress. Biochemical and molecular comparison of major hemolipoproteins across tick species and their significance to tick biology will be discussed.

Molecular detection of several tick-borne pathogens from ticks in Japan.

H Inokuma, H Hiraoka, S Taroura, T Beppu, Y Yoshizaki, Y Shimada, Y Sakata, K Itamoto, M Okuda.
Faculty of Agriculture, Yamaguchi University, Yamaguchi 753-8515, Japan; inokuma@yamaguchi-u.ac.jp

Detection and analysis of several tick-borne pathogens, including *Rickettsia, Ehrlichia, Hemoplasma, Borrelia* and *Babesia,* from ticks recovered from dogs and cats in Japan were attempted using molecular techniques. A total of 1136 tick samples from dogs and 132 from cats were examined for tick-borne pathogens by using genus- and species-specific PCR, and sequence analysis. Some well-known pathogens such as *Anaplasma platys, Mycoplasma haemofelis, Mycoplasma haemominutum, Babesia gibsoni, Babesia canis* and *Borrelia garinii*, were detected and some new information on their distribution in Japan were added. DNA fragments of some new species were also found in the present study. Several rickettsial DNA closely related to *Rickettsia japonica, R. helvetica, R. canada,* or *R. akarii* were detected. Ehrlichial DNA closely related to a nevel *Ehrlichia* sp. detected in Tibet, Thailand and Africa were detected from *Hamaphysalis* ticks. Unique sequences that were similar to those of *Babesia odocoilei* and *Babesia divergens* were also obtained from *Ixodes ovatus*. *Borrelia valaisiana*-like DNA were detected from *Ixodes granulatus* in Okinawa. The combination of PCR and sequence analysis used in this study was demonstrated to be useful for detection of tick-borne pathogens from ticks. These can be excellent tools for epidemiological study of tick-borne diseases.

Species composition and dispersal of nuisance flies breeding on poultry farms in southern Australia

PJ James, C Krawec, NA Schellhorn, P Pepper
Department of Primary Industries, Animal Research Institute, LMB No 4, Moorooka, QLD, 4105 Australia; peter.james@dpi.qld.gov.au

"Ability to disperse and vectorial capacity makes flies a significant biosecurity and food safety risk on poultry farms. Although the species and biology of flies breeding on these farms has been widely studied overseas there have been few studies in Australia. We monitored numbers and species of flies breeding on egg farms in southern Australia over a 12 month period and assessed the dispersal of the major species using mass marking of resident fly populations with fluorescent dye. The little house fly, *Fannia cannicularis* and to lesser extent false stable fly *Muscina stabulans* were the major species for most of the year. In contrast to most overseas studies, *Musca domestica* was absent or present in only low numbers at most times. Most *F. cannicularis* remained within 700 m of the farm whereas marked *M. stabulans* were trapped at distances of up to 2 km. Modelling of total trap catches by distance predicted maximum dispersal distances of 1.6 km for *F. cannicularis* and 2.4 km for *M. stabulans.*

y-Season mosquito breeding associated with irrigation at Kununurra, Western Australia: potential impact on arboviral disease transmission.

A Jardine, MD Lindsay, J Heyworth, P Weinstein
M431, School of Population Health, The University of Western Australia, 35 Stirling Highway, Crawley, WA, 6009, Australia; andrewj@sph.uwa.edu.au

This study describes a preliminary investigation into the role of the Ord River Irrigation Area at Kununurra in mosquito production during the dry season. Specifically, the study aimed to test the hypothesis that irrigation has provided the opportunity for year-round breeding of arbovirus vector mosquitoes. A ten-day adult and larval mosquito sampling survey revealed that breeding was occurring during August, the iest month of the year at Kununurra, supporting the hypothesis that mosquitoes can breed year-round. Significantly larger numbers and percentages of adult *Culex annulirostris*, an important disease vector in Australia, were collected within the irrigation area (n=3706, 44.6%) compared to reference areas outside the irrigation area (n=363, 9.8%) (mean difference 76.2 per trap per night; 95% CI 38.6, 113.7; p<0.001). Larval *Cx. annulirostris* were also collected at several sites within the irrigation area, whereas none were collected at reference areas. Year-round mosquito breeding at Kununurra may increase human health risk from arboviral disease, as has been borne out by recent elevated notifications of Ross River virus disease in the late y-season compared to other towns in the Kimberley region. Mosquito management needs to be given a high priority to ensure this health risk is not further exacerbated. Strategies to reduce mosquito breeding should primarily focus on modification of breeding habitats and altering of irrigation protocols.

Comparative analysis of Calliphoridae complete mitochondrial genome sequences with other dipterans.

ACM Junqueira, AML Azeredo-Espin
"Universidade Estadual de Campinas – Unicamp, Lab. Genética Animal, CBMEG, Campinas, SP, Brazil. PO Box 6010, 13083-875; anacmj@unicamp.br"

In the view of the medical, veterinary, economic and forensic importance of Calliphoridae species, a comparative analysis of their nucleotide sequences with other dipterans would be useful for the molecular evolutionary studies of this family. Mitochondrial DNA (mtDNA) has been used mainly because of its maternal inheritance, accelerated rates of substitution, and lack of recombination. Of the 1020 Calliphoridae species described, 45 are listed in GenBank, including two complete mitochondrial genomes of the species *Cochliomyia hominivorax* and *Chrysomya chloropyga*. The comparison of the nucleotide content, skewness, aminoacid sequences, and codon usage between the mtDNA of Calliphoridae species and among the dipteran species can provide important features for studies in different taxonomic levels. Until now, the *cox1* gene is the most used molecular marker for studies among Calliphoridae and across a broad range of insects, but the comparison of individual and concatenated sequences of another mitochondrial genes among dipteran species have shown distinct degrees of conservation, indicating that some of them also should be employed as reliable molecular markers. The complete mitochondrial genomes are an useful source for improving primer designing, molecular identification of species, and for elucidate the potential of individual and combined genes for molecular systematic studies of Diptera.

Dispersal of house flies in the agricultural and urban environment: population dynamics Study using microsatellite markers

S Chakrabarti, S Kambhampati, L Zurek
Kansas State University, 123 West waters Hall, Manhattan, Kansas-66506, USA.

The house fly, *Musca domestica* L., is a synanthropic species with worldwide distribution. Due to their unrestricted movement, mode of feeding, developmental habitats, and attraction to places where food is prepared and stored, house flies greatly amplify the risk of human exposure to food-borne and other pathogens. Flies that develop in animal productions where antibiotics are frequently used for prophylaxis and growth promotion carry antibiotic-resistant bacteria that maybe transmitted to food intended for human consumption, leading to illnesses that are difficult to treat. However, no studies have been undertaken to quantify the extent of house fly movement between rural to urban areas. Therefore, our objective is to examine the population genetics of house flies and estimate the extent of dispersal/migration from rural to urban areas and *vice versa* in Kansas. As a first step, we developed polymorphic microsatellite loci for house flies. Here we report on the isolation, characterization, and optimization of microsatellite loci and preliminary results on population dynamics of house flies.

Comparative study on the nocturnal behavior of *Aedes* mosquitoes using a new device equipped with photoelectric sensor

H Kawada, M Takagi,
"Department of Vector Ecology & Environment, Institute of Tropical Medicine, Nagasaki University, Nagasaki, Nagasaki 852-8523, Japan;
vergiss@net.nagasaki-u.ac.jp"

The nocturnal behavior of non-blood fed *Aedes aegypti* and *Ae. albopictus* females was observed using a new automatic recording device equipped with photoelectric sensor. Carbon dioxide, heating and the contrast of black and white color were used for the attractive factors for mosquitoes. The nocturnal host seeking activity positively correlated to the increasing light intensity in both species. *Ae. aegypti* was found to be more sensitive to light than *Ae. albopictus.* The threshold of light intensity for activation of the nocturnal host seeking activity was < 0.1 lux (ca 0.01 foot candle) in *Ae. aegypti* and > 10 lux (ca 1 foot candle) in *Ae. albopictus,* respectively. Complete darkness in the daytime, on the other hand, deactivated the host seeking activity of *Ae. aegypti,* irrespective of their intrinsic circadian rhythm, which might well explain the importance of the sense of sight in *Ae. aegypti.*

Rainfall events determine the abundance of carrion feeding beetles in a West African savanna

FT Krell, M Boutros, S Krell-Westerwalbesloh, C Linder
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, U.K.; f.krell@nhm.ac.uk

Using carrion beetles on goat and warthog skins as a model system, we studied the influence of single rainfall events on the abundance and flight activity of insects in a tropical savanna (Parc National de la Comoé, Côte d'Ivoire). Although the attraction of the skins declined with time (due to degradation and desiccation), the freshness of the resource was not the major factor determining the abundance of carrion beetles. After rainfall events the number of beetles sharply increased, even with older skins. We recorded the same effect in regularly watered skins (simulating continuing freshness), showing that the humidity of the resource was not responsible for the peaks. The sharp abundance peaks after rainfall events is of relevance for both ecological field studies which have often a standardized sampling programme ignoring weather, and for forensic studies relying on a predictable succession of carrion users which can be strongly influenced by weather.

Environmental parameters of habitat on breeding behavior of *Aedes albopictus* in Chonju, Korea

JJ Lee, W Akram, KHAhn
"Faculty of Biol. Resources Science, Chonbuk Nat'l Univ., Chonju 561-756, Korea; (jjlee@chonbuk.ac.kr)"

Aedes albopictus during present studies has been associated with tree, automobile tires, very rarely apartment basements and open outdoor garbage containers. However, a contrast to the habitats of this insect is found; at one stage it seems that this mosquito can live in almost all places wherever there is debris, standing water regardless of the pH acidic or alkaline. Whereas, in certain cases it is evident that this insect is confined to a particular habitat, during the present investigation, it was quite evident that the outbreak of adult *Aedes* is very much dependent upon the percent humidity and temperature. The artificial habitats, that is abandoned tanks, cans, stray automobile tires if they are close to plantation or are in shade for most of the photoperiod they tend to be positive breeding sites for *Aedes* sp. In other situations, the same habitat in open with sunlight throughout the day tends to be negative breeding site. Water level in containers is also known to effect the population and species of the mosquitoes. Temperature and precipitation have been found to impose serious effects not only on the distribution of *Aedes* but also the size of the immature and adults as well.

Sheep lice control with entomopathogenic fungi

D Leemon, P James
"Animal Research Institute, Locked mail bag No 4, Moorooka, QLD, 4105, Australia; Diana.Leemon@dpi.qld.gov.au"

Preliminary investigations into the potential for the biological control of the sheep body louse (*Bovicola ovis)* by the entomopathogenic fungi *Metarhizium anisopliae* and *Beauveria bassiana* are reported. Scanning electron microscopy was used to investigate the uptake of inoculum from the wool by lice and bioassay methodologies using a wool substrate were developed to test pathogenicity. Fungal strains were identified that caused a 100 % mortality of lice after 5days. The level of lanolin in the wool and stage of louse development had a significant effect on mortality rates but there was no effect of temperature within the range of 31^{o}C to 38^{o}C. Further studies are investigating factors that influence the pathogenesis of fungal disease in lice.

The mitochondrial DNA control region of Muscidae species (Diptera: Calyptratae): evolution and structural organisation

MT Oliveira, AML Azeredo-Espin, AC Lessinger
Laboratório de Genética Animal, Centro de Biologia Molecular e Engenharia Genética (CBMEG), Universidade Estadual de Campinas (UNICAMP), CP 6010, CEP 13083-875, Campinas, SP, Brazil; lessinge@unicamp.br

The control region of insect mitochondrial DNA (mtDNA), also called A+T-rich region, is an interesting target for studies regarding the structure and evolution of the mtDNA. This non-coding region has an biased AT content, putative regulatory elements for transcription and replication processes, high levels of nucleotide substitutions and ins/dels events, and structural instabilities related to the organisation of internal sequence elements and its flanking genes. The sequence of *Haematobia irritans* and *Musca domestica* (Diptera: Muscidae) control regions have been determined and the sequencing of *Stomoxys calcitrans* control region is being conducted. Conserved sequence elements described for insect mtDNA control regions (such as poly-T streches, TA(A)n in tandem repeats, 'stem-and-loop' secondary structure and G+C-rich region) and conserved sequence blocks previously described for other Calyptratae species (myiasis-causing flies) have been identified in the Muscidae mtDNA control region. The share of such structural homologous elements among Muscidae and myiasis-causing flies suggests that Muscoidea and Oestroidea superfamilies have a similar regulatory mode for mtDNA transcription and replication processes. Intraspecific analysis of *H.irritans* populations using control region as a molecular marker are being conducted and length variation among specimens from Brazil, Argentina, Uruguay, Venezuela and Malaysia were already identified.

Key diagnostic characteristics of the third instar larvae of *Calliphora croceipalpis* and *Sarcophaga cruentata*

S Brink, TC van der Linde, L Basson, PWJ van Wyk
Department of Zoology & Entomology, University of the Free State, P.O. Box 339, Bloemfontein 9300 South Africa; vdlindet.sci@mail.uovs.ac.za

Following the death of a human, various insects involved in the decomposition process invade the corpse. This invasion takes place in an orderly sequence, called insect succession. This poster deals with those morphological characteristics used to distinguish between third instar larvae of the secondary invader *Calliphora croceipalpus* (Jaennicke) and the tertiary invader *Sarcophaga cruentata* (Meigen). All aspects of larval morphology were studied, but specific note was taken of the following aspects for diagnostic purposes: nature of the spines and spine band, anterior spiracles, posterior spiracles and the spiracular atrium of the posterior spiracles. The distinguishing characteristics of *S. cruentata* were the deeply recessed atrium cavity and the scalloping of the inner margin of the posterior spiracular plate. In *C. croceipalpus* the distinguishing characteristics were the shallow posterior spiracular atrium and the orientation of the spiracles. These key characteristics were compared to the key characteristics of the third instar larvae of the other species that form part of this study *viz. Lucilia cuprina* (Wiedemann), *Chrysomya chloropyga* (Wiedemann), *Chrysomya marginalis* (Wiedemann) and *Chrysomya albiceps* (Wiedemann).

The effect of temperatue on the development of the immature stages of *Hemilucilia segmentaria* (Fabricius) and *Hemilucilia semidiaphana* (Rondani) (Diptera: Calliphoridae).

PJ Thyssen, AX Linhares
"Departament of Parasitology, Institute of Biology, UNICAMP, CP 6109, CEP 13083-970, Campinas, SP, Brazil; aricio@unicamp.br "

Diptera larvae are among the most important carrion insects, because they are one of the most frequent and abundant organisms involved in animal decomposition process. This work objectived to determine the effect of temperature on the development of immatures of *Hemilucilia segmentaria* (Fabricius) and *Hemilucilia semidiaphana* (Rondani), two species of Neotropical blowflies commonly associated with animal carrion in rural and natural areas of Brazil, being two of the most important forensic indicators in the neotropics. The rearing of the immatures of both species was done using growth chambers with temperatures set at 10, 15, 20, 25, 30 and 35ºC, 12h photoperiod and 60 ±10% relative humidity. The mean developmental time from egg to pupation decreased as temperature increased. There were also differences in larval length, width and weight. These data were used to determine logistic growth curves to be used in estimating the age of the immatures of both species.

Larval competition differentially affects arbovirus infection and dissemination in *Aedes albopictus* **and** *Aedes aegypti*

BW Alto, LP Lounibos, S Higgs, SA Juliano
"University of Florida, Florida Medical Entomology Laboratory, 200 9th St. SE, Vero Beach FL 32962, U.S.A.; lounibos@ufl.edu"

We determined the species-specific effects of intra- and interspecific larval competition between the mosquitoes *Aedes albopictus* and *A. aegypti* on adult susceptibility to infection with the arbovirus Sindbis. We found higher infection rates and whole-body viral titer, but lower dissemination rates, for *A. albopictus* than for *A. aegypti*. For *A. albopictus* but not *A. aegypti*, intra- and interspecific competition resulted in greater infection rates compared to low-competition rearing conditions. Size-dependent and size-independent effects of competition influenced arboviral infection and dissemination of *A. albopictus* in opposite ways. At a single level of competition (i.e., at a single density), higher viral titers occurred in larger *A. albopictus,* but between competitive treatments adults from low-competition larval rearing conditions had greater mean body size and lower body titer and a lower proportion infected, compared to adults emerging from high-competition conditions. Competition experienced by larvae had no detectable effect on acquisition of infection by *A. aegypti*. Higher dissemination rates and less sensitivity of *A. aegypti* females to effects of larval competition are consistent with the greater role of this species as a vector of viruses to humans.

Mitochondrial DNA variability in screwworm fly from Uruguay.

ML Lyra, P Fresia, S Gama, J Cristina, AML Azeredo-Espin.
"PO Box 6010, CBMEG, UNICAMP, CEP 13083-875, Campinas-SP, Brazil; marilyra@unicamp.br"

The New World Screw-worm fly (NWS), *Cochliomyia hominivorax* (Diptera: Calliphoridae), is an obligate ectoparasite that causes primary myiasis in warm-blooded vertebrates throughout Neotropical regions. In Uruguay this pest is responsible for important economic looses to cattle breeding sector. In this work RFLP and PCR-RFLP analysis of mitochondrial DNA (mtDNA) were used to examine the genetic variability and population structure of six NWS geographic populations from Uruguay. RFLP analysis was performed using 5 restriction endonucleases and there were found 12 haplotypes. PCR-RFLP was used to survey mtDNA variation in control region and Cytochrome Oxidase subunits I and II. There were found 8 haplotypes utilizing 3 restriction endonucleases. The two techniques revealed the same pattern of haplotypes distribution, three haplotypes widely distributed and the remaining locally distributed. DNA diversity and divergence were estimated and the preliminary results revealed high genetic variability but no population subdivision. Our data are being compared with previous works that analyzed Libya samples collected during 1988 infestation in order to elucidate the origin of the introduction. The characterization of NWS intra specific genetic variability at the geographic level is necessary to monitoring the expansion in the current distribution and into screw-worm free areas. Financial support: FAPESP, CNPq, IAEA.

Paternal genome elimination in the human body louse, *Pediculus humanus* Linnaeus, 1758.

CJ McMeniman, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD 4072, Australia; c.mcmeniman@uq.edu.au

Eight F_1 and two F_2 families of human body lice, *Pediculus humanus*, were bred to examine the inheritance of alleles in this species. Alleles at four autosomal microsatellite loci segregated in two ways in these lice: (i) in a Mendelian fashion i.e. diplo-diploidy, and (ii) in a non-Mendelian fashion. We interpret the latter as paternal genome elimination, where parental males transmit, exclusively, their maternal genome to their offspring (functional haplodipoidy). Further investigations of this extraordinary finding may provide insight into how haplodiploidy evolves in insects.

Anthropogenic ecological change and insects of health concern in New Zealand.

M McIntyre, D Slaney, J Derraik, P Leisnham, A Snell, L Villa.
Ecology & Health Research Centre, Department of Public Health,Wellington School of Medicine & Health Sciences, Wellington South, New Zealand; mary.mcintyre@wnmeds.ac.nz

Key components of anthropogenic ecological change include land conversion to human uses and the fragmentation and disturbance of native ecosystems. This is combined with the spread of alien species and human commensals and loss of locally evolved species. New Zealand is a microcosm of some global issues in this regard. Our research examines ecological change and changes in the habitat, distribution and productivity of native and exotic mosquitoes, the relation of mosquitoes and potential arbovirus vector species, and the disease burden of bee & wasp stings in New Zealand.

Paternal genome elimination in the human body louse, *Pediculus humanus* Linnaeus, 1758.

CJ McMeniman, SC Barker
Department of Microbiology and Parasitology, and Institute for Molecular Bioscience, University of Queensland, St Lucia, QLD 4072, Australia; c.mcmeniman@uq.edu.au

Eight F_1 and two F_2 families of human body lice, *Pediculus humanus*, were bred to examine the inheritance of alleles in this species. Alleles at four autosomal microsatellite loci segregated in two ways in these lice: (i) in a Mendelian fashion i.e. diplo-diploidy, and (ii) in a non-Mendelian fashion. We interpret the latter as paternal genome elimination, where parental males transmit, exclusively, their maternal genome to their offspring (functional haplodipoidy). Further investigations of this extraordinary finding may provide insight into how haplodiploidy evolves in insects.

An *in vitro* larval immersion microassay for screening candidate Acaricides

WH White, PR Plummer, CJ Kemper, RJ Miller, RB Davey, JA Gutierrez, JA Meyer, CK Smith
Elanco Animal Health, 2001 W. Main St., op Code GL21, Greenfield, Indiana, USA; meyerje@lilly.com

Acaricide resistance in *Boophilus microplus* is rising dramatically in regions of the world where this ectoparasite is prevalent, posing significant economic burdens on cattle production and productivity in Central and South America, South Africa and Australia. While *Boophilus* has been eradicated from the United States, acaricide resistance will increase the threat of reintroduction into southern portions of the U.S. New chemical agents are needed that combine potent activity with novel modes-of-action not exhibiting cross-resistance to existing acaricide classes. Currently, none of the available *in vitro* tick bioassays offers the flexibility, speed, and sensitivity required to rapidly screen large numbers of compounds for candidate acaricides. We have optimized and characterized a larval immersion microassay (LIM) that offers superior sensitivity, the flexibility to accommodate multiple solvents and detergents, and a robust capability for screening compounds in a relatively short period of time using a minimal quantity of test article for evaluation. Dose-mortality studies were conducted against multiple ixodid ticks, including ug-resistant *B. microplus*, with representative formamidine, organophosphate, synthetic pyrethroid, pyrazole, macrocyclic lactone and carbamate acaricides. The rationale for using this method to screen chemical or natural product libraries and identify, characterize, and prioritize compounds for further development will be highlighted.

Incidence of bed bugs (Hemiptera: Cimicidae) in shared Accommodation In Sydney, Australia

PF Miller, BA Peters, N Ryan
Department of Health Sciences, University of Technology, Sydney, PO Box 123 Broadway NSW 2007, Australia; Peter.Miller@uts.edu.au

Bed bugs have remerged as significant pests in Australia and worldwide in the past ten years, The results of a survey of the incidence of bed bugs in shared accommodation in Sydney is presented. The survey examined the incidence of the bed bugs and the relationship of the infestation to a number of factors including, season, building construction and furnishings. It also examined control methods, their frequency and effectiveness. The results demonstrated widespread incidence of bed bugs with the majority of premises reporting an infestation in the previous 12 months and with many premises having multiple infestations throughout that period. Current control measures did not seem to be eliminating the problem as recurrence of the pest was common. A more comprehensive control strategy for bed bugs needs to be developed to manage this pest in shared accommodation.

Characterization of the enzymatic activities present in extracts of various mites.

MS Morgan, LG Arlian
Dept. of Biological Sciences, Wright State University, Dayton, OH 45435; Marjorie.morgan@wright.edu

Many of the previously-characterized allergens of house dust mites are known to be proteases and this enzymatic activity is thought to contribute to their allergenicity. Other astigmatid mites are also known to be allergenic but little or nothing is known about their enzymatic activities. The purpose of this study was to characterize the enzymatic activities present in extracts from 9 species of astigmatid mites, several of which have not previously been investigated. Extracts were prepared from 5 stored product mites (*Chortoglyphus arcuatus, Lepidoglyphus destructor, Blomia tropicalis, Tyrophagus putrescentiae, Acarus siro*), 3 house dust mites (*Dermatophagoides farinae, D. pteronyssinus, Euroglyphus maynei*) and one parasitic mite (*Sarcoptes scabiei*). ApiZym strips were used to screen for the presence of 19 individual enzyme activities. Digestion of 9 other substrates was also evaluated by spectrophotometric or electrophoretic methods. All mites exhibited some form of phosphatase, esterase, aminopeptidase and glycosidase activity although their substrate specificities varied considerably. Scabies mites did not possess detectable serine peptidase activity nor were they able to hydrolyze gelatin or casein while all other mites exhibited these activities. Storage mites possessed enzymes capable of degrading the widest range of substrates while scabies mites had the most limited proteolytic capacity.

Klinotactic orientation of the northern fowl mite to heat

JP Owen, BA Mullens, RT Cardé, KA Justus
Department of Entomology, University of California, Riverside, CA 92521; (bradley.mullens@ucr.edu)

The northern fowl mite (NFM) (*Ornithonyssus sylviarum*) is a cosmopolitan bird ectoparasite and a serious pest of the U.S. poultry industry. Mite infestations spread within a flock, even when direct bird-to-bird contact is prevented, and heat is a suspected orientation cue. NFM movement patterns were evaluated in a spatial heat gradient, as well as in an environment with temporal fluctuation of temperature (spatially uniform). Mites were filmed and the movement tracks were digitally analyzed for changes in velocity, angular shift and mean bearing. NFM significantly increased linear velocity when exposed to heat (35 °C) relative to control mites in ambient conditions (~27 °C). Mean track bearings were significantly associated with the position of the heat source in a spatial gradient, while track bearings of mites in ambient conditions were randomly directed. Temporal shifts in temperature from heated to ambient condition caused NFM to execute turns ≥ 90° within 5 seconds. Shifts in temperature from ambient to heated condition did not consistently cause NFM to execute turns ≥ 90°. These experiments indicate NFM orient to a heat source by comparing temperatures at different points in time (longitudinal klinotaxis) and executing turns based on internally stored (idiothetic) proprioceptive information.

Screening medicinal plant extracts for effects on *Aedes aegypti* (Diptera : Culicidae) and toxicity to a non target organism

S Promsiri, A Naksathit, M Kruatrachue, U Thavara
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand; grans@mahidol.ac.th

A preliminary study was conducted to find out the effects of the extracts of 112 medicinal plant species, collected from the southern part of Thailand, on *Aedes aegypti*. Studies on larvicidal properties of plant extracts against the third and fourth instar larvae of *Ae. aegypti* showed fourteen species with high toxicity. Six plant species were comparatively more effective against the larvae at very low concentration. These extracts demonstrated no or very low toxicity to guppy fish (*Poecilia reticulata*). Three plants with promising larvicidal activity, *Mammea siamensis*, *Anethum graveolens* and *Annona muricata,* were used to study of the impact of the extracts on the life cycle of *Ae. aegypti*. The results showed that these plants affected the reproductive potential of surviving adults by reducing the number of eggs laid and egg hatchability. The first instar larvae were very susceptible to *A. muricata* and the second instar larvae were susceptible to *A. graveolens* while the third and fourth instar larvae were susceptible to *M. siamensis*. These extracts delayed larval development and inhibited adult emergence.

The prevalence rate of *Leishmania* infection among *Phlebotomus* collected from Abardejh of Varamin Iran

H Nekouie, M Assmar, MR Razavi
Department of Parasitology, Pasteur Institute of Iran; h_nekouie@yahoo.com

Cutaneous Leishmaniasis is a prevalent tropical parasitic disease, which is caused by Leishmania protozoa. The infection can be limited in immun-compitant person, but it could progress to a chronic and ulcerative disease in immuno-comprmised person. The reservoirs are carnivore and rodents and the vectors are Phlebotomus. Abardejh of Varamin is located in southeast of Tehran and there is a tropical ecosystem in its eastern border. There is a suitable condition by the Tamarisk and rodents exist for *Phlebotomus* activity. In this study we investigated the prevalence of Phlebotomus population in Abardejh district. The collected sandflies by funnel trap from rodents' barrows transferred to the department of Parasitology at Pasteur Institute of Iran .The sampling was continued during the spring and summer in periodicals dates. The collected sand flies were studied to define the genius and species before parasitological culture in NNN media. The data revealed that the maximum activities of Phlebotomus were in Jun and July months. The results indicated the high prevalence rate of infection among the sand flies. This could be a matter of debate because of human and agricultural environments are located closely to this district. Therefore application of chemical control, environmental sanitation seems to be required to control of tranfection from sand flies to man.

The molecular identification of closely related calliphorids (Diptera: Calliphoridae) of forensic importance.

LA Nelson, JF Wallman, M Dowton
"Institutes of Biomolecular Science and Conservation Biology, School of Biology, University of Wollongong, Wollongong NSW 2522;
lan51@uow.edu.au"

Blowfly larvae (Diptera: Calliphoridae) are one of the most useful groups of insects utilised during the investigation of human deaths because they are among the first colonisers of a cadaver. The identification of such larvae is a critical step when estimating the the postmortem interval (PMI), as the rate of larval development can vary substantially between species. Two blowflies that have the potential to feature in forensic investigations are *Chrysomya semimetallica* and *Ch. latifrons.* The identification of these species is hampered by their almost indistinguishable morphologies, even as adults. The species were differentiated on the basis of two highly variable regions of the ribosomal DNA genes – the internal transcribed spacer (ITS) sequences. The amplification of ITS2 from both species was readily accomplished, however only ITS1 from *Ch. semimetallica* amplified successfully. The ITS2 differences correspond to 1.22 % sequence divergence between the species. A rapid, cost-effective strategy for species identification would involve PCR amplification of the ITS regions, followed by restriction fragment length polymorphism (RFLP) analysis. Despite the differences within ITS2, no restriction sites were observed that could differentiate the two species. Assessment of this possibility in ITS1 will be achievable once the remaining data is obtained from *Ch. Latifrons*.

A global presence of *Wolbachia* in human lice?

GK Kyei-Poku, MA Perotti, P Coghlin, R Speare, DD Colwell, KD Floate, HR Braig
School of Biological Sciences, University of Wales Bangor, Bangor, Gwynedd, LL57 2UW, UK; bssc13@bangor.ac.uk

Wolbachia are intracellular bacteria of general interest. The profound effects on the reproductive fitness of their insect hosts have resulted in plethora of phenotypes, which still await a full characterisation. Infections of *Wolbachia* in lice affecting humans are of particular interest. Endosymbionts of lice have a great potential for the control of these insects. Previous research in Canada suggests that infections of *Wolbachia* occur in all species of lice (Anoplura, Mallophaga). Independent and concurrent research in Wales provides substantiating evidence. The current study represents the subsequent joint efforts to test for the ubiquity of *Wolbachia* infections in populations of human lice (i.e, head lice - *Pediculus humanus capitis*, body lice - *Pediculus humanus humanus*, pubic lice - *Pthirus pubis*) from different continents.

Field efficacy of a personal insect repellent based on essential oils from Australian native plants against the mosquito (Diptera: Culicidae) and the biting midge (Diptera: Ceratopogonidae)

BA Peters, PF Miller, JA Staton
Department of Health Sciences, University of Technology, Sydney, PO Box 123 Broadway NSW 2007, Australia; Bryce.Peters@uts.edu.au

Field trials were carried out in a wet tropical climate at separate sites in Cairns, Far North Queensland, Australia in Autumn 2002. One site consisted of a fresh water creek infested by mosquitoes and the other site a mangrove wetland infested by biting midges. Both studies were carried out during daylight hours and were conducted by periodically exposing human volunteers with bare lower legs (knee to ankle) to mosquitoes or biting midges over a four-hour period. Counts were made of mosquito landings over a five-minute period and biting midge landings over a three-minute period. Both legs of each volunteer were used to give five replicates of the repellent formulation and five replicates of the untreated control. Against mosquitoes, primarily *Verrallina carmenti* and biting midges, primarily *Culicoides ornatus*, the formulation significantly reduced the landing rate compared to untreated legs over the entire four-hour study period. This study demonstrated that this formulation provided protection against mosquitoes and biting midges for up to four hours after application.

Natural promastigote infection of *Phlebotomus caucasicus* in a new focus of visceral leishmaniasis in north west of Iran

Y Rassi, F Kaverizadeh, E Javadian
PO Box 6446,Tehran 14155, I.R. Iran Dept. of Medical Entomology &Vector Control, School of Public Health& Institute of Health Research, Tehran University of Medical Sciences

An investigation was carried out in Ahar County (a new focus of Visceral Lieshmaniasis) in order to determine the vector (s) of disease. This study was done in eastern Azarbaijan, North-west of Iran during the summer of 2003. Sand flies were collected using sticky papers, CDC light traps as well as aspirators. All of the collected sand flies were dissected in a op of normal saline for surveying of promastigote. Head and the two last abdomen segments of specimens were mounted in a op of Puri,s medium for species identification. Totally, 215 sandflies were collected including: *Phlebotomus kandelakii* (57.2%), *P.perfiliewi* (18.1%),*P.caucasicus* (11.2%), *P.sergenti* (7.9%), *P.papatasi* (3.3%) and *P(.adlerius)sp.*(2.3%). Only 1 out of 24 *P.caucasicus*(4.2%) was found naturally infected with parasites. This is the first infection report of *P.caucasicus* in this region. The ecology and some behavioural aspects of the vector will be discussed in details.

Application of a new *Aedes* surveillance method in Botucatu, Brazil.

LA Nogueira, LT Gushi, NG Madeira, PEM Ribolla
PO. Box 510, Parasitology, UNESP, 18618-000, Botucatu, Brazil; pribolla@ibb.unesp.br

In Brazil, infection by dengue virus has increased significantly in the last two decades, after the reintroduction of mosquito vector *Aedes aegypti*. Epidemiological surveillance remains the only way to prevent dengue outbreaks. Currently, the control program applied in *Aedes albopictus* and *Aedes aegypti* populations are larval surveys. An interesting alternative is the using of a new control strategy named PCI (Premise Condition Index). This model relates the property condition, like house condition, yard condition, and degree of shade; to the occurrence of *Aedes sp* oviposition. The present study is based on the application of PCI in properties located in the urban area of Botucatu. Ovitramps have been set in 105 spots all over the city and their properties qualified. Results from properties analysis by PCI showed that 64.7% ones with scores 8 and 9 (considered bad condition houses) were positive to *Aedes albopictus* while only 19% of properties with scores 3 and 4 (good condition houses) were positive. This analysis demonstrated the accuracy of PCI method, since major occurrence of *Aedes sp* has been observed in properties with highest scores. There is a positive correlation ($r=0.76$, $p<0.025$) between PCI and positive house percentage, showing the significance of the method.

Molecular population genetics of *Aedes aegypti* in Brazil using RAPD

KS Paduan, JP Araújo-Junior, PEM Ribolla
PO.Box 510, Parasitology, UNESP, 18618-000, Botucatu, Brazil; pribolla@ibb.unesp.br

Random amplified polymorphic DNA (RAPD) analysis technique has been used in studies of arthropod molecular taxonomy and in epidemiological studies of relatedness of geographic populations and vector movement. In Brazil, little is known about genetic structure among *Aedes aegypti* populations. We use RAPD to examine patterns of *Aedes aegypti* genetic structure in 11 populations from 6 Brazilian states. We found high genetic polymorphism (H_S = 0.38) and high levels of genetic differentiation exist both between population from different states (G_{ST} = 0.43) and between populations from cities in same state (G_{ST} = 0.41). These results indicate significant differentiation between *Aedes aegypti* populations in Brazil. There is a clear correlation between genetic structure and geographic localization showing that, if new populations are been introduced, they are not significant. Principal Component Analysis (PCA) of receive allele frequencies could separated populations in 3 different groups regarding geographic origin.

Biological characteristics of three domiciliated vectors of Chagas disease in Mexico.

PM Salazar-Schettino, M Cabrera, I de Haro, M Vences, M Bucio, A Ruiz, G Rojas.
Lab Biol Parásitos Fac Med UNAM Edif. A, 2º piso México CP 04510; pazmar@servidor.unam.mx

Mexico has a great population of triatomine bugs actually are reported seven genera and 24 species of Triatoma genus. Due to this great amount and diversity, surveys were made for to know ecotopes and biology of three species of the Triatoma genus. The objective is to show laboratory and fields observations made in regions where Trypanosoma cruzi vectors predominate: Triatoma barberi recollected in Queretaro state, T. pallidipennis in Morelos and T. dimidiata in Veracruz. T. barberi is an exclusive species of Mexico, it prefers walls, T. dimidiata is found in floor and the middle of the wall downwards, both in beooms, and T. pallidipennis prefers floor and clothes, also wildlife. Life cycle is 523 and 510 for Triatoma barberi and T. dimidiata, respectively and for to T. pallidipennis is 171 days. T. barberi feeds and defecates at the same time, the others two species defecated among 10 and 30 minutes. Infection index percentage was is 56.6 for T. barberi, 29.0 for T. pallidipennis and 15.7 for T. dimidiata. Percentage of infective forms in bugs feces were 76, 26 and 15 for T. barberi, T. pallidipennis and T. dimidiata respectively. T. barberi is the best vector of T. cruzi in Mexico

Droneflies occurring from effluent of manure in Hokkaido, Japan (Diptera: Syrphidae)

H Sasaki, A Mikami
"Laboratory of Entomology, Rakuno Gakuen University, 582-1 Bunkyodai-Midorimachi, Ebetsu, Hokkaido 069-8501, Japan; h-sasaki@rakuno.ac.jp"

Three genera and 5 species of droneflies (Diptera: Syrphidae), namely Eristalis (Eoseristalis) cerealis, Eristalis (Eoseristalis) roccica, Eristalis (Eristalis) tenax, Eristalinus (Lathyrophthalmus) tarsalis and Helophilus (Helophilus) virgatus, occurred from the ovitraps using the effluent of manure as attractant and media in Hokkaido, Japan.These droneflies were reared in the laboratory and the specimens of each developing stages were examined their morphological characters by the binocular and scanning electron microscopes. The following differences between the species were observed:Units of eggshell of H. virgatus were glabrous and those of the other 4 species were rhizoids.Sensilla of the 3rd instar larvae of E. rossica and E. tarsalis were spinous and those of the other 3 species were setae.Only E. tarsalis have spine rows at the 7th proleg and only H. virgatus have 3 pairs of lappets at anal segment of the 3rd instar larva.Trachae of the 3rd instar larva of H. virgatus are waved and those of the other 4 species were strait.Anterior spiracles of puparium of those species are all characteristic shaped.According to the combination of morphological characters above mentioned, it is easily distinguish the species at all developing stages.

Bioconversion with *Hermetia* to solve problems of manure accumulations and produce valuable feedstuff

DC Sheppard, GL Newton, GJ Burtle, CR Dove, W Watson, GC Rains, M Coulibaly
"University of Georgia, Tifton Campus, P. O. Box 748, Tifton, GA 31793, USA; Sheppard@tifton.uga.edu"

Black soldier fly, *Hermetia illucens* can eliminate many of the problems associated with large manure accumulations and with other putrescent wastes. The larvae consume fresh waste rapidly in managed systems and assimilate nutrients that otherwise might produce odors, pest flies and cause environmental pollution. Mature prepupae are self-collected for use as an animal feedstuff with about 42% protein and 35% fat. As a ration component, prepupae meal supported better fish growth than otherwise similar rations using fish meal. Data will be presented on this and other feeding studies with prepupae meal, amino acid and fatty acid profiles, elimination or reduction of several malodorous gasses, control of pest flies and reduction of waste dry matter by 50% or more and reduction in concentration of potentially polluting nutrients within that residue.

Prevalence of dengue virus in *Aedes* mosquitoes during y season by semi-nested reverse transcriptase-polymerase chain reaction (Semi-nested RT-PCR)

R Taksinvarajarn, P Tanayapong, S Pongratanaman, P Hansasuta, P Bhattarakosol, P Siriyasatien
Department of Parasitology, Faculty of Medicine, Chulalongkorn University, Bangkok, 10330 Thailand; fmedpsy@md.chula.ac.th

Dengue hemorrhagic fever remains a major health concern in Thailand. Much effort has focused on the prevention and control of the disease. Detection of dengue virus infection rate in mosquito would evaluate dengue control programs and predict the epidemics of dengue hemorrhagic fever. To determine dengue virus infection rate in mosquito by Semi-nested RT-PCR. A total of 400 mosquitoes were collected from Rom Kao Community representing a crowded community and another 9 non-crowded communities in Bangkok. Mosquitoes were then divided into 40 pools, each contained 10 mosquitoes. A total of 391 *Aedes aegypti* and 9 *Aedes albopictus* were screened for dengue virus. Mosquito infection rate in Rom Klao community is 2.5% of mosquito pool equal to that found in non-crowded communities. Both groups are found to be dengue virus serotype 3. Our study suggests a circulation of dengue virus serotype 3 in both crowded and non-crowed communities, the infection rates of which are indifferent during dry season.

Field evaluation of bifenthrin 10WP and bifenthrin 80g/L SC on dengue vectors at high-rise flats in Kuala Lumpur , Malaysia.

S Sulaiman, HF Othman, ZA Pawanchee, N Shaari
Department of Biomedical Science, Faculty of Allied Health Sciences, Universiti Kebangsaan Malaysia, Jalan Raja Muda Abdul Aziz 50300, Kuala Lumpur, Malaysia; salsul@medic.ukm.my

Bifenthrin 80g/L SC and Bifenthrin 10WP were evaluated against the sentinel sugar fed adults and 4th instar larvae of *Aedes aegypti* at 17 storey high-rise flats in Kuala Lumpur.The impact of both pyrethroid formulations on field populations of *Aedes aegypti* and *Aedes albopictus* larvae was monitored weekly using bottle containers.Both formulations of Bifenthrin showed adulticidal effects causing between 96% and 98% of *Aedes aegypti* mortality in the field compared to 18-19% in the control. However,both Bifenthrin formulations had not shown larvicidal effects when sprayed with ULV. This field trial indicated that both Bifenthrin formulations had potential for use in future dengue vector control programs.

Geographical range predictions of *Anopheles* mosquitoes in northern Australia using a genetic algorithm and data mining methods

AW Sweeney, NW Beebe, RD Cooper
IBID, University of Technology Sydney, Westbourne St reet, Gore Hill, NSW 2065 Australia; Tony.Sweeney@uts.edu.au

An appreciation of the environmental factors which influence the geographical ranges of mosquito vectors of malaria is of considerable interest from both ecological and epidemiological viewpoints. GARP (the Genetic Algorithm for Rule-Set Prediction) was used for ecological niche modelling of *Anopheles farauti* ss, *Anopheles farauti* 2 and *Anopheles farauti* 3 in northern Australia. Models were developed using 41 environmental layers together with species locality datasets derived from systematic mosquito surveys in northern Queensland and the Northern Territory. For each species the predicted ranges included almost all presence records and excluded areas in which that species was not found in repeated collections. The datasets were analysed with CART (Classification and Regression Tree Analysis) and KnowledgeSeeker to investigate associations between environmental variables and the record/no-record collection sites for each species. The outputs were used for further model development with GARP to produce accurate range maps of *A. farauti ss* and *A. farauti* 3 using only 6 or 7 of the most significant environmental layers identified by decision-tree software. Further data mining analyses showed that the use of simulated absence data in lieu of no-record collection data may highlight significant environmental variables in datasets which do not have records for species absence.

A new pediculicide based on isopropyl myristate

T Foard, K Palma, RG Todd
"Insect Control & Research, Inc., 1330 Dillon Heights Avenue, Baltimore, MD 21228-1199, USA; inscontrolres@aol.com"

New pediculicides need to be effective, safe, and to act differently from other products so as to prevent or delay resistance. Isopropyl myristate (IPM) is approved for many cosmetic uses and is thus safe for topical use. IPM is not known to be neurotoxic to insects, unlike most other pediculicides. IPM in cyclomethicone was tested against body lice and their eggs (*Pediculus h. humanus*) as surrogates for head lice (*P. h. capitis*) by the ASTM methods. IPM gave 100% knockdown at +1 hour and 88.8% at +4 hours. 24-hour mortalities were: 15% IPM; 68.8%, 50% IPM; 97.1%, 100% IPM; 100%. Ovicidal action was slight, with mortalities under 20% The mode of action is unresolved, but is likely to be related to IPM's spreading and penetrating action. Symptoms were, however, similar to those from a neurotoxic synergized-pyrethrin pediculicide; Rid®. Toxicity was lower in lice exposed orally to IPM (56.0%) than by direct contact with a treated substrate (90.4%). Direct contact gave signs of desiccation, oral exposure did not. A cuticular route of action is indicated. An IND has been submitted to FDA and Phase II clinical trials start in April 2004.

Development of new microsatellite markers in the New World screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae)

TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

Microsatellites are a highly informative class of DNA markers, consisting of tandem repeats of 2-6 bp distributed throughout eukaryotic genomes. Microsatellite loci stand out as codominant and multiallelic markers with high polymorphism and expected heterozygosity value. Due to these characteristics, they were the molecular markers chosen to continue our efforts to investigate the genetic variability and population structure of the New World screw-worm (NWS) *Cochliomyia hominivorax* (Coquerel). This species is one of the most important parasitic insect pests in Neotropics, causing myiasis and, consequently, significant losses to livestock industries in these regions. In order to generate new microsatellite markers for NWS, an enriched genomic library for microsatellite inserts was constructed. Of 56 clones inserts sequenced, 30 had a microsatellite and of these, 10 sequences with repeats of di-, tri-, tetra- and hexanucleotides were selected. Primer pairs were generated for the ten selected loci and eight of them were successfully amplified in NWS DNA samples. Polymorphism of each locus will be evaluated and the informative markers, in combination with ten polymorphic microsatellite markers previously described, should provide high resolution for assessing the fine-scale genetic structure in NWS.

Genetic structure and diversity in new world screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae) populations from Uruguay revealed by microsatellite markers

TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

The New World screw-worm (NWS), *Cochliomyia hominivorax* (Coquerel), is one of the most important parasitic insect pests that cause invasive myiasis in warm-blooded vertebrates. Because of the substantial economic losses to livestock rearing caused by this pest throughout the neotropics, an international effort has been involved in a program to eradicate the NWS from endemic areas of Central and South America and to prevent invasions into screw-worm-free areas. It is crucial to characterize the genetic variability of target populations in order to maximize the effectiveness of the eradication program. Ten polymorphic microsatellite loci previously isolated from an enriched library constructed for *C. hominivorax* are currently being used to investigate the genetic variability and population structure across its current geographic distribution. Preliminary results obtained from Uruguayan populations indicated a considerably high genetic variability. Statistical analysis indicated that most of the genetic variation is contained within populations, while low levels of differentiation were found between them. The investigation into the genetic variability and population structure of NWS from Central and South American populations should provide fundamental information for future eradication strategies.

Isolation of microsatellite loci in the blowfly *Chrysomya chloropyga* (Diptera: Calliphoridae)

RA Rodrigues, TT Torres, AML Azeredo-Espin
"PO Box 6010, Laboratório de Genética Animal, CBMEG – UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br "

The species *Chrysomya chloropyga* (= *Chrysomya putoria*) (Wiedmann) is a synanthropic blowfly native from African regions. The adults feed and breed in carrion, feces, urban garbage and carcasses. Due to these biological features, *C. chloropyga* have great medical-veterinary importance acting as a vector of pathogens and is considered of potential forensic importance. This fly was probably introduced into Brazil around 1975 with the influx of Angolan refugees. Since then it has spread rapidly in Brazil and other countries of South America affecting the ecological scenario of the native Calliphoridae fauna. Genetic studies based on mitochondrial DNA revealed insufficient polymorphism at a fine scale. Since microsatellites are one of the most powerful markers for studying inter- and intrapopulation relationships, our goal is to develop a set of polymorphic microsatellite markers for *C. chloropyga*. A genomic library enriched for the motifs poli-AC/TG and poli-AG/TC was constructed. We are currently screening this library for microsatellite-containing clones. Of 54 clones inserts already sequenced, 26 had a microsatellite and 12 are useful sequences for designing primers. After polymorphism evaluation, these loci should contribute to population dynamics studies and for understanding the evolutionary context of the introduction of this species in the New World.

Survey of new world screw-worm *Cochliomyia hominivorax* (Diptera: Calliphoridae) for the presence of a point mutation associated with esterase-mediated organophosphate resistance

RA Carvalho, TT Torres, AML Azeredo-Espin
PO Box 6010, Laboratório de Genética Animal, CBMEG - UNICAMP, 13083-875, Campinas, SP, Brazil; tttorres@unicamp.br

The *Cochliomyia hominivorax* (Coquerel) is the main agent of primary myiasis in the South America, generating severe economic losses to livestock industry. In Brazil, its control has been done by the application of insecticides, but the inappropriate use of these chemical agents can select resistant flies. It has been shown in another species of the Calliphoridae family, *Lucilia cuprina*, that a Gly137®Asp substitution in the enzyme carboxylesterase (E3) converts its typical activity to an organophosphate (OP) hydrolase activity resulting in the development of OP resistance in this species. Preliminary efforts to isolate and characterize the E3 gene in *C. hominivorax* using primers previously described for *L. cuprina* resulted in a gene fragment of ~200 bp containing the site of the Gly137®Asp mutation. This region showed high similarity to the orthologous region in *L.*cuprina. The intron position is conserved, however its physical size and nucleotide sequence are not. The partial exon sequence differed from that in *L.cuprina* at 2 nucleotide sites, but no amino acid substitution was predicted. Further analysis will be conducted to determine the association of this point mutation OP resistance in *C.hominivorax* strains. This characterization should allow the identification of resistant individuals, enabling more effective control strategies.

Evaluation of prepared Thai plant-based repellents against mosquito bites under field condition

Y Trongtokit, Y Rongsriyam, N Komalamisra, P Krisadaphong, C Apiwathnasorn
"Department of Medical Entomology, Faculty of Tropical Medicine, Mahidol University, Bangkok, Thailand; g4148061@student.mahidol.ac.th"

The experimental repellent products in the gel dosage form contained 20% clove oil (*Syzygium aromaticum*) and 10% clove plus 10% makaen (*Zanthoxylum limonella*) oil mixture were evaluated theirs efficacy against daytime- and nighttime-biting mosquito comparing with 20% deet (di-methyl benzamide) under field condition using a human bait method. One gram of the product was applied evenly from knee to the ankle of each leg. Shorts and shoes were worn to standardize the exposure area. Other exposed untreated parts of the body were protected against mosquitoes attack by wearing a jacket with hood and gloves, covering the thighs with a plastic sheet. For daytime-biting, 20% clove showed complete protection for 4.0 h and gave 95.7% repellency after 5 h application, whereas 10% clove plus 10% makaen oil mixture and 20% deet provided only 86.8 and 82.7% repellency after treatment, respectively against *Aedes aegypti*. For nighttime-biting, the 3 developing repellents yielded equally excellent (average 97.1% repellency for 5 h against the predominant *Culex quinquefasciatus* and *Mansonia uniformis* but they gave 89.0% repellency against *Cx. tritaeniorhynclus* and *Cx. gelidus*. This finding demonstrates that the repellency of 20% clove oil and 10% clove plus 10% makaen oil mixture in the gel dosage form are possible used against various different mosquito species.

Host grooming efficiency and its influence on the distribution of cat fleas, *Ctenocephalides felis*

MH Hsu, YL Yang, WJ Wu
27, Lane 113, Roosevelt Road, Section 4, Taipei 106, Taiwan; wuwj@ccms.ntu.edu.tw

Grooming is usually supposed to be the main factor to affect the final distribution of ectoparasites on hosts, that is, the distribution of ectoparasites can be changed when the grooming ability is refrained or can be different between those on the good and poor groomers. Therefore, in this study we compared the distribution of cat fleas, *Ctenocephalides felis* (Bouché)(Siphonaptera: Pulicidae), on the cat with good or poor ability of grooming and the cat wearing an Elizabethan collar or not. As expected, the results show that cat's grooming efficiency against fleas was significantly varied among individuals and greatly reduced by wearing an Elizabethan collar. However, the effect of grooming efficiency on the distribution of fleas on the host body is not significant. Regardless of cat's grooming efficiency, mean percentages of fleas detected at 24 or 96 hours after initial infestation were always highest on the neck (52 – 71.67%) among body regions (other regions ranging from zero to 30%). Fleas seem to prefer the anterior regions of cats including the head, neck, and front back. Moreover, male (60.17%) and female (61.18%) fleas have the same trend to move to the cat's neck.

Impact of anthelmintics on the growth of dung beetles and dung breeding flies in Japan.

N Yamashita, M Iwasa, S Shimano, N Yoshida , A Watanabe, A Mikami
National Agricultural Research Center for Tohoku, Arai, Fukushima, Fukushima, 960-2156 Japan; yama@affrc.go.jp

Most of anthelmintrics like an Ivermectin is excreted in the feces as a mixture of parent compound and metabolites. So, the use of anthelmintrics in livestock has potential impact on nontarget invertebrates, for example, dung beetles, flies, that depend on dung pats and contribute dung degradation in grassland. This study examined the impact of the anthelmintics residue on the dung degrading fauna in grassland. Dung samples were collected on 1, 3, 7, 14, 21, 28 and 35 day after pour on and bioassayed using the dung beetles and flies. Ivermectin residues attained maximal concentration from 1st to 3day after pour on followed by a linear decline to 35day. Dung pats collected 1 to 14days after treatment with ivermectin were lethal to larval development of native dung beetle, *Onthophagus lenzii* and native dung breeding flies, *Musca hervei*. Dung collected 1 to 3days after treatment was lethal to larval development and pupation of native dung beetle, *Aphodius elegance*. In field experiment using emergence trap, number of emerged flies were 3,655 (18families) in control dung and 2,234 (16 families) in treated dung.

Investigation of alternative insecticides for the treatment of bed nets and for indoor residual spraying to control *Anopheles* mosquitoes.

AL Yates, AN Asidi, M Rowland
The Gates Malaria Partnership, Disease Control and Vector Biology Unit, London School of Hygiene and Tropical Medicine, Keppel Street, London, WC1E 7HT, UK

There is an urgent need to investigate alternative insecticides for the control of pyrethroid resistant *Anopheles* mosquitoes, vectors of malaria. Resistance to DDT and pyrethroids among *Anopheles* (especially *gambiae* and *funestus*) species has been reported in western, southern, and eastern Africa. Alternative insecticides with novel modes of action remain may have potential for use on nets or indoor residual sprays. The Gates Malaria Partnership at LSHTM is working with WHO and industry to identify new actives. Bioassay tests were carried out using new insecticides including a phenylpyrazole (fipronil), an organophosphate (chlorpyrifos methyl, "Reldan"), an oxadiazine (indoxacarb) and a pyrrole (chlorfenapyr). Some of these compounds were tested in mixtures to investigate their possible synergistic interaction with pyrethroid insecticides. Laboratory studies with fipronil on netting have shown some irritant effect against *An. stephensi* and some synergisms between fipronil and deltamethrin. Different formulations of Reldan sprayed on various substrates (mud, plaster and wood) to investigate the efficacy of the formulations for indoor residual spraying (IRS) showed good residual performance up to 6 months especially on plaster. On the treated nets, Reldan performed well against wild populations of pyrethroid resistant mosquitoes. Indoxacarb and chlorfenapyr showed a slow acting effect in terms of mortality and KD but indoxacarb was better on netting when mixed with deltamethrin.

Evidence supports two cytologically different races of *Anopheles pullus* in Korea

CH Yu, W Choochote, A Jitpakdi, A Junkum, SJ Kim, SJ Park, GS Min
"Depart of Biological Science, Inha University, Incheon 402-751, Korea; chyu@inha.ac.kr"

Despite the medically-importance of anopheline mosquitoes as vectors of Korean vivax malaria, differentiation among Korean anopheline mosquitoes are obscure and difficult by traditional morphological taxonomic criteria. To verify the species status of two ambiguous species of *An. pullus* and *An. yatsushiroensis* (*An. pullus form yatsushiroensis*) mosquitoes from Korean, we established isofemale lines and investigated their genetic relationship by metaphase karyotypes, hybridization experiments, DNA sequence comparisons of rDNA ITS2 and mitochondrial COI and COII. Two isofemale lines showed different chromosomal shapes in sex chromosomes of X and Y, the reciprocal crosses between the two isofemale lines, however, provided viable progeny with completely synaptic salivary gland polytene chromosomes. DNA analyses also strongly supported the conspecificity of these isofemale lines. Based on these evidences, we conclude that two *An. pullus* forms which differ distinctively in morphological, cytological and ecological traits remain in interfertile status.

Incompatible hybridization between two sympatric species of *Anopheles sinensis* and *Anopheles pullus* (Diptera: Culicidae) in Korea.

CH Yu, W Choochote, A Jitpakdi, A Junkum, SJ Kim, MH Park, GS Min
"Depart of Biological Science, Inha University, Incheon 402-751, Korea; chyu@inha.ac.kr"

Hybridization tests of laboratory-raised, iso-female lines of *Anopheles sinensis* Form B and *An. pullus* Form A and B were conducted by induced copulation. The three iso-females line were established based on morphological characteristics of wild-caught, fully engorged females and three distinct types of metaphase karyotypes. They were *An. sinensis* form B (X, Y_2), *An. pullus* form A (X_1,Y_1) and form B (X_2,Y_2). The results of reciprocal and back crosses among *An. sinensis* and *An. pullus* indicated that *An. sinensis* was genetically incompatible with *An. pullus*, providing low viability of F_1-hybrid larvae with completely asynaptic of salivary gland polytene chromosomes, sex distortion of adults, abnormal development of ovarian follicles of F_1-hybrid females, and atrophy of accessory glands and testes of F1-hybrid males. The results strongly suggested that these two morphological species exhibited entirely reproductive isolation.

Tick & tick borne diseases: antigen selection in a genomic era.

Attractiveness and food value of plants for aphids

V Afonina
Department of Entomology, Faculty of Biology, Moscow State University 119992 Russia

Plants of chrysanthemum, pink and cineraria were grown in greenhouse under either normal composition of elements (nitrogen, phosphorus, potassium), excess (+N,+P,+K) or shortage (-N,-P,-K) of one of these elements. Attractiveness of plants for aphids *Coloradoa rufomaculata* Wils. and *Myzodes persicae* Sulz. was determined as a number of adults, which occupied the plants. All the plants had maximal attractiveness at +N treatment, and the minimal at -N. The excess of the other elements resulted in increase in attractiveness compared to normal composition, the shortage led to decrease of attractiveness. Food value of plants was determined by fecundity, periods of development and reproduction, and longevity of the aphids. Fecundity was maximal under +K and especially +P, it was minimal under shortage of these elements. Treatments +N and -N did not differ from control and from each other. Plants under +P contained maximum of free amino acids. Longevity and reproduction period were increased under -N, however no difference between other treatments was observed. Development time did not depend on the treatments. Therefore the plants +N most attractive for aphids were less favourable for their population.

Ludwigia **flowers (Onagraceae): a rich food source for solitary bees in South Brazil**

I Alves-dos-Santos
Diretoria de Pós Graduação. UNESC. Caixa Postal 3167. Criciúma, SC 88806-000 Brazil

Species in the genus *Ludwigia* (Onagraceae) probably originated in wet habitats of the tropics of South America, being this area considered the centre of diversity for the genus, and containing the most primitive species. There are approximately 80 species of *Ludwigia* that occurs predominantly in the Neotropics. The habitat of *Ludwigia* includes swamps, marshes and wet places, being therefore common found in the lowlands of the Brazilian territory. The flower visitors of *Ludwigia* species were sampled periodically in southern Brazil (Santa Catarina and Rio Grande do Sul - 28° to 30°'S), where the coast plain is broad and with big freshwater lagoons from the Quaternary. The insects were sampled with entomological net and observed during the visits. More then 30 bee species were identified as frequent visitors of the *Ludwigia* flowers. Furthermore, at least 16 species were considered oligolectic to these plants, which means that they are specialized to collect pollen from one or more species of *Luwigia*. In other words the female and the larvae of the bee depend on the floral resources of the *Ludwigia* species. These plants can be considered important components of the melittophilous vegetation since they support around 10% of the local bee fauna.

Applying GIS for finding distribution patterns of arboreal Coleoptera: cultivating a seed program for inventories and conservation planning in western Amazonian forests.

V Aschero, TL Erwin
Laboratorio de Investigaciones Ecológicas de las Yungas, CC34, 4107, Yerba Buena, Tucumán, Argentina; liey@tucbbs.com.ar

Over the last decades, descriptions of tropical forests beetles have made a large taxonomic contribution in Coleoptera, but the mechanisms and rules explaining the species distribution and abundance in the tropics are still poorly understood. Data collected from a canopy arthropod biodiversity study conducted in Ecuadorian Amazonian forests between January 1994 and July 2002 is here used for exploring spatial and temporal distribution patterns of beetles responding to tree species occurrence and microhabitat characteristics. Point maps of beetle distributions were produced at a scale of meters using ArcViewGIS and the emergent distribution pattern was tested against canopy variables, such as: tree species composition; strata structure; occurrence of dry leaves, lianas and epiphytes, and light measures. Using GIS techniques was justified by the high diversity and complexity of Amazonian forests. Distribution patterns of beetles at a fine scale responding to forest composition and structure should reflect animal–plant ecological relations, so our results set a starting point in developing further studies which will seek to understand functioning of the richest biotic communities on Earth. Abundance distribution information for beetles at a very fine scale can also be directly applied in planning inventories studies and taking local conservation decisions.

Correlation of stylet penetration behaviours and an EPG waveform with inoculation of *Xylella fastidiosa* **by the glassy-winged sharpshooter,** *Homalodisca coagulata*

EA Backus, J Habibi, FM Yan
USDA-Agric. Research Service, 9611 So. Riverbend Ave., Parlier, CA 93648, USA; ebackus@fresno.ars.usda.gov

Stylet penetration behaviours of the glassy-winged sharpshooter, *Homalodisca coagulata* Say, are being studied to determine the behavioural mechanism of inoculation of *Xylella fastidiosa* (Xf) in plants. To do this, we are using AC and DC electrical penetration graph (EPG) monitoring of feeding, videomicrography of stylet movements, and histology of both salivary sheaths in plants and Xf aggregations in vector precibaria. We report herein correlations of GWSS AC waveforms A1 and A2 with salivary sheath formation, B1 and B2 with other pathway activities, and C with excretory oplets (presumed ingestion). Results presented also implicate the B1 waveform in inoculation of Xf near identified probes, and discuss whether bacterial populations in the vector precibarium can be correlated with bacterial expulsion and/or any waveforms. The ultimate goal of our research is to develop a Stylet Penetration Index using EPG monitoring of feeding, which could provide a rapid means of screening grape varieties for host plant resistance to the vector.

Correlations of probing behaviour by glassy-winged sharpshooter, *Homalodisca coagulate* **(Say), with AC electrical penetration graph (EPG) waveforms using video and artificial diets**

PH Joost, F Yan, EA Backus
USDA, 9611 S. Riverbend Ave. Parlier, CA USA 93648; ebackus@fresno.ars.usda.gov

Glassy-winged sharpshooter (GWSS), *Homalodisca coagulate* (Say), is the main vector of *Xylella fastidiosa,* the casual bacterium of Pierce's Disease in grapevine. A detailed understanding of GWSS probing behaviour is important because *X. fastidiosa* is acquired and inoculated when GWSS feeds. To further elucidate GWSS probing behaviour we used the AC electrical penetration graph technique (AC EPG) and video to correlate GWSS probing behaviours with EPG waveforms in artificial diets. Three previously described waveforms, A1, B1 and B2, were correlated with GWSS stylet activity. Fascicle protraction, alternating mandible retraction and maxillary tip fluttering were correlated with subdivisions of the A1 waveform. Salivary sheath formation was also observed in A1. Waveform B1 was correlated to maxillary fluttering within the salivary sheath. Termination of the B1 waveform and maxillary fluttering would sometimes occur when the maxillae were inside the saliva sheath and always when the maxillae exited the salivary sheath. Waveform B2 was associated with stylet path branching within the salivary sheath. During B2, GWSS would "saw" a new stylet branch in the salivary sheath by rapidly retracting and protracting its stylet fascicle in an eschewed direction from the original branch. Termination of B2 occurred when the stylets "sawed" through the salivary sheath.

Investigations on possible plant factors which may contribute to the spatial distribution pattern of aphid species living on tansy (*Tanacetum vulgare* L.)

SN Bauer, E Komor
University of Bayreuth, Department of Plant Physiology, Universitaetsstr. 30, 95440 Bayreuth, Germany; susanne.bauer@uni-bayreuth.de

Tanacetum vulgare L. (Asteraceae) is the host plant for a guild of aphid species, all feeding on the phloem, but utilizing different feeding niches, for example fresh shoots, senescing leaves or the root collar. The aim of this study was to investigate if plant morphological and physiological factors, i.e. food accessibility and its nutritional quality in different plant parts, contribute to the aphid species' feeding site preferences. Light microscopical measurements of the distance between epidermis and phloem tissue revealed that food accessibility in most plant parts was not restricted by the stylet length of the examined aphids. Phloem nitrogen content in form of free amino acids is hypothesised to affect aphid performance and acceptance of host plants significantly. The amino acid composition of plant tissue extracts, aphid honeydew, as a waste product of the ingested phloem sap, and exudates from excised leaves in EDTA solution were determined. Samples derived from young, mature and old leaves were analysed. Preliminary results suggest similar within-plant amino acid profiles while inter-plant patterns may vary considerably.

Evaluation of R genes for durability of gall midge resistance in rice

JS Bentur, S Amudhan, RM Sundaram, CNR Neeraja, B Mishra
"Directorate of Rice Research, Hyderabad 500 030, AP India; jbentur@yahoo.com"

The Asian rice gall midge (*Orseolia oryzae)* is a serious pest of rice in several Asian countries. Development and deployment of resistant varieties has been the key approach for tackling the pest menace. However, rapid development of new virulent biotypes of the pest breaking down the resistance has been the main limitation. One of the breeding strategies now being adopted is to pyramid two or more genes in the same cultivar through marker assisted selection. The critical question now is to know which gene combinations are likely to provide desired durability. We have been addressing this question through several different approaches. Through a simple method to test the virulence spectrum of individual mated female of the rice gall midge *Orseolia oryzae,* we have noted changing virulence through time and space across several pest endemic locations. Through studies on inheritance of virulence it is observed that virulence acquired through the sex linked recessive gene (*vGm2*) tends to be less durable compared the somatic recessive gene (*vGm1*). Fitness cost associated with virulence against *Gm1* gene may be responsible for the observed unstable virulence. Some of the gene combinations when tested under multi-location testing have displayed potentiating effects, while other combinations are just additive.

Symbiotic control of Pierce's disease: biology of mutualistic bacteria in grapevines and bioassay of reagents to disrupt pathogen transmission

B Bextine, C Lauzon, D Lampe, TA Miller
University of California, Department of Entomology, Riverside, CA 92521-0314, USA; blake.bextine@ucr.edu

The grape strain of *Xylella fastidiosa* (*Xf*) causes Pierce's disease (PD) in grapevines and is transmitted by sharpshooter insects. The most efficient vector for transmission is the glassy-winged sharpshooter (GWSS), *Homalodisca coagulata*. Symbiotic control employs mutualistic bacteria to deliver anti-Xf compounds to disrupt transmission of the pathogen to new host plants. *Alcaligenes xylosoxidans* var. *denitrificans* (*Axd*) is a prime candidate for control of PD because it inhabits the foregut of GWSS and the xylem of plants and has access to the pathogen, *Xf*. Registration of Axd as a microbial pesticide requires the ecology of *Axd* to be determined along with any side-effects. Candidate toxins for use in *Axd* have disrupted disease transmission. *Axd* colonized and travelled within 6 host plants, reaching the highest titers in lemon. *Axd* colonized the foregut region of two alternate *Xf*-vectors, the blue green and smoke tree sharpshooters, and was not identified in predatory arthropods that fed on *Axd*-positive GWSS. *Axd* genetically modified with a fluorescent marker gene did not contaminate the berries of grapevines in commercial vineyards.

An ecological-based approach to drug discovery using plant-insect interactions

RG Cates, J Donaldson
Department of Integrative Biology, 425 WIDB, Brigham Young University, Provo, UT USA; rex_cates@byu.edu

Ecological-based approaches to drug discovery use plant-herbivore theories to make predictions about secondary metabolite distributions within the plant kingdom. The ecological-based approach used here models an aspect of the plant apparency/plant predictability theories, and predicts that herbivores select for a diverse array of plant chemicals. Based on the feeding patterns of 32 specialized and generalized herbivores, we predicted that deciduous woody perennial shrubs and trees would be the most likely plant growth form to produce a diverse group of chemicals effective against human infectious diseases. Test results from 63 Sonoran Desert plant species indicated that woody perennials and several long-lived herbaceous perennials were the most inhibitory to *Staphylococcus aureus* and *Candida albicans* when compared to the annual and evergreen life forms. Of these 63 plant species, 31 were used by indigenous peoples to treat infectious diseases, and 32 were randomly selected. In both cases about 44% of the species were active against the above microbes. Overall, the results indicate that plant-herbivore interactions can be used to enhance the opportunity to find extracts effective against human diseases.

Is bluegreen aphid resistance in *Medicago truncatula* induced?

R Creasy, J Klingler, O Edwards, H Spafford Jacob
School of Animal Biology, Faculty of Natural and Agricultural Sciences, University of Western Australia, WA 6009

Bluegreen aphid (*Acyrthosiphon kondo*) survival and growth is reduced on the aphid-resistant (R) *Medicago truncatula* cultivar Jester compared to the near-isogenic susceptible (S) cultivar Jemalong. Electrical penetration graph (EPG) assays have indicated reduced phloem ingestion on Jester, suggesting phloem-based resistance. This study further characterise the resistance by assessment at the whole plant or tissue level, and examining the effect of prior aphid exposure on feeding behaviour. Performance of nymphs was assessed on shoot tips from both Jester (R) and Jemalong (S), either on the plant or excised from the plant and maintained on supplemented agar. Fecundity, survivorship and colony growth was reduced ($P<0.05$) on the Jester (R) compared to Jemalong (S), however no differences were observed between the excised tips from these same cultivars. This suggests at least one factor is absent from the excised tissue that is necessary for resistance to be manifested. Feeding behaviour of individual aphids was assessed using EPG on previously aphid-infested vs. uninfested plants of Jester (R) and Jemalong (S). Phloem ingestion was significantly reduced on the resistant Jester plants, confirming previous studies. Phloem ingestion on previously infested plants of both Jester and Jemalong was also reduced, indicating systemic activation of a phloem specific resistance.

Integrating optimal foraging and optimal oviposition theory in plant–insect research

J Scheirs, L De Bruyn
Evol. Biol. Group, University of Antwerp, Groenenborgerlaan 171, 2020 Antwerp, Belgium; jan.scheirs@ua.ac.be

Most research on host selection by arthropods is based on optimal oviposition theory. This theory, also called the oviposition preference–offspring performance hypothesis, predicts that a female will choose those hosts for oviposition on which larvae perform best. Yet, many phytophagous insects do not only use plants for larval feeding but also as adult resources. As a consequence, optimal foraging by adults may also shape host preference. This hypothesis predicts that adults will prefer the host(s) optimal for their own performance (= realised fecundity). We show that at least in three phytophagous insects, there exists strong evidence that adult females feed and oviposit on the hosts that are optimal for adult nutrition rather than on those optimal for offspring development. Therefore and because optimal foraging and optimal oviposition may oppose conflicting needs to phytophagous insects, we plea for an integration of optimal foraging and optimal oviposition in plant–insect research.

Temporal variations in the community of galling insects associated to *Baccharis acunculifolia* (Asteraceae): effects of weather, resource abundance, plant sex and gall competition.

MM Espírito-Santo, FS Neves, FR Anade-Neto, GW Fernandes
Departamento de Biologia Geral/ICB, Universidade Federal de Minas Gerais, CP 486, CEP 30161-970, Belo Horizonte-MG, Brazil; esanto@icb.ufmg.br

This study aimed to verify the effects multiple factors on the abundance of three galling insect guilds (stem, leaf and bud galls) supported by the dioecious *Baccharis acunculifolia* throughout one year. Five plant traits were sampled: number of fourth-level shoots, shoot growth rate and number of ramifications, leaves, and inflorescences. The effects of weather and plant traits on temporal variations in the abundance of each guild were analysed, as well as the interactions between gall species and differences in plant traits and gall abundance between male and female plants. *Baccharis acunculifolia* supported 14 insect gall species. This gall community was characterized by a strong dominance of the leaf galling psyllid *Baccharopelma acunculifoliae*, which accounted for 80% of gall occurrences. The weather did not affect gall abundance directly, but influenced the number of fourth-level shoots. This variable indicates the amount of plant meristems, a fundamental tissue to gall induction. The abundance of *B. acunculifoliae* negatively affected the abundance of other galling species, possibly indicating interspecific competition. There were no intersexual differences in plant traits and gall abundance. As a whole, these results corroborated the "resource abundance hypothesis", since gall abundance was affected by the amount of resources offered by *B. acunculifolia*.

The sensory receptors of the labio-maxillar complex of larvae in Colorado potato beetle, *Leptinotarsa decemlineata* Say (Coleoptera: Chrysomelidae)

H Farazmand, S Yu Chaika, EE Sinitsina
Moscow State University, Moscow, Russia and Plant Pests & Diseases Research Institute, Tehran, Iran; hfarazmand@yandex.ru

The Colorado potato beetle, *Leptinotarsa decemlineata* Say, is a devastating pest of potatoes and other solanaceous crops. The types, numbers and distribution of sensory receptors on the labio-maxillar complex of larvae were studied with the scanning electron microscopy. A total of 32 sensilla 3 basic morphological types - basiconic, trichoid, and digitiform are present on the maxillary and labial palps. The labial palp has 11basiconic sensillae. All this sensilla are placed on the distal apex of palp. The length mean of basiconic sensillae were 29 micron. The maxillary palp has 16 basiconic, 4 trichoid and 1 digitiform sensilla. All basiconic sensilla are placed on the distal apex of the third segment. The length mean of basiconica sensilla were 31.2 micron. Also were observed 2 morphological types of basiconic sensilla. In other word, placed 3 trichoid sensilla on the distal of the second segment and 1 trichoid sensillae on the lateral side of third segment. Also 1 digitiform sensillae were observed on the lateral side of third segment of maxillary palp. The length and wide of these sensilla were recorded 16.5 and 3 micron, respectively. The percentage composition of the types of receptors present: basiconica 84.4%, trichoid 12.5% and digitiform 3.1%. The work was supported by RFBR (grant # 04-04-48779).

Life history of ***Macrosiphum euphorbiae*** **on tomato plants previously infested with** ***Bemisia tabaci***

EI Garzo, M Duque, G Nombela, M Muñiz, A Fereres
Centro de Ciencias Medioambientales, CSIC. Serrano 115 dpdo, 28006 Maid. Spain; afereres@ccma.csic.es

Macrosiphum euphorbiae and *Bemisia tabaci* are two important pests of tomato crops and efficient vectors of plant viruses. Induced resistance (IR) is a promising mechanism for crop protection that offers a long lasting defence against a broad spectrum of diseases in various plant species. IR may be elicited by previous infestation by other herbivores. However, host plant induced responses are not necessarily negative and could produce beneficial effects on other insect pests. We evaluated the effect of a previous infestation by *B. tabaci* on the life history of *M. euphorbiae* on tomato plants in laboratory conditions for 48h. Two alate aphids were put on these tomato plants during 24h and removed, leaving two nymphs per plant, born during this period. We evaluated the offspring after 10 and 20 days, i.e. the total number of nymphs and adult aphids per plant. Our results indicate that the population of *M. euphorbiae* increased to a greater extend when tomato plants had been infested previously with *B. tabaci* than if not previously infested.

Genetic and biochemical differences in host-plant use by the aphid *Myzus persicae* (Sulzer)

CC Figueroa, LM Briones, HM Niemeyer, CE Fuentes-Contreras
Instituto de Ecología y Evolución, Universidad Austral de Chile, Casilla 567, Valdivia, Chile; christianfigueroa@uach.cl

Specialization in phytophagous insects is mainly mediated by a differential adaptation to the host's allelochemicals. Aphids are ubiquitous sap-sucking insects that frequently constitute agronomical pests. One of the most generalist aphid species is *Myzus persicae*. However, *M. persicae* has developed a particularly well adapted subspecies (*M. persicae nicotianae*) on tobacco (*Nicotiana tabacum* L.), that exceptionally has been detected on other hosts. This high level of specialization must comprise a genetic/biochemical base. Seventy-six aphids were sampled from different host-plants in Central Chile. We characterized 14 generalist genotypes and one single genotype on tobacco using microsatellite markers. Biochemical and genetic differences were compared between a generalist genotype reared on pepper (*Capsicum annuun* L.) and the single genotype specialized on tobacco. Significant differences in activities of the detoxification enzymes cytochrome *P*-450, general esterases, and glutathione *S*-transferase between genotypes were found. The tobacco-specialized genotype on tobacco showed the highest activity for cyt *P*-450, but the lowest for the other enzymes in comparison to the generalist genotype. We are investigating if those results are due to differences in genotypes or in gene expression.

Ultrastructural contributions to the study of the glassy-winged sharpshooter feeding and Pierce's disease.

TP Freeman, JR Buckner, RA Leopold, SA Payne, JA Moore
Electron Microscopy Center, Northern Crop Science Laboratory, North Dakota State University, Fargo, North Dakota, 58105. USA;
thomas.freeman@ndsu.nodak.edu

The glassy-winged sharpshooter (GWSS) is a vector for the transmission of the bacteria *Xylella* fastidiosa, which causes Pierce's Disease in grapes, leaf scorch in oleander and almonds, variegated chlorosis in citrus as well as causing diseases in avocados, peaches, plums, apricot, cherries, alfalfa, and many trees and ornamentals. This xylophagous leafhopper feeds on more than 100 different host plants from more than 35 plant families. Recent ultra structural studies have contributed significantly to our understanding of sharpshooter feeding. Our continuing studies on sharpshooter feeding have elucidated the damage that the stylets can cause to host plant tissues during the penetration process. The penetrating stylets damage the cells of the plant host on the route from the epidermis to the xylem tissue. Examination of the walls of vessel elements show that they are often shattered during GWSS stylet penetration. The salivary sheaths formed by the sharpshooter during penetration and feeding may be simple or highly branched and terminate in parenchymatous or vascular tissues of the host plant. Salivary sheath material was also observed to occlude the lumina of the vessel elements, presumably preventing the normal translocation of xylem fluid.

Does voltinism in temperate insect herbivores depend on defences of their host plant? Comparative analysis using European butterflies

L Cizek, Z Fric, M Konvicka
School of Biological Sciences, University of South Bohemia, Branisovska 31, CZ-37005 Ceske Budejovice, Czech Republic; zdenek.fric@tix.bf.jcu.cz

According to theories of plant antiherbivore defences, leaf-chewing insects feeding on apparent plants should synchronise hatching with appearance of fresh leaves. In contrast, such a synchronisation should be less pronounced in insects feeding on unapparent, qualitatively protected plants. We hypothesised that in seasonal temperate environments, quantitative plant defences should constrain the annual number of insect generations. Testing the hypothesis using European butterflies corroborated the prediction. Apparency in a broader sense (woody plus gramineous plants) performed as a strong predictor of low generation numbers; when controlled for phylogeny, even a narrower definition of apparency (woody plants) predicted low number of generations. Other significant predictors of monovoltinism were living in arctic/alpine environments and having large bodies; large body size was a weaker predictor than host apparency. The nature of host plant defences may explain several little understood patterns in phenology of temperate insects, including scarcity of late-season monovoltines, and a high numbers of generations in insects associated with ruderal plants.

Transmission of citrus endophytic bacterium *Methylobacterium* by sharpshooters (Insecta: Cicadellinae): vectors of *Xylella fastidiosa*, the causal agent of variegated chlorosis of citrus.

CS Gai, WL Araújo, JRS Lopes, JL Azevedo
Av. Pádua Dias, 11, PO Box 83, 13400-970, Piracicaba, São Paulo, Brazil; csgai@esalq.usp.br

Endophytic bacteria are those that can be isolated from surface disinfected plant tissues and have no deleterious effects on the host plant. These microorganisms have shown potential benefits as biocontrol agents of pests and diseases. The Citrus Variegated Chlorosis is caused by the bacterium *Xylella fastidiosa,* which is transmitted from infected to healthy plants by sharpshooters: *Dilobopterus costalimai, Oncometopia facialis* and *Acrogonia* sp. In citrus plants, *X. fastidiosa* and endophytic *Methylobacterium* may colonize xylem vessels, allowing endophyte transmission by the same way of pathogenic bacteria. Trying to elucidate this point, bacteria were isolated from heads of insect vectors and citrus plants. *Methylobacterium* was the most frequent bacterial specie in both situations and shown *in vitro* interaction with *X. fastidiosa*. *Methylobacterium* expressing GFP gene was obtained, and further used to study the transmission of this bacterium by sharpshooters. The insects were fed in membrane with the GFP bacteria and than trapped in *Catharanthus*, a model plant. After 40 days, plants were surface disinfected and macerated to isolate bacteria. It was observed that transmission of the GFP bacteria occurred in 13.3% of the plants, showing that the endophyte is being transmitted to plants by the same vector of *X. fastidiosa*.

Discrimination of host plants by *Rhopalomyia* species at various levels of botanical variation

T Ganaha, N Uechi, M Nohara, J Yukawa
Entomological Laboratory, Faculty of Agriculture, Kyushu University, Fukuoka 812-8581, Japan; ganaha@agr.kyushu-u.ac.jp

Most gall midges (Diptera: Cecidomyiidae) are monophagous or oligophagous, although a few are polyphagous and three species exhibit host alternation. This suggests that speciation of gall midges may have occurred in association with evolutionary processes of plant species. It is an interesting study subject to investigate whether or not gall midges can discriminate, in the course of host range expansion, differences among their host plant individuals or populations. In this study, we examined morphological and molecular information on all 11 nominal Japanese *Rhopalomyia* species that induce galls on several species of the genus *Artemisia* (Asteraceae). We found that some of the Japanese *Rhopalomyia* species could not discriminate differences in the polyploidy among their host plant individuals. In six species out of the 11, the host range did not expand beyond the botanical section and no gall midge had a host range beyond different botanical genera. This may indicate that the gall midges cannot recognize the early stage of plant speciation and they expand their host range without knowing the genetic changes in plant species. Plant speciation that is initiated by chromosomal changes may provide associated gall midges with a chance to be isolated geographically or chronologically in the future.

Dirty cropping and insect community structure: can relaxed weed control benefit pest control in Brassicaceae crops?

BW Gaolach
919 SW Grady Way, Suite 120, Renton, WA 98055-2980; gaolach@wsu.edu

To assess the impact of increased vegetational diversity and complexity on insect abundance, mechanical weed control was relaxed on four organic farms in western Washington. By using commercially producing farms and production level plot sizes for Brassicaceae crops, I tested the feasibility of using relaxed weed control (dirty cropping) as a cultural pest control strategy. The four farms varied in the degree of implementing relaxed weed control, resulting in different densities of weeds in the dirty plots. The importance of how much weed control was practiced depended on which pest species was examined. Adult flea beetles (*Phyllotreta cruciferae*, and *Phyllotreta striolata* Chrysomelidae: Alticidae) were influenced at all levels of relaxed weed control. A suite of lepidopteran pests (*Pieris rapae*: Pieridae, *Plutella xylostella*: Plutellidae and *Trichoplusia ni*: Noctuidae) were not affected by any commercially viable level of relaxed weed control. Aphids (*Brevicoryne brassicae, Myzus persicae* and *Lipaphis erysimi* (Kaltenbach): Homoptera: Aphididae) had a slight dependence on the degree of relaxed weed control. Possible behavioural mechanisms and impacts of natural enemies are discussed to explain the observed results. The impacts on yield weight and quality for broccoli are presented for two of the farms.

Association between the deodar weevil *Pissodes nemorensis* (Coleoptera: Curculionidae) and the pitch canker fungus *Fusarium circinatum* in South Africa

S Gebeyehu, MJ Wingfield
Forestry and Agricultural Biotechnology Institute, University of Pretoria, Pretoria 0002 South Africa; solomon.gebeyehu@fabi.up.ac.za

The deodar weevil *Pissodes nemorensis* is an important pest of pines, widely distributed in South Africa. The pitch canker fungus *Fusarium circinatum* is a serious pathogen in South African forestry nurseries, but has not been found on mature trees, possibly due to the lack of an effective insect associate. A Potential association between *P. nemorensis* and this pathogen is considered a serious threat. Greenhouse experiments were conducted where Fusarium-free weevils, weevils contaminated with *F. circinatum*, direct inoculation of *F. circinatum* into wounds and untreated controls were included. *Pinus patula* trees exposed to Fusarium-treated weevils showed dieback after six weeks while symptoms on *P. elliottii* were observed after ten weeks. All *P. patula* and *P. elliottii* trees had died after ten and twelve weeks respectively. Trees inoculated directly died more slowly than those exposed to Fusarium-infected weevils. No symptoms were seen on control trees. These results elevate concerns regarding a future association between *P. nemorensis* and *F. circinatum* in South Africa.

Globular structure and its morphological changes in mycangia of *Platypus quericivorus* (Coleoptera: Platypodidae).

H Goto, H Sato
FFPRI, Matsunosato 1, Tukuba, 305-8687, Japan; gotohide@ffpri.affrc.go.jp

Platypus quercivorus is a vector of a pathogenic fungi *Raffaelea quercivora*, causal agent of Japanese oak disease. Females of *P. quercivorus* have about ten mycangial pit on their pronotum that is the storage organ for ambrosia fungi. In this study, globular structure was observed in each mycangial pit. This structure is consisted of several cells with thick cell wall covered by thick outer wall, and is almost large enough to occupy the space in its pit. We observed the temporal changes of the structure in mycangia from female enter the new gallery. We inoculated female beetle into logs that have been killed and inoculated male in advance. Twelve hours after the female inoculation, the outer wall of the globular structure partly broke, and after twenty fore hours, each cell inside became into a lump of yeast-like smaller cells in several pits of each individual. No globular structure was observed any more in the pits with yeast-like cells. Secretory cells around the mycangia were thick for these periods. Then the contents in all mycangial pits were a lump of yeast-like cells two days after inoculation, and secretory cells have been thin.

The origins of olfactory preference in an aphid parasitoid

PG Vamvatsikos, J Hardie, HF van Emden
Imperial College London, Aphid Biology Group, Department of Biological Sciences, Silwood Park Campus, Ascot, Berks U.K.; j.hardie@imperial.ac.uk

Aphidius colemani (Viereck) parasitoids emerging from peach-potato aphids, [*Myzus persicae* (Sulzer)] reared entirely on plants of the Brussels sprout variety Winter Harvest (*Brassica oleracea* L. var. *gemmifera* Zenker) were tested for odour preference in an olfactometer. When parasitoids were allowed to choose between a Brussels sprout plant odour and clean air, they preferred the plant odour irrespective of whether that variety was the host aphid's food plant. However, when the parasitoids were tested against two different varieties of Brussels sprout they consistently preferred the host's food plant (Winter Harvest). This preference was retained even when they eclosed from mummies isolated from the plants or when the parasitoid pupa was surgically removed from the mummy case, prior to emergence. We are presently examining the origin of preference using aphid hosts reared on an artificial, plant-free, diet.

Evolution of gall induction in *Lachnodius* Maskell (Hemiptera: Coccoidea: Eriococcidae)

NB Hardy, PJ Gullan
Department of Entomology, UC Davis, One Shields Avenue, Davis CA 95616-8584; nbhardy@ucdavis.edu

Lachnodius, interesting in terms of its aberrant cytogenetics, is one of a handful of eriococcid genera inducing galls on eucalypts in Australia. In comparison with these other genera, *Lachnodius* is unusual in containing species that are both free-living and that induce a variety of galls ranging from shallow pits to more elaborate, enclosing structures. We estimate relationships among *Lachnodius* species and some of their relatives from a phylogenetic analysis of the morphology of first-instar, second-instar, and adult females. The evolution of gall-induction is explored by mapping gall traits onto the consensus tree. The free-living species of *Lachnodius* are sister to the gall-inducing species. Multiple transitions from the simple pit-gall form to the superficially more complicated enclosing galls have occurred. *Lachnodius* is paraphyletic with respect to both *Opisthoscelis* Schrader and *Sphaerococcopsis* Cockerell, in which adult females exhibit an extreme bias towards the development of the hind legs.

Root application of b-aminobutyric acid (BABA) inhibits growth and reproduction of the pea aphid (*Acyrthosiphon pisum*) on legumes.

S Hodge, GA Thompson, G Powell
Dept. of Agricultural Sciences, Imperial College London, Wye Campus, Ashford TN25 5AH, UK; g.powell@imperial.ac.uk

b-aminobutyric acid (BABA) is a non-protein amino acid that is an effective inducer of resistance against a variety of plant pathogens. However, examples of BABA-induced resistance against insect herbivores are scarce. We applied BABA as a soil drench to various legumes and monitored its effect on the pea aphid (*Acyrthosiphon pisum* (Harris)). On tic beans (*Vicia faba* v. *minor*) BABA caused a dose-related reduction in the mean relative growth rate (MRGR) of individual aphids and also in the intrinsic rate of population increase (r_m). BABA (25ml of 50mM solution per plant) also caused significant reductions in MRGR of *A. pisum* on peas (*Pisum sativa*), broad beans (*Vicia faba* v. *major*), runner beans (*Phaseolus coccineus*) and red clover (*Trifolium pratense*). The concentrations of BABA used in our assays were high compared to those used to induce resistance against phytopathogens such as viruses, bacteria and fungi. It is possible that the reduction in aphid performance was due to a BABA-induced phytotoxic stress-response in the plant, although no obvious reductions in plant health were observed. Alternatively, BABA may exhibit direct toxicity against aphids. Current experiments are investigating the mechanisms by which BABA reduces aphid performance.

The role of indigenous pollinators in New Zealand onion crops.

BG Howlett, DAJ Teulon, LE Newstrom, BJ Donovan, J McCallum
Crop and Food Research, Private Bag 4704, Gerald St, Lincoln; HowlettB@crop.cri.nz

Arthropods are important vectors for pollen transfer in many cropping systems. Their movement and effectiveness as pollinators have major implications for pollination services, contamination of certified seed crops and for the coexistence of GE and non-GE crops. To assess the potential risk of gene escape from transgenic crop plants, pollen mediated gene flow needs to be estimated. This requires an evaluation of pollinator assemblage diversity and the ability of vectors to move viable pollen over distance. *Allium* crops across New Zealand have been chosen as one model system for a multi-site, multi-year assessment of variation in pollinator assemblages and abundance. Assemblage differences due to seasonal influences and environmental factors are being examined as they can can produce uncertainty in risk assessments. Data from the first year of results will be presented to illustrate the diversity of Arthropods carrying conspecific pollen within onion fields.

Fungus gnats and their possible association with the pitch canker fungus in South African pine nurseries

BP Hurley, P Govender, T Coutinho, BD Wingfield, MJ Wingfield
Forestry And Agricultural Biotechnology Institute (Fabi), University Of Pretoria, Pretoria, 0002, South Africa; brett.hurley@fabi.up.ac.za

Fusarium circinatum is the causal agent of a serious disease of seedlings in South African pine nurseries. Insects and especially fungus gnats (Diptera: Sciaridae, Mycetophlidae) were suspected of transmitting this fungus in nurseries. The aim of this study was to ascertain which species of gnats are present in South African pine nurseries, and to consider whether these and other Diptera carry *F. circinatum*. Adult Diptera were surveyed in four major forestry nurseries between 2000 and 2001. Fungi were isolated from these insects and resulting *Fusarium* spp. were identified. *Bradysia difformis* was the only species of fungus gnat found and it occurred in all nurseries that were surveyed. This is the first report of *B. difformis* in South Africa. Other dipteran families collected included Agromyzidae, Cecidomyiidae, Chironomidae, Ephyidae, Muscidae, Simulidae and Tachinidae. Of these, only Ephyidae has a history of interaction with plant pathogens. *Fusarium circinatum* was not isolated from any of the Diptera. *Fusarium oxysporum* and *F. stilboides* were isolated from Chironomidae, but these fungi are not considered important pathogens of pines in the nurseries surveyed.

Effect of cultivars of cabbage *Brassica oleracea* var *capitata* in the biology of *Plutella xylostella* (L. 1758) (Lepidoptera: Plutellidae)

AL Boiça Junior, AL Torres, R Barros
Department of Entomology- FCAV/UNESP, Jaboticabal, SP, 14884-900 Brazil; aboicajr@fcav.unesp.br

This research proposed to study the effect of eight cultivars of cabbage subordinate to *Plutella xylostella* attack, in two successive generations. The duration and viability of the larval phasis, the duration and viability of the pupa phasis, pupa's weight in 24h of life, period of pre-emplacement of the eggs, sexual reason, number of eggs per female, period of hatching and viability of eggs were evaluated in the two generations. The corrected reproductive potential was calculated. The experimental delineation was completely casualized, in factorial scheme of eight cultivars and two generations, with five repetitions. The results were submitted to an analysis of variance (Schefer Test) and the averages were compared by test of Tukey (a =0,05). The cultivars of cabbages that were evaluated, affected the biology in the *P. xylostella*, being Ruby Ball, Bull's Heart and Matsukase Sakata moderately resistant, while, Mad of Summer, Flat of Yard and Red Giant Mamuth and Toshin Takii were susceptible, and the Sixty Days was highly susceptible to *P. xylostella*. Matsukase Sakata and Ruby Ball were those ones that most affected the corrected reproductive potential of the plague.

Insecticidal aqueous vegetable extracts effects against *Ascia monuste orseis* **at kale**

AL Boiça Junior, CAM Medeiros
Departament of Entomology– FCAV/UNESP, Jaboticabal, SP, 14884-900 Brazil; aboicajr@fcav.unesp.br

The aim of this work was to study the aqueous extracts effects of *Azadirachta indica* almonds and *Sapindus saponaria* fruits against *Ascia monuste orseis.* The CL_{50} estimated for larvae of first instar were 0.0117% (w/v) and 1.0342% (w/v) for *A. indica* and *S. saponaria* extracts, respectively. The lethal concentration for *A. indica* and *S. saponaria* were respectively 0.0858% and 6.8826%. The CL_{50} for *A. indica* and *S. saponaria* extracts with the addition of adhesive spreading were 0.0133% and 1.0461%, respectively. Mortalities of the insects were similar with or without the use of adhesive spreading. The concentrations of aqueous vegetable extracts affected the insect biology. The extracts affected the eggs number oviposited and feeding of the *A. monuste orseis*, due to theirs repellents and/or deterrents effects and/or feeding suppressor presence. The extracts presented insecticidal action at the embryonic development and at recently hatched larvae with respective concentrations of 0.5% and 0.1% for *A. indica* and 3.0% and 6.0% for *S. saponaria.* The insecticidal effects were bigger at eggs treated with 48 hours of life than those eggs that had just oviposited. The results demonstrated that the aqueous extracts of *A. indica* almond and of *S. saponaria* fruits are promising for *A. monuste orseis* control.

Feeding behavior of the bean bug, *Riptortus clavatus* (Thunberg), on seeds of a resistant mungbean variety

JK Jung, JK Moon, JH Park
National Institute of Crop Science, RDA, Seodun-dong, Suwon 441-857, Rep. Korea; jungjk@rda.go.kr

The bean bug, *Riptortus clavatus*, couldn't survive when supplied with seeds of a mungbean (*Vigna radiata* (L.) Wilczek) variety, Jangannokdu, though it normally developed on seeds of most other mungbean varieties. The feeding time of the fifth instar nymph per day on a resistant variety was not significantly different from that on a susceptible variety. In a preference test in a petri-dish, the number of puncture marks, stylet sheaths, formed on seeds was not significantly different between the two kinds of varieties. However, the feeding amount (ca. 1.9 mg) per day of the fifth nymph on a resistant variety was significantly less than that (ca. 4.5 mg) on a susceptible variety. The results, therefore, indicated that the bean bug couldn't feed on seeds of the resistant variety although it inserted its stylet into the seeds. When the coat-removed seeds were provided for the bean bug, the survival rate was very low to show that the seed-coat didn't have a resistant factor. When the bean bug was reared using artificial diets mixed with the seed powder of both varieties, the survivorship of the insect decreased, depending on the dose of the powder of a resistant variety.

Biochemical analysis on the induced resistance to pathogens in rice plants infested by *Sogatella furcifera*: accumulation of defense-related chemicals in rice plants, such as jasmonic acid, salicylic acid and phytoalexins.

H Kanno, M Sato, M Hasegawa, O Kodama
Kyushu Okinawa National Agricultural Research Center, 2421 Suya, Nishigoshi, Kumamoto 861-1192 Japan; hkanno@affrc.go.jp

We reported that the rice plants previously been infested by the white-backed planthopper, *Sogatella furcifera*, strongly induce the systemic resistance to the rice blast fungus caused by *Magnaporthe grisea* (Kanno and Fujita, 2003). Moreover, we recently found that the rice plants infested by *S. furcifera* also acquired resistance to the bacterial blight caused by *Xanthomonas oryzae*.

To clarify the mechanism of such induced resistance, we analysed some defense-related chemicals, such as jasmonic acid, salicylic acid and phytoalexins (Momirakton-A and Sakuranetin) in rice plants using LC-MS. Accumulation of these chemicals in *S. furcifera* infested plants was higher than those in uninfested control plants. Especially, in *S. furcifera* infested plants, both phytoalexins, Momirakton-A and Sakuranetin, that indicate strong antimicrobial activity to the fungus were much more accumulated than that in uninfested control plants. These results suggest that the defence systems, such as jasmonic acid pathway and salicylic acid pathway, must be activated so that phytoalexins are biosynthesized in rice plants.

Inoculation of the adult beetles of *Platypus quercivorus* to Japanese oak trees

H Kinuura, M Kobayashi
Nagaikyutaro 68, Momoyama, Fushimi, Kyoto 612-0855, Japan; kinuura@ffpri.affrc.go.jp

The adult beetles of *Platypus quercivorus* were artificially inoculated to Japanese oak trees (*Quercus crispula*). Two inoculation methods were set, A) a high density inoculation with the pipette chips and B) an inoculation by release into the netting. Four of five trees which were inoculated by the pipette chips were dead, and five trees which were inoculated by the netting were all dead. Seven of nine dead trees were presented the same wilting symptom as the current mass mortality of oak, and withered completely within 1-2 weeks. *Raffaelea quercivora*, which was confirmed as the pathogenic fungus of the wilt disease and was usually isolated from mycangia of *P. quercivorus*, was isolated from all the inoculated dying trees. The earlier the death time of the dying tree was, the higher the isolation rate of *R. quercivora* was, and the rate of the discoloured area of the wood was also higher, and the number of gallery which succeeded in the propagation was also higher. For the above reasons, it was completely proved that *P. quercivorus* was vector of *R. quercivora,* and the mass mortality of Japanese oak trees was caused by mass attack of *P. quercivorus*.

A study on preimaginal development of sweetpotato whitefly *Bemisia tabaci* Gen (Hom.: Aleyrodidae) on melon, cucumber and okra

F Kocheili, MS Mossadegh, K Kamali, A Soleiman Nejadian
Department of Plant Protection, College of Agriculture, Chamran University; Kocheilif@yahoo.com

Primaginal development of sweetpotato whitefly *Bemisia tabaci* Genn. (Hom., Aleyrodidae) were studies on Melon, Cucumber and Okra under laboratory conditions in temperature 15,25, 30 °C R.H. 60%±5 and photoperiod L:D 14:10 hours. The result showed that total preimaginal development on Melon were 51.51,21.42 and 15.7 days at 15,25 and 30 °C, respectively. On cucumber and Okra this rate was 51.97, 20.99, 13.42 and 66.7, 32.13 and 17.02 days at 15,25 and 30°C, respectively. Statistical calculations showed that there are significant variation among preimaginal development of this pest on melon, cucumber and okra at 15°C at 25 and 30°C , there are significant variation between egg and nymphal stages on okra, melon and cucumber but there aren't any significant variation at pupal stage on these three plants.

Cysteine proteases in latex protect papaya and fig trees from herbivorous insects

K Konno, C Hirayama, M Nakamura, K Tateishi, Y Tamura, M Hattori, K Kohno
National Institute of Agrobiological Sciences, Tsukuba 305-8634, Japan; konno@affrc.go.jp

The primary roles of proteins and enzymes often found in plant latex are as yet poorly understood. We found that cysteine proteases in latex of the Papaya tree (*Carica papaya*, Caricaceae) and a wild fig (*Ficus virgata*, Moraceae), are crucial factors in the defences of these plants against lepidopteran larvae such as oligophagous *Samia ricini* (Saturniidae) and two polyphagous pests, *Mamestra brassicae* (Noctuidae) and *Spodoptera litura* (Noctuidae). Leaves of the two plant species showed strong toxicity and growth inhibition against lepidopteran larvae. When the latex was washed off, the leaves lost toxicity. Latexes of both species were rich in cysteine-protease activity. E-64, a cysteine protease-specific inhibitor, completely deprived the leaves of toxicity when painted on the leaf surface. Cysteine proteases, such as papain, ficin, and bromelain, all showed toxicity. The results suggest that plant latex and the proteins in it, cysteine proteases in particular, provide plants with a general defence mechanism against herbivorous insects.

Carrot psyllid *(Trioza apicalis)* host plant ecology – studies of perception, selection and migration.

L Kristoffersen, O Anderbrant
Pheromone Research Group, Ecology Department, Lund University. Ecology Building, SE-223 62 LUND, Sweden; lina.kristoffersen@ekol.lu.se

The carrot psyllid, *Trioza apicalis* (Homoptera: Psylloidea), is a serious pest on carrots in northern and central Europe. Up to date, monitoring and control methods are inadequate, and the species seems insensitive, if not resistant, to pesticides. Carrot psyllids are univoltine and adults hibernate on conifers. In early summer they appear in carrot fields, where reproduction and egg laying take place. Fairly little is known of the behaviour and biology of this species. In order to suggest alternative, sustainable control and monitoring methods for carrot psyllids, we study their ecology and behaviour. Our goals include identifying host plant odours, and possibly also pheromones, that may be used as attractants or repellents in improved monitoring and push-and-pull strategies. Relating to host plant ecology, we also wish to tease out the factors that control migratory behaviour, host alternation and host choice. Field studies have provided some information about migratory abilities and winter host preferences. In the lab, behavioural assays and extractions of semiochemicals have been unsuccessful so far. To guide electrophysiological efforts, we have studied antennal morphology, revealing a very sparse setup of sensilla. This may suggest that this species is less reliant on olfaction than anticipated.

Symbiotic control of Pierce's disease: the social life of *Alcaligenes xylosoxidans* var. *denitrificans*.

C Lauzon, B Bextine, D Lampe, TA Miller
"California State University, Department of Biological Sciences, 25800 Carlos Bee Boulevard, Hayward, CA 94542-3090, USA; clauzon@csuhayward.edu"

Alcaligenes xylosoxidans var. *denitrificans* (Axd) is a symbiotic bacterium isolated from the foregut of the sharpshooter insect, *Homalodisca coagulata* (Say) and is often present in the xylem fluid of several host plants. Axd is a candidate to deliver factors to control (symbiotic control) the grapevine strain of *Xylella fastidiosa* (Xf) that causes Pierce's disease because both Axd and Xf occupy the same niche in vector insects and host plants. In our studies, Axd was not found in predators that fed on Axd-containing sharpshooters. Axd did not establish on or within table grapes or in grapevines inoculated artificially with Axd. Axd did not survive in a variety of red and white wines. The bacterium also did not establish in a variety of soil types unless the soil was first sterilized. Axd catabolized a variety of organic compounds but did not produce certain extracellular enzymes considered to be virulence factors. An auxotrophic subpopulation that requires cysteine for growth was isolated. Competition studies using *Pseudomonas* spp., *Escherichia coli* and *Staphylococcus aureus* revealed the influence of environmental conditions on survival and growth of Axd in mixed culture.

Nutritional adaptation of galling insects investigated by globular gall of *Trioza shuiliensis* (Yang) on *Machilus japonica* var *kusanoi* (Hyata)

Liao, LH Liao, MM Yang, CM Yang, ST Chiu, SY Hwang
Department of Entomology, National Chung Hsing University, 250 Kuo Kuang Road, Taichung 40227, Taiwan lineshue@yahoo.com.tw

Nutritional adaptation of a galling psyllid, *Trioza shuiliensis*, was investigated based on anatomy and component analyses. On the analyses of primary metabolites, protein content in gall tissues is 2 folds than that of leaf tissue while the total non-structural carbohydrate 2-3.6 folds. In contrast, nitrogen content is only half as much as in gall tissues than in the leaf tissues. The secondary metabolite flavonoid has 5 folds content in leaf than in gall, but anthocyanidin only one tenth. By photo-pigment analyses, the content is only one tenth for Chl *a* and *b* in gall than in leaf. PPIX in gall is much higher than in leaf. It suggests that there are some troubles during the transformation from PPIX to MGPP in gall tissues in chlorophyll synthesis. The gall should not have the ability to work normally in photosynthesis as indicated by the analyses of the contents of chlorophylls. Anatomy of gall tissue through paraffin sectioning reveals a circling of vascular bundles on the larval chamber, which suggests the gall should play a function to convey assimilates. High nutritional component contents in the gall should come from other tissues and the gall may imitate a sink to provide galling insects with more nutritional benefit than free-living herbivores.

A survey of arthropod-plant relationships in Mokolodi nature reserve, Gaborone, Botswana

NM Makate, MP Setshogo
Department of Biological Sciences, Private Bag UB 00704, University of Botswana, Gaborone, Botswana; makaten@mopipi.ub.bw

The semi-arid climatic conditions prevalent in Botswana are amenable to a diversity of arthropods that in turn associate with different plant species. A survey was carried out at the Mokolodi Nature Reserve that is located about 15km south of Gaborone city. The nature reserve harbours a savanna type of vegetation. Arthropods found around the vegetation were mainly of the order Hemiptera. They were found to be associated mainly with members of the tree genus *Acacia*. Observations have shown that, several factors have influenced the abundance and associations of this Order with this particular tree genus. Some of these include, egg-laying, feeding habits and pollination behaviour. Acacias are characteristic of typical savanna vegetation, which attracts arthropods by their leaves, barks and flowers throughout the year.

Conserved regulatory elements in the promoters of two allelochemical-inducible cytochrome P450 genes differentially regulate transcription

CM McDonnell, R Petersen Brown, MR Berenbaum, MA Schuler
320 Morrill Hall, 505 S. Goodwin Ave., Urbana, IL 61801, USA; cmcdonne@uiuc.edu

CYP6B4, a cytochrome P450 gene from the tiger swallowtail *Papilio glaucus*, is transcriptionally induced in the midgut by dietary furanocoumarins, plant allelochemicals that can crosslink DNA in their UV-activated form. The *CYP6B4* promoter contains an overlapping EcRE/ARE/XRE-xan element similar to that used for basal and xanthotoxin-inducible expression of the *CYP6B1* promoter from the black swallowtail *Papilio polyxenes*. Transfection of the *CYP6B4* promoter: CAT reporter construct into Sf9 cells demonstrates that the basal and xanthotoxin-inducible expression levels observed reflect the relative expression levels of this gene in the midguts of tiger swallowtail larvae. Transfections of mutant *CYP6B4* promoter constructs into Sf9 cells indicate that the EcRE/ARE/XRE-xan element is necessary for *CYP6B4* induction by xanthotoxin but not for its minimal basal expression. In addition to these elements, the *CYP6B4* and *CYP6B1* promoters also contain putative XRE-AhR elements identical to the aryl hydrocarbon response elements present in mammalian phase I detoxification genes. Transfections of *CYP6B4* and *CYP6B1* promoters containing EcRE/ARE/XRE-Xan and XRE-AhR elements indicate that both are induced significantly by benzo(ɑ)pyrene, an aromatic hydrocarbon widespread in the environment, as well as by xanthotoxin, an allelochemical encountered in their host plants.

Speciation in gall thrips on ***Acacia***

MJ McLeish, TW Chapman
School of Biological Sciences, Flinders University, GPO Box 2100, Adelaide, S. A. 5001, Australia. Ph: +61 - 8 - 8201 2540;
michael.mcleish@flinders.edu.au

Australian gall-thrips are a phytophagous insect group that parasitise Australian *Acacia* trees by inducing galls and producing brood within the enclosed structure. The *Klaadothrips rugosus* species complex consists of up to 14 host-related 'races,' and in nearly all cases, each 'race' induces a morphologically discrete gall. Current evidence suggests that these 'races' represent sibling species. Of particular interest are three known instances where each of two different 'races' induces different gall structures on the same host species. Several questions emerge. Is the divergence between each race on the same host at a species level? Does speciation occur by host shifting, cospeciation, sympatric speciation, or a mixture of all these mechanisms? We used data from microsatellite and mitochondrial DNA markers to infer genetic divergence between three pairs of these 'races' that each shares a different *Acacia* host species.

Toxicity of pellitorine, an amide isolated from *Piper tuberculatum* Jacq. (Piperaceae) to the pollinator *Apis mellifera* L. (Hymenoptera: Apidae)

JE Miranda, HMD Navickiene, RH Nogueira-Couto, S.A. De Bortoli, M Furlan, V da S Bolzani, MJ Kato
Embrapa Algodão, CP 714, 74001-970 Goiânia, Go, Brazil; miranda@cnpa.embrapa.br

Pellitorine, an amide isolated from *Piper tuberculatum* (Piperaceae), has been studied as a biopesticide against agricultural pests in Brazil. In order to investigate their impact on non-target organisms, particularly pollinator insects, research were performed to evaluate the acute toxicity action of the compound on larvae and newly emerged adults of honeybee *Apis mellifera* by means of contact and ingestion bioassays. Workers in the larval and adult phase were separated in groups, which received pellitorine in different concentrations. The larvae were maintained in their own original cells, receiving feeding and normal care from the nurses. The adults were confined in wooden cages with screens, receiving artificial diet made up of sugar and water (1:1). The concentrations of 40, 200, 1000, 5000 and 25000 ng a.i./individual were obtained diluting pellitorine in 98% ethanol. LD_{10} values of 39.14, 36.16 and 13.79 ng a.i./insect were determined for larvae, for adults by ingestion and adults by contact, respectively. The honeybee larvae were shown to be highly susceptible to the amide pellitorine. The amide pellitorine was shown to be more active when its absorption took place via dermal contact (by topical application).

Effects of coexistence with a water lily *Trapa natans* on embryonic development, larval growth and oviposition process of a water strider, *Gerris nepalensis*

T Harada, J Yamashita, T Miyashita
Laboratory of Environmental Physiology, Faculty of Education, Kochi University, Kochi 780-8520, Japan; haratets@cc.kochi-u.ac.jp

"This study tries to clarify the influence of coexistence of a water strider, *Gerris nepalensis* with a water lily, *Trapa natans* as a component of symbiosis. *Materials and Methods* Adult *G. nepalensis* and *T. natans* were collected from a water way in Kochi (33ºN) in August, 2002 and used for rearing experiments under 15h light-8.5h dark, at 25±2°C. Offspring of *G. nepalensis* were also used. Coexistence with the waterlily leaf during larval or adult stage caused shorter preoviposition period (Mann-Whitney U-test, $P<0.05$) and higher number of eggs laid ($P<0.01$) by *G. nepalensis*. Larval period with the waterlily leaf was shorter than that with a mimic leaf made of thin (1mm) sryrene form ($P<0.01$). Eighty percent of eggs laid by females which were reared with the lily leaf in larval and/or adult stage(s) were successfully developed and higher than forty percent without the lily leaf (χ^2-test, $P<0.01$). Co-existence of *G. nepalensis* with *T. natans* seems to make the individual number of *G. nepalensis* increase and lead to higher foraging pressure to the lily leaf beetle, *Galerucella nippnensis*. Symbiosis between *T. natans* and *G. nepalensis* exists via *G. nippnensis*.
"

Resistant mechanism of tea plants, *Camellia sinensis* **O. Kuntze to mulberry scale,** *Pseudaulacaspis pentagona* **Targioni (Hemiptera: Diaspididae)**

T Mizuta
Kawaminami 17070, Miyazaki, 889-1301, Japan; tmizuta@pref.miyazaki.jp

The mulberry scale, *Pseudaulacaspis pentagona* is the most serious pest of tea plants in Japan. The control effect by chemicals against *P. pentagona* was insufficient, since the insect settling in the tea bushes. The use of resistant cultivars against *P. pentagona* is one of the effective control methods. The resistant cultivars such as Sayamakaori and Minamisayaka, inhibited the development and reproduction of *P. pentagona*. The total number of laid eggs and ovarian eggs per female adults on the resistant cultivars was 5 to 10 % of that on the susceptible cultivar, Takachiho. Moreover, there was a significant positive correlation between the egg reproduction per female and the degree of infestation in tea fields. The weight of scale cover in females reared on the resistant cultivars was significantly lighter than that on the susceptible ones, suggesting that nutritional ingestion was insufficient in the former. When the stylet of female adults was severed, the frequency and amount of exuding phloem sap through the severed stylet was significantly lower on the resistant cultivars than that on the susceptible ones. This difference is presumably related to the mechanism of antibiosis against *P. pentagona*.

Effects of experience of *Cassida nebulosa* L. (Coleoptera: Chrysomelidae) on preference for spinach

A Nagasawa, K Matsuda
Laboratory of Insect Science and Bioregulation, Graduate School of Agricultural Science, Tohoku University, Sendai 981-8555, Japan;
nagasawa@bios.tohoku.ac.jp

A tortoise beetle, *Cassida nebulosa* feeds on chenopodiaceous weeds, *Chenopodium album* and *C. album* var. *centrorubrum* as its main hosts. When the adults were reared on a chenopodiaceous plant, spinach, they feed on spinach as well as *C. album* var. *centrorubrum*. However, the adults reared on *C. album* var. *centrorubrum* did not consume spinach immediately. Methanol extracts of spinach showed a strong feeding-deterrent effect to *C. album* var. *centrorubrum*-reared adults. An active fraction was separated from methanol extracts by solvent partitioning, ODS and silica gel column chromatography. The feeding-deterrent activity on spinach-reared adults was less than that on *C. album* var. *centrorubrum*-reared adults. In addition, when adults were reared on leaves of *C. album* var. *centrorubrum* treated with the active fraction, they accepted spinach as well as *C. album* var. *centrorubrum*. These results indicate that exposure to the deterrent reduce deterrent activity on *C. nebulosa*. Therefore, alternation of activity of the deterrent contained in spinach is responsible for difference of acceptability of spinach by different feeding experience.

Parasitoid communities of herb gall wasps (Hymenoptera:Cynipidae: Aylacini) from Europe

JF Gómez, RR Askew, O Plantard, M Hernández-Nieves, I Izquierdo, JL Nieves-Aldrey
Museo Nacional de Ciencias Naturales (CSIC). José Gutiérrez Abascal, 2, 28006 Maid, Spain; aley@mncn.csic.es

We compiled literature data and unpublished qualitative and quantitative information on the parasitoid community (Hymenoptera Chalcidoidea) of herb gall wasps (Hymenoptera, Cynipidae, Aylacini) from Europe. This essay is aimed to contribute the knowledge of the composition and diversity of one of the most complex, structured and diverse insect communities associated to insect galls. The host gall community is composed of 40 cynipid species inducing galls on 21 plant genera from four families (Asteraceae, Lamiaceae, Papaveraceae and Rosaceae). The studied associated parasitoid community accounted more than 12.000 individuals from 101 species belonging to six chalcidoid and one figitid families as follows: Eulophidae (9), Eupelmidae (9) , Eurytomidae (24), Ormyridae (10), Pteromalidae (25) and Torymidae (23) (Hym., Chalcidoidea); Figitidae (1) (Hym., Cynipoidea). The community presented a high percentage of monophagous, specific-associated parasitoids (about 56%) whereas the estenophagous and poliphagous components were much lower (about 25% and 20%, respectively). Some of the most species-rich parasitoid communities were from cynipids species inducing cryptic galls, indicating that herb galls wasp diversities could be non dependent of size or structural complexity of the host galls.

Two new species of herb gall wasps of the genera *Iraella* and *Aulacidae* (Hymenoptera: Cynipidae: Aylacini) from Spain, including description of their terminal larvae and galls

JL Nieves-Aldrey
Museo Nacional de Ciencias Naturales (CSIC). José Gutiérrez Abascal, 2. 28006. Maid; aley@mncn.csic.es

Two new species of herb gall wasps (Hym., Cynipidae, Aylacini) are described from Spain: *Iraella hispanica* sp. n. and *Aulacidea martae* sp. n. *Iraella hispanica* sp. n., was collected in Tarragona and Zaragoza (North Eastern Spain). The new species represent the second described species from the former monotypic *Iraella* genus and is related to *I. luteipes* that induces cryptic galls in stems of the opium poppy. However galls of the new species are formed in common poppies heads (*Papaver spp*, Papaveraceae) and for this feature is also related to species of the genera *Aylax* and *Barbotinia*. Galls of the new species showed high percentages of parasitism by the figitid species *Parnips nigripes* (Cynipoidea, Figitidae). *Aulacidea martae* sp. n. induces cryptic galls on twigs of *Launaea arborescens* (Asteraceae), a plant living in sand dunes from the Natural Park of Cabo de Gata-Nijar (Almeria), a protected desert habitat at South Eastern of Spain. The host plant of the later new species is recorded for the first time as host of a cynipid gall wasp. Adults of the two new species are described and fully illustrated with SEM pictures. Data are also given on the biology of the two new species described, including description of their terminal larvae and galls.

Morphology and biology of terminal-instar larvae of Ormyridae (Hymenoptera, Chalcidoidea)

M Hernández-Nieves, SF Gayubo, JF Gómez, JL Nieves-Aldrey
Museo Nacional de Ciencias Naturales (CSIC). José Gutiérrez Abascal, 2, 28006 Maid, Spain; aley@mncn.csic.es

Comparative larval morphology of nine ormyrid species (Hym., Chalcidoidea, Ormyridae) from Europe is for the first time presented. The species are representatives of the different life cycles and host plant associations presented for the family in Western Europe: *O. pomaceus*, *O nitidulus*, *O. rufimanus*, *O. diffinis*, *O. wachtly*, *O. capsalis* and *O. papaveris*, parasitoids of oak and herb gall wasps; *O. cupreus*, parasitoid of eurytomids inducing galls on *Ephea* and *O. orientalis*, a parasitoid of tephritid flies in head flowers of *Centaurea* species. The terminal-instar larva of the listed species was prepared for observation under SEM at low vacuum and pictures were taken of the ventral body, head, mouth parts and mandibles. We describe the external ormyrid larval morphology, comparing with the larva of related chalcidoid groups, namely Eurytomidae and Torymidae, as well as we summarize the qualitative variation among the studied larvae. Some diagnostic characters could characterize the family: presence of scarce and short pilosity on the body, rough tegument on parts of head and first segments of body, one toothed mandibles, and a trilobate labrum without deep divisions in the centre.

Bioinsecta - software for insect biology analyses

AL Boiça Neto, AL Boiça Junior, AL Torres , JEM Oliveira, RT Thuler
Computation Engineering - PUC, Campinas, SP. Brazil

The BIOINSECTA is software developed in WindowsÒ platform with the finality of helping researchers of the entomology area to execute analyses related to insect biology study. This software contains pre-established spreadsheets that can be used to evaluation of experiments related to the insect's biology, facilitating this way, the annotation and organization of data to insertion in the program. Trough a simple interface and easy application, the user creates, her/his data bank that can be as stored as impressed. During the typewriting of data to create the archive, the user can visualize in real time, the results from biological parameters that are being calculated by the program with the application of pre-established mathematical models. The calculated parameters can be visualized in a separated screen, and they'll be stored for posterior application or impress, according the user choice. Its creation wait to facilitate the biological calculus and reduce the waste time with its execution, without lose the necessary accuracy. This software has been in phase of analysis for register, but a Demo version will be able to be found at: www.bioinsecta.hpg.com.br

Diversity and biology of gall-inducing Lepidoptera in Costa Rica

K Nishida
Sistema de Estudios de Posgrado en Biología, Escuela de Biología, Universidad de Costa Rica, 2060 San José, Costa Rica; knishida@cariari.ucr.ac.cr

Thus far some 100 species (*ca.* 9% of arthropod-induced galls in Costa Rica) of gall-inducing Lepidoptera belonging to at least 10 families and 8 superfamilies have been found, and are associated with *ca.* 80 species of vascular plants belonging to 20 plant families of dicotyledons. More than half of these lepidopterans are undescribed species of *Mompha* (Coleophoridae), nearly all of which occur on Melastomataceae. Other lepidopterans are: Nepticulidae (1 sp.), Gracillariidae (3), Glyphipterigidae (1), Elachistidae (4), Cosmopterigidae (7), Sesiidae (5) Tortricidae (5), Alucitidae (3), Thyrididae (1). Remaining lepidopterans have not yet been identified. Galling is unknown in butterflies or any other lineage of Macrolepidoptera. Galls were found on stems, leaf veins, petioles, flowers, fruits, and roots. The galls are induced by the larva hatching from an egg laid on the host plant surface and range from simple inconspicuous swelling to complex tissue and organ modification. Many inducers spend their entire larval and pupal stages inside their galls, while others pupate away from the gall. Excrement is packed in the gall chamber or ejected through an orifice. As in other gall formers, gall-inducing Lepidoptera are highly host specific and some could be potential biological control agents for invasive weeds.

Role of PGR-brassinosteroids on the development of a plant-parasitic nematode

P Ohri, SK Sohal, R Bhardwaj
Department of Zoology, Guru Nanak Dev University, Amritsar-143005, Punjab, India; ohri_puja_11@rediffmail.com;

Brassinosteroids, a recently explored group of plant growth regulators, controls a spectrum of physiological responses in a variety of test systems. Their effects on some insects and animals have been well documented in literature but their effect on nematodes has not been studied much. Nematodes have a very intimate association with their host plant. Any change occurring in the host plant is bound to effect the development and physiology of the associated nematode. Keeping this in mind, the present piece of work envisages the role of isolated (mixture of brassinosteroids) and synthetic (28-homobrassinolide) brassinosteroids on the development of a plant-parasitic nematode, *Meloidogyne incognita*. The egg masses of *M. incognita* were exposed, *in vitro*, to six different concentrations (10^{-5}M to 10^{-10}M) of isolated brassinosteroid and 28-homobrassinolide for 7 days. Observations recorded, revealed an enhanced percentage of hatching in treated egg masses when compared with control. Hatched/hatching juveniles were further allowed to develop on plants for 45 days. Brassinosteroids treated juveniles resulted into more gall numbers and larger sizes of galls as compared to untreated ones.

Amount of green leaf volatiles emitted from *Arabidopsis* plants affects their attractiveness to parasitic wasps of cabbage butterfly larvae

R Ozawa, K Shiojiri, K Matsui, G Arimura, T Nishioka, J Takabayashi
"Center for Ecological Research, Kyoto University, Otsu, 520-2113, Japan and Core Research for Evolutional Science and Technology (CREST), Japan Science and Technology Corporation, Kawaguchi, 332-0012, Japan; ozawar@ecology.kyoto-u.ac.jp, "

When infested with cabbage butterfly (*Pieris rapae*) larvae, cruciferous plants emit volatiles that attract a specialist parasitic wasp, *Cotesia glomerata*. This wasp is also attracted to volatiles emitted from mechanically damaged crucifers. Because green plants, such as crucifers, emit six-carbon (C_6-) volatiles through the lipoxygenase pathway in response to mechanical damage, it is likely that some C_6-volatiles are involved in attracting *C. glomerata* to host-infested cruciferous plants. To test the effects of C_6-volatiles on the attraction of *C. glomerata*, Arabidopsis (Cruciferae) seeds treated with mutagens were screened in order to identify mutants in which production of C_6-aldehydes was suppressed (or increased). We obtained a mutant that produced lower levels of C_6-aldehydes than wild-type plants, and this mutant was designated aldehyde less (*all*) *84*. *All 84* also produced lower amounts of other C_6-volatiles when compared to wild-type plants. Laboratory bioassays showed that *C. glomerata* were attracted to *all 84* plants infested by *P. rapae* larvae over uninfested ones. However, when comparing *P. rapae*-damaged *all 84* plants to *P. rapae*-damaged wild-type plants, the wasps preferred the wild-type plants. These data suggest that the amount of C_6-volatiles emitted from *P. rapae*-infested crucifer plants in part determine the degree of attractiveness to *C. glomerata*. Herein, we also discuss the possible effects of a modification in the lipoxygenase pathway of *Arabidopsis* on wasp attraction.

Influence of feeding of *Frankliniella occidentalis* Pergande (Thysanoptera: Thripidae) on the polyphenolic complex in the leaves

M Papadaki, V Harizanova, S Dagnon
Technological Education Institute of Crete. P. O. BOX 1939, 710 04 Heraklion, Crete, Greece; mpapa@steg.teiher.gr

Production of polyphenolic complex compounds in plants contributes to protecting them against herbivores and often determines their forage nutritional value and the insect preference for them. The thrip *Frankliniella occidentalis* is one of the most important insect pests in vegetable crops in greenhouses in the island of Crete (Greece). We recently showed that its preference for several vegetables is variable, ranging from highest levels for eggplants to minimum ones for tomato plants. To test whether this differential preference was associated with the production of polyphenolic compounds in the leaves, we compared the profile of polyphenols, in control (undamaged) and damaged leaves (evoked by *F. occidentalis* attack) of eggplant and tomatoes, by using reverse phase HPLC. We showed that feeding of *F. occidentalis* causes alterations in the relevant quantity of several phenolic acids (chlorogenic acids) and flavonic glucosides (rutins), which are believed to play an important role in plant defence against insect pests. These alterations were different in tomato compare to eggplant leaves, indicating that changes in the production of polyphenolic complex compounds might be associated with the differential preference of *F. occidentalis* for these vegetable hosts.

Canopy management and variety morphology influence in the European grapevine moth (*Lobesia botrana* Den. y Schiff.)

H Peláez, S Moro, M Sinovas, CM Moreno, MC Martin, Y Santiago, R Maraña, JR Urbez, J Barrigón, DO Rueda
Crop Protection. Instituto Tecnológico Agrario de Castilla y León. 47071 Valladolid. Spain; pelrivho@jcyl.es

The influence in the European grapevine moth attack of the canopy management in some of the most important Spanish vine varieties can be modified by different morphology features, in special the cluster structure. The work was carried out during two years, 2000 and 2001, in different plots in Castilla y León (Spain). Four varieties: Tempranillo, Garnacha, Viura and Verdejo, were studied under two different training systems: one trellis-training system with vertical shoot position and the second one, head system without shoot position. In general, there are two generations in the Spanish North Meseta, with two different kind of damage. The goal of this study was to evaluate how can influence canopy management, and other features like cultivar susceptibility of clusters or grapevine phenological stages, on the clusters damages.

Chemical characteristics in the vineyard wood and its possible relationship with *Xylotrechus arvicola* attacks (Olivier, 1795) (Coleoptera: Cerambycidae)

CM Moreno, MC Martin, Y Santiago, H Peláez
Crop Protection. Instituto Tecnológico Agrario de Castilla y León. 47071. Valladolid. Spain; morvarca@jcyl.es

Xylotrechus arvicola (Olivier, 1795) (Coleoptera: Cerambycidae) is a cerambycid which attacks vineyards. The larvae tunnel into the stem in all directions. This is causing economic damages to grapevines in some regions of Spain: Castilla – La Mancha, Castilla y León and La Rioja, because there is a decrease of vascular capacity. The target of this work is to establish the possible relation between the percentage of infested vines and the variety of vines. For this, we have chosen a vineyard in the D.O Bierzo (León). In this, we have selected three varieties: Tempranillo, Sauvignon Blanc and Mencía. During the winter 2003 - 2004, we have prospected the external symptoms of this insect: tunnels made for larvae and round exit holes made for adults. Also, we have analyzed in laboratory some chemical characteristics of wood: holocellulose, lignin and extracts, in some vines of these varieties. The results showed that Mencia is the variety less attacked in these years and Tempranillo is the most attacked. We have made an ANOVA. There are significant differences in holocelulosa, lignin and extracts between the less and more attacked varieties by *Xylotrechus arvicola*. The highest percentage of holocellulose in the most attacked variety offers to the insect a best quality of food. The highest percentage of extracts in Mencia variety could mean that they act as inhibit substances of larval development or as phytoalexin.

Novel activity from *Piper* (Piperaceae) plant secondary compounds against insecticide-resistant and susceptible insect pests of the home and garden

IM Scott, SB Symington, JM Clark, H Jensen, BJR Philogène, JT Arnason
Biology Dep., U. Ottawa, 150 Louis Pasteur, Ottawa, Ontario, Canada, K1N 6N5; bphilog@science.uottawa.ca

Extracts from two pepper species, *Piper nigrum* L. and *P. tuberculatum* Jacq., were tested against insect pests of vegetables and ornamentals in laboratory trials. Based on *P. nigrum* 24 hr LC_{50} values, the larvae of introduced pine sawfly (0.01%); eastern tent caterpillar (0.02%); European pine sawfly (0.05%) and forest tent caterpillar (0.05%) were more sensitive than viburnum leaf beetle (0.1%); gypsy moth (0.28%); Colorado potato beetle (0.5%) and spruce budworm (1%). 24 hr LC_{50} values for *P. tuberculatum* extract showed that both Pyrethroid-resistant house flies and multiple-insecticide-resistant Colorado potato beetles were as sensitive or only two-fold less sensitive than susceptible strains of each species. Preliminary experiments using synaptosomes found that piperamides do affect neuronal Ca^{2+} influx and glutamate release. This evidence coupled with the demonstrated inhibitory effect of piperamides on insect microsomal activity indicates a unique dual activity for these botanical insecticides. *Piper* botanicals therefore have the potential to provide an alternative control product against insect pests of economic importance for organic and conventional horticulturalists, even with populations which have developed resistance to widely used synthetic products.

Arabidopsis thaliana **as a model host plant to investigate the effect of a cyanogenic glucoside on host plant-** *Plutella xylostella*- *Cotesia plutellae* **interactions**

JE Barker, CC Payne, BL Møller, GM Poppy
School of Biological Sciences, University of Southampton SO16 7PX, U.K.; G.M.Poppy@soton.ac.uk

The presence of cyanogenic glycosides in plant material has been shown to confer resistance to some herbivorous pests. Cyanogenic glycosides have not been found naturally in members of the Brassicaceae. Therefore specialist Brassicaceae pests, such as *Plutella xylostella,* are unlikely, in evolutionary terms, to have encountered cyanogenic glycosides recently as natural constituents in their feed and so been exposed to any direct selection pressure to evolve detoxification processes specific to cyanogenic glycosides. Because of this, the effect of cyanogenic glycosides on previously unexposed pests could have very interesting applications for potential pest control strategies. The recent availability of lines of the Brassicaceae *A. thaliana* that have been transformed to produce a cyanogenic glycoside, dhurrin, make it possible investigate such scenarios. The aim of these studies was to use the transformed *A. thaliana* lines to investigate the effect of dhurrin, on the herbivore pest *P. xylostella* and its specialist parasitoid *C. plutellae.* Dhurrin expression did not affect *P. xylostella* in terms of growth, development, fecundity or preference. *C. plutellae* development time was extended by dhurrin, and at lower concentrations, the resulting parasitoid was larger. Dhurrin also disrupted the processes of olfactory choice in host searching by the parasitoids. These studies suggest that dhurrin is not advantageous to protection of the host plant from *P. xylostella.*

Oviposition site selection and phenotypic plasticity in the number of larval instars of a lichenivorous *E. depressum*

H Pöykkö
University of Oulu, Department of Biology, P.O.Box 3000, 90014 Oulu, Finland, heikki.poykko@oulu.fi

Although one might intuitively expect a tight correspondence with female host preference and larval performance, several studies have reported relatively poor preference-performance correlations in herbivorous insects. I compared the host preference and subsequent larval performance of lichenivorous *Eilema depressum* on four common, epiphytic lichens. Females did not show clear host preference towards any of the host lichens. However, *Melanelia exasperata*, on which larvae grew faster and bigger than on other lichens, resulted in the best performance measures of larvae. Moreover, the number of larval instars varied between 6 and 13. Over-wintering larvae had considerably more instars than larvae, which developed without over-wintering to adult stage. Host lichen also had a weak impact on the number of instars. I discuss the importance of larval responses to nutritionally varying hosts in the absence of host preference of ovipositing females and the significance of phenotypic plasticity in the instar number of a lichenivorous species.

Micromorphology of the mouthparts of specialist eucalypt browsing cockchafers *Heteronyx* spp.: an insight into adaptation to a novel adult host plant

HLH Redgrove, PB McQuillan
Co-operative Research Centre for Sustainable Production Forestry, Private Bag 12, Hobart, Tasmania, 7001, Australia; hilton.redgrove@ffp.csiro.au

The adaptation of morphological structures facilitating host specialization is a key factor in insect-host associations. Endemic phytophagous Melolonthine cockchafers are serious pests during the establishment of exotic *Eucalyptus nitens* plantations in Tasmania. The mouthparts and associated sensory structures of two species, *Heteronyx crinitus* Blackburn and *H. dimidiata* (Erichson) were examined by ESEM for specialization. *H. crinitus* displayed highly developed mandibles capable of excising tough foliage of its *Eucalyptus* host. Defences of the *Eucalyptus* host such as leaf toughness seem insufficient to deter scarab browsing. The modified environs of production forestry exposes *Eucalypt* seedlings to attack by native insects which evolved with other hosts in the near vicinity.

Application of multivariate analysis to electrical penetration graphs using manual and automate waveform recognization from the planthopper *Peregrinus maidis* feeding on susceptible and resistant maize

J Dintinger, B Reynaud, C Buduca, J Lecoq, P Turpin, M Grondin, F Chiroleu
CIRAD, Pôle de Protection des plantes, 7 chemin de l'IRAT 97410 Saint Pierre la Réunion, France; reynaud@cirad.fr

The stylet penetration activities of *Peregrinus maidis* (Ashmead) (Homoptera: Delphacidae), vector of *Maize mosaic virus* (MMV) and *Maize stripe virus* (MStV) were studied by electrical penetration graphs (DC-EPG) on resistant and susceptible maize inbred lines. Multivariate analyses were applied to two sets of data obtained by manual and automate methods of waveform recognization from digital EPG recordings. For both methods, the variables, which mostly explained the resistance-susceptibility status of the maize lines, appeared to be related to the passive ingestion in phloem vessel but also to the stylet pathway and in a less extent to active ingestion in xylem and to non-penetration. In spite of a great variability within each genotype, three groups of individuals could be distinguished separating genotypes assumed as susceptible, slightly resistant and resistant to the virus transmission. These results are discussed in relation to the possible mechanism of maize resistance to *P. maidis* and the usefulness of automate waveform recognition with the software "EPG soft" for plant breeding.

Feeding behaviour of the planthopper *Peregrinus maidis* on maize analysed by digital signal processing of EPG and MET structure of stylet pathway

B Reynaud, D Gargani, J Lecoq, P Turpin, M Grondin, M Peterschmitt, JM Lett
CIRAD, Pôle de Protection des plantes, 7 chemin de l'IRAT 97410 Saint Pierre la Réunion, France; reynaud@cirad.fr

Peregrinus maidis (Asmead)(Hemiptera, Delphacidae) is the only known vector of *Maize mosaic virus* and of *Maize stripe virus*, both circulative and propagative viruses. In order to better understand the feeding behaviour of *P. maidis* the electrical penetration graph technique was used (DC-EPG), according to this tool five different waveforms were characterised. Based on the correlation between waveforms and the fine structure of stylet pathways observed by transmission electron microscopy, active ingestion was restricted to xylem vessels, and passive ingestion and watery salivation occurred intermittently in sieve tubes. Spectral and time-frequencies analysis of digital data obtained with the "EPG-Soft" software allowed us to better distinguish ingestion and salivation activities in sieve tubes. Ingestion and watery salivation are essential phases of the feeding behaviour of piercing sucking insects, respectively correlated with acquisition and inoculation of circulative viruses.

Three new host plants of the *Brevipalpus*-borne virus found in United States

JCV Rodrigues, DS Achor, CC Childers, EW Kitajima
University of Florida, Citrus Research and Education Center, 1028 Bldg. 970 Natural Area, PO Box 110620, Gainesville, FL 32611-0620, USA;
carlos@lal.ufl.edu

Mites within the genus *Brevipalpus* (Acari: Tenuipalpidae) have been incriminated with the transmission of a series of new viruses in South America. During a survey for mites and viruses in ornamental plants in Florida, the following plant species had ringspot symptoms in association with *Brevipalpus* mite infestations: *Pittosporum tobira* (Thunberg) Aiton (Pittosporaceae), *Hedera canariensis* Willdenow (Araliaceae) and *Trachelospermum asiaticum* Nakay (Apocynaceae). Transmission electron microscopy of plant tissues within the lesion areas of each of the three species showed rod-like particles within the cell nucleus and one prominent nuclear viroplasm, as well as particles accumulated in the cytoplasm adjacent to the nucleus. These cytopathological alterations in the cells are typically linked with the 'nuclear type' of viruses associated with *Brevipalpus* mite vectors. So far, the virus associated with *Hedera* has been experimentally transmitted by *Brevipalpus* mites.

A rapid method in laboratory to screen resistance of potato plants against *Myzus persicae*

V Le Roux, C Vincent, J Saguez, P Giordanengo
UPRES 2084-2085, Biologie des Plantes et Contrôle des Insectes Ravageurs, Université de Picardie Jules Verne, 33 Rue St Leu, 80039 Amiens Cedex, France; vincent.leroux@u-picardie.fr

In the objective to develop potato resistance against aphids, we propose a rapid screening method with *Myzus persicae* (Sulzer) in laboratory. Our study focussed on two objectives, i.e. to optimize the duration of the whole procedure and to decrease the frequency of measurements. In a first experiment, no significant differences were observed between intrinsic rate of natural increase (r_m) values of adult aphids reared throughout their entire life and adults reared only during a period equivalent to their pre-reproductive period. In a second experiment, four groups of aphids were distinguished according to the sampling frequency, i.e. those whose biological parameters were evaluated every single, second, third and fourth day. Except for the fourth day experiment, the r_m values estimated every single, second and third day were not significantly different for all potato lines. Thus screening efforts in laboratory can be largely optimized by checking adult aphids only during a period equivalent to their pre-reproductive period and assessing *M. persicae* populations every third day. Our method is reliable and adapted to screen a large number of potato plants against *M. persicae* as it leads to an average 70% reduction in the time required for the whole experimental process. Our laboratory screening method must be complemented with a field-screening program.

Woolly apple aphid electrical penetration graph - 'A' waveform

M Sandanayaka, P Sutherland, V Bus

New Zealand; msandanayaka@hortresearch.co.nz

Molecular biological analysis on the induced resistance to pathogens in rice plants infested by *Sogatella furcifera*: expression of defense-related genes and induction of pathogenesis-related (PR) proteins

M Sato, H Kanno, Y Ohashi, I Mitsuhara, K Kuroda
National Agricultural Research Center for Kyushu Okinawa Region, 2421 Suya, Nishigoshi, Kumamoto 861-1192 Japan; msatou@affrc.go.jp

We found that infestation of white-backed planthopper, *Sogatella furcifera*, induced significant resistance to rice blast fungus-infection in the rice plants; the number of lesions formed on rice leaves by infection of blast fungus, *Magnaporthe grisea*, was quite few in the plants which had been exposed to the planthoppers compared with control plants. When exposure was restricted to stem, the number of lesions in the exposed plants was also smaller than that of control plants. The level of incidence by blast fungus-infection after infestation by male planthoppers was similar to that by female planthoppers. Moreover, we found that rice plant which had been infested by the planthoppers acquired resistance to the bacterial blight caused by *Xanthomonas oryzae pv. oryzae*. To study the mechanism of induced resistance, we analysed expression of defense-related genes, accumulation of pathogenesis-related (PR) proteins in the rice plants which were infested by the planthoppers. Interestingly, we found that expression of some defense-related genes and accumulation of PR-1a, PR-2 and PR-5 proteins were considerably increased. These results suggest that the induced resistance by the planthopper mimics the acquired resistance to pathogen-infection in plants which has been extensively studied.

Host selection by pine processionary moth *Thaumetopoea pityocampa* females

M Cappucci, A Battisti, M Faccoli, G Birgersson, Y Hillbur, F Schlyter
Chem. Ecol., SLU, P. O. Box 44, SE-230 53 Alnarp, Sweden; freik.schlyter@vv.slu.se

Thaumetopoea pityocampa (Den. & Schiff.) (Lep.: Thaumetopoeidae) is one of the most destructive defoliators of natural and artificially established *Pinus* spp in the Mediterranean region. Infestation rates differ dramatically among species and tree individuals, suggesting female choice of hosts during egg-laying. We have identified two main factors affecting the host selection process: (i) Tree silhouette, suggested as a dominant factor in the literature. In a rearing room we offered to moths several *Pinus nigra* trees, a preferred species, of different sizes. A significant positive correlation was found between the number of egg masses laid on each tree and both tree height and silhouette. (ii) Volatiles of host plant may play an important role in habitat selection. We investigated the olfactory host recognition mechanisms of females by the gas chromatographic-electroantennographic technique (GC-EAD). We tested natural volatile blends and a synthetic mixture of monoterpenes present in pine needles. Repeatable responses were among others to minor compounds like *E*-ocimene, -terpinol and neodihydrocarveol. In addition, the identification of suitable needles through contact sensilla on tarsi is evaluated as an additional input for the host choice by females.

The suitability of honeydew as a food source for aphid antagonists

K Schmidt, FL Wäckers, R Meyhöfer
172, Waimairi Rd; Ilam, Christchurch , New Zealand; schmidtk@lincoln.ac.nz

Honeydew is a carbohydrate-rich excretion produced by sap-feeding insects. Honeydew can be particularly crucial for survival and fecundity of aphid parasitoids, as well as for aphid predators. The suitability of honeydew as a food source can vary largely, depending on the plant and sap-feeder species. Besides different sugars and nitrogen-rich compounds, honeydew may contain secondary plant compounds. Here we address the nutritional suitability of honeydew from two aphid species, *Myzus persicae* and *Brevicoryne brassicae*, feeding on *Brassicae nigra* (secondary plant compound sinigrin, glucosinulate). The two honeydew types were fed to *Chrysoperla carnea* larvae and *Aphidius colemani* adults, to determine their effect on the survival of these two antagonists. In addition, *C. carnea* was fed with the aphids directly. Secondary plant metabolites present in the honeydew and present in the insects were analysed by HPLC in order to trace their pathways. The results show significant differences in the amount of secondary plant compounds in the honeydew from the two aphid species as well as temporal differences relative to the age of the aphid colony. These patterns correspond with the differences in survival of the natural enemies in the longevity experiments. Tritrophic effects in this plant-herbivore-antagonist system are discussed.

Interactions between Caryophyllaceae species and their pollinating fruit predators

S Dötterl, A Jürgens, B Weißbecker, S Schütz
Institute for Forest Zoology and Conservation, University of Goettingen, Buesgenweg 3,

The larvae of all noctuid *Hadena* species and of *Sideridis rivularis* feed exclusively on Caryophyllaceae species, mostly on the fruits. As shown for *Hadena bicruris* and its important dioecious host plant *Silene latifolia*, the moths reproduce within female flowers they pollinate. The moths are very specific by the choice of plants for egg deposition. Also, comparisons of pollen spectra, prepared from different museum specimens and species indicated in some cases a narrow nectar-plant spectrum of the moths. In case of *H. bicruris* and *S. latifolia* it was demonstrated that the nocturnal flower scent attracts the moths, however, nothing was known about the role of single scent compounds. We identified about 60 different floral scent volatiles, and revealed a high variability in the scent of *S. latifolia*. Sixteen electrophysiologically active compounds were identified using the GC-EAD method. Wind tunnel bioassays indicated that some of the EAD active compounds are very attractive for *H. bicruris*. Differences in the chemical composition of total-flower volatiles and pollen volatiles could be important for *H. bicruris* to distinguish between male and female flowers, because eggs are deposited only in female flowers.

Orientation of larvae of gram podborer, *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae), to hexane extracts of susceptible and resistant varieties of pigeonpea, *Cajanus cajan*

AK Singh, S Ganta
Department of Zoology, University of Delhi, Delhi-110007, India; singhak@vsnl.net

Orientation response of neonate larvae of the gram podborer, *Helicoverpa armigera* (Hübner) to crude hexane extracts of leaves, buds, flowers, and pods of susceptible (ICP 11965) and resistant (ICP 11957) cultivars of pigeonpea was studied in the olfactometer under choice conditions. Extracts from the susceptible variety presented at one end against an opposite blank elicited significantly greater attraction of the larvae towards all the test samples. Compared to the blank end, there was greater orientation towards extracts from leaves, buds, flowers, and pods of the resistant variety. In both the cases attraction was highest for flower extract and lowest for leaf extract. In two-choice tests, the orientation response towards extracts of buds, flowers, and pods of the susceptible variety was significantly higher compared to extracts of the same parts from the resistant variety, but the response for the leaf extracts was similar for both varieties. The orientation preference of larvae for extracts from pods, buds, and flowers of the susceptible variety was respectively 35 %, 41 % and 56 %. This indicates presence of hexane-extractable semiochemicals in the reproductive parts of the plants, contributing towards the greater arrival of podborer larvae, and hence possibly one of the mechanisms of relative susceptibility of ICP 11965.

Mother doesn't always know best – oviposition preferences of *Delia radicum*

J Soroka, J Holowachuk, L Grenkow, M Gruber
Agriculture and Agri-Food Canada, 107 Science Place, Saskatoon, SK, S7N 0X2, Canada; sorokaj@agr.gc.ca

For insect larvae with limited mobility, the choice of oviposition host by the adult female largely determines the plants on which the offspring feed. In greenhouse trials, laboratory-reared cabbage root maggot *Delia radicum* L. female flies oviposited significantly greater numbers of eggs near yellow mustard *Sinapis alba* roots than near oilseed rape *Brassica napus* plants. This ovipositional preference was maintained in trials comparing each of four *S. alba* lines varying in glucosinolate and erucic acid levels with the control *B. napus* cultivar. Although previous research has shown that females prefer larger plant crowns on which to oviposit, in the current study *B. napus* plant crowns were larger than those of *S. alba*. Despite this ovipositional preference, roots of *S. alba* consistently supported fewer *D. radicum* maggots than did those of *B. napus*, a condition frequently found in the field. The possible reasons behind this anomaly are discussed. In this case oviposition preference is not a reliable measure of host plant resistance towards cabbage root maggots. *S. alba* appears to have components detrimental to the survival of *D. radicum* larvae.

Feeding behaviour of *Myzus persicae* on potato plants infected by potato leafroll virus

AE Alvarez, EI Garzo, M Verbeek, B Vosman, M Dicke, F Tjallingii
Laboratory of Entomology, Wageningen University Binnenhaven 7, 6709 PD, Wageningen, NL; Freddy.Tjallingii@wur.nl

Potato leafroll virus (PLRV) is highly dependent upon *Mysus persicae* for dispersal and transmission. Indirect interactions between PLRV and *M. persicae* occur through their mutual host plant *Solanum tuberosum* L. Any change in virus-infected host plants attracting and benefiting the insect vector would increase the probability of virus dispersion. In order to get a better idea of vector-host-virus interactions we studied the effect of PLRV infection on the feeding behaviour of *M. persicae*. We investigated this effect using the electrical penetration graph (EPG) technique, on a potato cultivar that shows a certain degree of resistance to the vector. This resistance avoided phloem sap ingestion (needed for PLRV acquisition) but did not avoid phloem salivation (needed for PLRV inoculation). The feeding behaviour was monitored in control (healthy) and virus-infected potato plants in three different stages; 1) before inoculation with PLRV, 2) 21 days after inoculation, when virus infection was confirmed by ELISA, and 3) when symptoms of the disease were expressed. An increased susceptibility, allowing phloem ingestion (PLRV acquisition) would be beneficial for the PLRV spread but not for the farmer.

Sequence analyses of two plant rhabdovirus genomes and identification of virus-binding insect vector proteins

CW Tsai, S Reed, K Willie, M Goodin, MG Redinbaugh, SA Hogenhout
1680 Madison Ave., Wooster OH 44691, USA; tsai.154@osu.edu

Insect transmission of rhabdoviruses is highly specific; a given rhabdovirus is transmitted only by one or a few closely related insect species. *Maize mosaic virus* (MMV) is transmitted by the planthopper *Peregrinus maidis*, whereas Maize fine streak virus (MFSV) is transmitted by the leafhopper *Graminella nigrifrons*. The goals of this study are to sequence the genomes of MMV and MFSV and to identify and characterize factors essential to vector specificity. The MFSV genome has seven open reading frames (ORFs) on the antigenomic strand in the order 3'-N-P-3-4-M-G-L-5', which is one ORF more than MMV having six ORFs in the order 3'-N-P-3-M-G-L-5'. Gene junctions with consensus sequences separate each ORF. *In planta* subcellular localization of fluorescent protein fusions was used to confirm the annotation of MMV and MFSV genes. MMV and MFSV-binding proteins of vector and non-vector insects were determined by virus overlay assays of one-dimensional Western blots. A 90 kDa *P. maidis* protein that bound to MMV and MFSV and a 65 kDa *P. maidis* protein that bound to MMV but not MFSV are being purified by two-dimensional protein electrophoresis and sequenced using tandem mass spectrometry.

The same sort of gall induced by different *Asphondylia* species (Diptera: Cecidomyiidae) on the same host organ and species

N Uechi, J Yukawa
Entomological Laboratory, Graduate School of Bioresource and Bioenvironmental Sciences, Kyushu University, Fukuoka 812-8581, Japan;
uechi@agr.kyushu-u.ac.jp

Many gall midges (Diptera: Cecidomyiidae) are monophagous or oligophagous and gall morph is specific to gall-midge species. Therefore, the gall is regarded as an extended phenotype of respective gall midges, except for some polyphagous species. In addition, there are many examples in which different sorts of gall are induced by congeners on the same host organ and species. However, we found three examples in which different *Asphondylia* congeners induce the same sort of gall on the same host organ and species: the chili-pod gall midge in the Mediterranean region (= *Asphondylia gennadii*) and Southeast Asia (*Asphondylia* sp.); the soybean-pod gall midge in Japan (= *Asphondylia yushimai*) and Indonesia (*Asphondylia* sp.); the *Ampelopsis*-fruit gall midge on the Nansei Islands, Japan (*Asphondylia* sp.) and in other areas of Japan than the Nansei Islands (= *Asphondylia baca*). We examined morphological and genetic differences between the congeners that induce the same sort of gall on the same host plant. Their ecological features including host-plant utilization and life-history pattern were also surveyed. Then, we concluded that the congeners on the same host plant were phylogenetically apart from one another. This implies interesting processes in the establishment of gall midge and host plant association.

Identification of sieve elements as the primary site of whitefly resistance in resistant alfalfa genotypes

GP Walker, YX Jiang
Department of Entomology, University of California, Riverside, California 92521, USA; walker@citrus.ucr.edu

Multiple techniques indicate that the mechanism of resistance in alfalfa genotypes previously identified as resistant to silverleaf whitefly, *Bemisia argentifolii* Bellows & Perring, reside in phloem sieve elements. Whiteflies experience very high mortality in the first instar on resistant genotypes compared to susceptible genotypes, but are equally successful in reaching vascular bundles and penetrating phloem sieve elements with their stylets on both genotypes. Phloem sap ingestion commences equally on both resistant and susceptible genotypes, but bouts of ingestion behaviour, as monitored by EPGs, are shorter on resistant genotypes than on susceptible genotypes. Conversely, bouts of a non-ingestion EPG waveform (presumably salivation) are longer on resistant than on susceptible genotypes. Honeydew production per unit time of ingestion is greatly reduced on resistant compared to susceptible genotypes. The combined effects of reduced time in ingestion behaviour and reduced amounts of honeydew produced per unit time of ingestion behaviour result in a drastic reduction of total honeydew production on resistant genotypes. Honeydew production on resistant genotypes ops to near zero levels about 2-3 days after hatching, and the nymphs fail to molt to the second instar.

Attraction of *Hyalesthes obsoletus* **to the Chaste Tree,** *Vitex agnus-castus*

R Sharon, V Soroker, S Wesley, T Zahavi, A Harari, P Weintraub
ARO, Gilat Research Center, D.N. Negev, 85280, Israel; phyllisw@volcani.agri.gov.il

The planthopper, *Hyalesthes obsoletus (Ho)*, is a known vector of phytoplasmas (the causative agent of "yellows" diseases of grapevines) in Europe and Israel; however, grape is a poor host plant. Therefore, we surveyed native plants in northern Israel to find preferred host plant(s). The chaste tree, *Vitex agnus-castus* L (*Vac*), was found to harbour large populations of adult *Ho*. We planted a belt (alternating groups of 5 plants each) consisting of known *Ho* hosts: *Vac*, *Myrtus communis* and *Convolvulus* sp. We monitored for the presence of *Ho* on these plants, and also at various distances from the belt into the vineyard, by vacuuming. Vacuuming *Ho* from the belt to the centre of the vineyard showed that the number of specimens appeared to decline as the distance from the belt increased. Behavioural studies using a Y-tube olfactometer showed that *Ho* preferred *Vac* over *Convolvulus* sp. or grapevines. Antennal electrophysiological response towards leaf volatiles collected from *Vac* was significantly higher than to grapes. These results suggest that *Vac* is attractive to *Ho* and indicate that host specific volatiles of *Vac* play a role in this phenomenon. Implementation of *Vac* as a trap plant in the control of "yellows" disease is discussed.

Electroantennogram or single cell recordings, what is the best?

A Wibe
Norwegian Centre for Ecological Agriculture, N-6630 Tingvoll, Norway; atle.wibe@norsok.no

In identifying the volatiles that insects use to locate suitable host plants, electrophysiological recordings of olfactory responses to plant volatiles may give important information. However, divergent results may be obtained with different recording techniques. To illustrate these differences, the results of a previous investigation using single cell recordings linked to a gas chromatograph (SCR-GC) are compared with the results obtained with an electroantennogram linked to a gas chromatograph (EAG-GC). Testing insects of the same species (*Hylobius abietis*) for the same test sample, 30 potent volatile compounds were identified by SCR-GC and 18 by EAG-GC. Of the 34 different compounds, 14 were identified by both techniques. Furthermore, when the same compound elicited detectable responses by both techniques, the response strength was usually not the same relative to the strongest response recorded by each technique. This shows that both EAG-GC and SCR-GC are important techniques in the identification of potent plant volatiles for insects. However, by using SCR-GC more information was obtained, information that can be crucial for understanding the insect-plant relationship.

Defense and regrowth in a willow hybrid population under a nutrient gradient

O Widenfalk, C Glynn, DA Herms
The Forestry Research Institute of Sweden, Uppsala Science Park, SE-751 83 Uppsala, Sweden; olof.widenfalk@skogforsk.se.

The relationship between plant regrowth and defense against herbivores under different nutrient regimes was investigated. We performed an experiment with artificial browsing on two willow species *Salix viminalis* and *S. dasyclados* and six of their F2 hybrids, under three different nutrient regimes (from low to high). We found variation in production of secondary metabolites but no variation in tolerance (biomass of browsed plants/biomass of non browsed plants). In all genotypes the plants in lower soil fertility invested more in root biomass. This may be a mechanism by which plants tolerate herbivory. Our results further suggest that, despite genotype differences in herbivore defense, these are not related to the different growth strategies, rather, the levels of secondary metabolites are related to nutrient levels. We found large effects of genotype on naturally-occurring leaf-hopper damage. However, this does not seem to be related to the levels of secondary metabolites. This in combination with the lack of response in the bioassay with the white marked tussock moth (*Orgyia leucostigma*), shows that the level of insect damage may be a more complicated story than just a matter of how much a plant allocates resources to production of defensive compounds.

Colonization and survival of *Cameraria ohridella* (Lepidoptera, Gracillariidae) on different species of the genus *Aesculus*

E Baraniak, U Walczak, P Zduniak
Department of Systematic Zoology, Adam Mickiewicz University, Frey 10, 61-701 Pozna, Poland; urszulaw@amu.edu.pl

Cameraria ohridella is a small leaf-mining moth which was initially recorded in Europe in 1985 (Deschka & Dimic 1986) and has rapidly colonized almost all its area (Sefrova & Lastuvka 2001). The sudden appearance of *C. ohridella* in Europe has been an unexplained issue so far. One of the likely hypotheses is that it has been brought with plant material from a distant region. The purpose of the presented research is to determine the supposed origin region of *C. ohridella* by observations of moth preferences for host plant. The tests concerning colonization and survival showed that *C. ohridella* went full development on four out of six *Aesculus* species examined and on five hybrids. The highest level of larvae infestation and survival was noted on Asian species: *Aesculus turbinata* and *A. wilsonii*, and on a European species *A. hippocastanum*. The other colonized plant was a North American species *A. glabra*, however the survival of larvae was significantly lower. Two other species from that area, *A. octana* and *A. parviflora*, were not infested.

Life history, gall anatomy and galling position of two urn-shaped cecidomyiid galls on *Machilus* spp. (Lauraceae) in Taiwan

MM Yang, YC Weng, SC Hsiao
Department of Entomology, National Chung Hsing University, 250 Kuo Kuang Road, Taichung 40227, Taiwan; mmyang@agon.nchu.edu.tw

Cecidomyiid galls represent the most abundant and complicated component of the gall fauna in Taiwan. They comprise about 40% of the galls found in Taiwan but their taxanomy and biology are little known. We studied the life history, gall anatomy and galling position of urn-shaped cecidomyiid *Dephnephila* galls which are commonly found in central Taiwan on two different hosts, *Machilus zuihoensis* and *M. mushaensis* (Lauraceae). Both insects are univoltine. The time of oviposition is influenced by the host phenology in spring and a retardation in development occurred after the hatched first instar larvae mined into the leaf blade until November. There is no correlation between the gall size and the leaf blade size. However, the gall size is influenced by the factors such as galling position, density of galls per leaf and parasitism. Highly differentiated gall tissues can be identified. Fungal mycelia are found on the inner gall surface and they are identified as ambrosia galls. Morphological differences were found for both the insects and their gall which suggest that these are two different species. The morphological consistency of these two similar but distinct galls also provides useful information for resolving the difficulty in identifying *Machilus* species.

Study on host plant selectivity of the leafminer, *Liriomyza sativae*

MX Zhang, B Ling, L Zeng, XF Pang
Laboratory of Insect Ecology, South China Agricultural University, Guangzhou 510642, China; mxzhang100@163.com

The selectivity of six plants species by *Liriomyza sativae* was evaluated with the number of larvae, degree of damage and cucurbitacin B content. The results showed: (1) The Mean number of larvae per cm^2 being 0.183 0.116 0.102 0.099 0.043 and 0.0 respectively for *Vigna sesquipedalis*, *Cucumis melo* var. *conomon* f. *albus*, *Benincasa hispida* var. *chieh-qua*, *Luffa cylinical*, *Cucumis sativus* and *Monordica charantia*. The average degree of larval damage was 23.42%, 13.47%, 8.78%, 5.83%, and 1.63% on *L. cylinical*, *V. sesquipedalis*, *B. hispida* var. *chieh-qua*, *C. melo* var. *conomon* f. *albus* and *C. sativus*, respectively. (2) The levels of cucurbitacin B of the six species were analysed using HPLC. There was a significant negative correlation between the number of larvae, the degree of damage and cucurbitacin B content. Results demonstrate that cucurbitacin B is one of an important factors influencing host selectivity of *L. sativae*.

Annual cycle of the African rice gall midge in southwestern Burkina Faso: host-plant relationships.

N.M. Ba, D. Dakouo, S. Nacro And P.A. Ouedraogo
Institut de l'Environnement et de Recherches Agricoles (INERA), CREAF de Kamboinsé, 01 B.P. 476 Ouagadougou, Burkina Faso (West Africa). Email: baniango@yahoo.fr

The African rice gall midge, *Orseolia oryzivora*, is a major pest in Burkina Faso. The present study was carried out during 4 consecutive crop seasons from 1999 to 2001 in three rice irrigated schemes in the southern part of the country. It aimed at monitoring the pest damage and its immature stage populations through observations on growing rice in farmer fields, on rice ratoons after harvest and on wild rice around rice fields. The pest survival in absence of rice was due to rice ratoons and wild rice, *Oryza longistaminata*. However, rice crop was the preferred host plant as over 15 % of galls were observed during wet seasons while damages and larval populations were very low in dry seasons. These results are important steps for the development of IPM for the pest control with regard to its host plant relationships.

"Role of pseudomonad induced resistance in tomato *Lycopersicon esculentum* against leafminer, *Liriomyza trifolii*"

"M.Murugan, N.Dhandapani and R.Samiyappan"
Centre for Plant Protection Studies, Tamil Nadu Agricultrural Univeristy, Coimbatore 641 003, India. Present address: Regional Research Station, Paiyur 635 112, India. email:entomurugan@rediffmail.com

Tomato is an important vegetable crop of India and it is frequently infested by the leafminer, *Liriomyza trifolii* resulting in yield loss. Insecticides offer less impact in its management and genetic resistance iS minimum in commercial cultivars. Induced resistance is found to be a source of pest reduction in crops like tomato. Hence, an attempt was made to induce the resistance in tomato using biological and chemical inducers. *Pseudomonas fluorescens* (strain Pf1) was used to treat the seeds, seedlings and was applied to soil and foliage. The incidence of *L. trifolii* was significantly reduced on plant basis (29.7%) and leaflet basis (19.9%), when compared to check (53.7 and 31.9% respectively). The induced plants showed non-preference for feeding and egg laying to female flies. Antibiosis was observed in larval growth and development. Egg to adult period was increased by 3.2d. The larval parasitism by *Chrysaonotomyia rexia* was 34.7% more on the induced plants. Leafminer infestation resulted in enhanced expression of the pathogenesis related (PR) proteins and defense enzymes *viz.,* peroxidase, polyphenol oxidase, phenylalanine ammonia lyase, 1-3 glucanase, proteinase inhibitors and chitinase. The defense chemicals *viz.,* total phenols, tannins and acylsugars were also high in the induced plants. Compatibility of induced resistance was also noticed with the neem products under field condition.

Quantification of silk trails made by lepidopteran larvae.

M-L Johnson, BW Cribb, DJ Merritt
Queensland Department of Primary Industries, Zoology and Entomology Department, University of Queensland, St Lucia, Qld, 4072, Australia;mjohnson@zen.uq.edu.au

Lepidopteran silk is made up of fibrous proteins extruded by a spinneret located near the mouthparts. The silk produced by lepidopteran larvae is known to play a role in feeding, survival, shelter and dispersal. It is also suspected that silk plays an important role in the adherence of larvae to substrates. Most studies have described the function of lepidopteran silking behaviour in relation to shelter building and construction of pupal cocoons. Our aim was to investigate the role of Lepidopteran silk in foraging behaviours such as crawling and feeding using the larvae of *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae), a major lepidopteran pest of crops world wide. Given that silk is practically invisible to the naked eye we developed a method for visualising silk trails in early instars using a fluorescent stain and fluorescence microscopy. This was combined with timelapse digital video-recording to correlate larval behaviour and rate of movement with the type and density of silk laid down over the animal's path. Distinctive silking patterns occur in association with larval foraging. Studies were conducted on whole plant material as well as a variety of artificial surfaces, leading to the development of a suitable model substrate.

Begomovirus Transription in *Bemisia tabaci*

C. L. McKenzie, X. H. Sinisterra, W. B. Hunter, and R. G. Shatters, Jr.
USDA-ARS, U. S. Horticultural Research Laboratory, 2001 South Rock Road, Fort Pierce, FL, 34945, USA, cmckenzie@ushrl.ars.usda.gov

Plant pathogenic begomoviruses have a complex association with the whitefly, their insect vector, and aspects concerning viral genetic activity (genome replication and gene transcription) within their insect vector remain highly controversial. Selected gene transcripts of Tomato mottle (ToMoV) and Tomato yellow leaf curl (TYLCV) begomoviruses were quantified in whiteflies after feeding on virus infected tomato plants and after subsequent transfer to cotton (a non-host for the selected begomoviruses). Real time rt-PCR (RT rt-PCR) was performed using specific primers for three ToMoV genes: AV1, BC1, BV1, and three TYLCV genes: V1, V2, and C3. The ToMoV gene transcripts were rapidly lost in whiteflies transferred from tomato to cotton, while, TYLCV transcripts increase in whiteflies transferred to cotton and allowed to feed on cotton for up to seven days. Plant viral transcriptional activity within the insect vector was associated with lower viral DNA titer in the plant and different viral DNA allocation patterns within the whitefly. This is the first quantitative report of a plant DNA virus transcriptional activity in an insect vector, and correlation of this activity with viral DNA abundance in the plant.

Identification of the Genes Associated with Tomato Irregular Ripening using Microarray Technology

CL McKenzie, XH Sinisterra, CA Powell, MG Bausher, JP Albano, and RG Shatters, Jr.
USDA-ARS, U. S. Horticultural Research Laboratory, 2001 South Rock Road, Fort Pierce, FL, 34945, USA, cmckenzie@ushrl.ars.usda.gov

Tomato irregular ripening (TIR) disorder has been associated with silverleaf whitefly (SLW) (*Bemisia argentifolii* Bellows and Perring) feeding. Symptoms of this physiological disorder do not appear on tomato foliage where whitefly feed, but appear as an uneven fruit color development. Plants infested with SLW can develop fruit with external longitudinal white or yellow streaks resulting in unmarketable fruit. TIR internal symptoms consist of a lack of internal coloring of the fruit, thereby reducing post harvest quality. The mechanism(s) associated with the development of TIR has not been identified. Gene array technology was applied to TIR as a model system. Our objective was to study gene expression over time in tomato plants subjected to a moderate infestation of whitefly and resulting in the development of TIR. Multiple plant harvests of old and young leaves, stems, roots, flowers and fruit from tomato with and without whitefly were processed for nutritional analysis and RNA extraction. RNA was labeled and hybridized to the gene array membrane to determine which genes SLW feeding influences. Plants infested with whitefly were larger, produced more leaves, flowers and fruit, but significantly less fruit ripened compared to plants without whitefly. Plant nutrition and RNA profiling results will be presented.

The *Bemisia tabaci* Functional Genomics Project

CL McKenzie, RG Shatters, Jr., JK Brown, and H Czosnek
USDA-ARS, U. S. Horticultural Research Laboratory, 2001 South Rock Road, Fort Pierce, FL, 34945, USA, cmckenzie@ushrl.ars.usda.gov

We propose the first genomics project on a hemipteran insect pest to agriculture, the whitefly *Bemisia tabaci*. This insect transmits many viruses to a variety of economically important crops in the USA, Israel, and worldwide. The B type (synonym *B. argentifolii*) is resident to Israel, and has invaded the Southern USA, reaching epidemic proportions. Despite its extreme economic importance, there is little molecular genetics information on *B. tabaci*. This project proposes the development and public presentation of a *B. tabaci* expressed sequence tag (EST) library and associated cDNA high-density arrays, and to use the arrays to analyze how begomoviruses influence the whitefly transcript profile. The cDNA libraries will be constructed by pooling populations of B biotype selected before and after they acquire mono partite (*Tomato yellow leaf curl virus*) and bipartite begomoviruses (*Tomato mottle virus*). Genes whose transcript abundance changes in response to acquisition and circulative movement of begomoviruses through the whitefly will be identified using array-based hybridizations. This project combines expertise in *B. tabaci* biology, plant-virus-vector relationship, genomics and bioinformatics, and is presented with the knowledge that understanding the molecular mechanisms underlying the biology of *B. tabaci* is a prerequisite for the creation of new strategies to curb the disastrous effects of this insect on many crops worldwide. Preliminary EST results will be presented from the various whitefly libraries.

Plant-mediated effects of drought, nutrient and heavy metal stress on a grass miner

J. Scheirs, *L. De Bruyn*
Evol. Biol. Group, University of Antwerp, Groenenborgerlaan 171, 2020 Antwerp, Belgium jan.scheirs@ua.ac.be

We investigated the predictions of the plant stress and the plant vigour hypothesis with the grass miner *Chromatomyia milii* (Diptera: Agromyzidae) on drought, nutrient and heavy metal stressed *Holcus lanatus* plants. Plant stress intensity was measured by recording plant growth. Plant growth was positively related to insect preference in the water and the heavy metal stress experiments. This corresponded with a decrease in performance of *C. milii* with increasing plant stress intensity. Our nutrient treatments had little effect on plant growth, except for a decrease in plant biomass when an excess of nutrients was supplied. Offspring survival was also lower on the *H. lanatus* plants that were stressed by an excess of nutrients. The decrease in performance on the water stressed plants was mainly caused by self-pruning of the *H. lanatus* plants. Heavy metal stressed plants were unsuitable resources because of an increasing accumulation of foliar cadmium, and a decreasing foliar carbohydrate concentration, with increasing heavy metal exposure. In conclusion, *C. milii* always showed a negative response to stressed plants. Yet, the mechanistic explanation for the decrease in performance on stressed plants differed among stress types.

A standardized method for monitoring solitary bee communities

G LeBuhn, S Droege, T Griswold, R Minckley, T Roulston, N Williams, O Messenger, F Parker, V Tepedino, J Cane, C Kremen, S Buchmann, G Frankie, J Grixti, Q McFrederick, M Richards, A Rogers.
"Dept. of Biology, San Francisco State University, 1600 Holloway Avenue, San Francisco, CA 94132 United States; lebuhn@sfsu.edu"

Bees are the principal pollinators of flowering plants in most terrestrial ecosystems of the world and arguably no taxonomic group has been more important for the evolution and function of these ecosystems. Bee activity translates broadly and directly to human well-being. In North America alone, estimates of the value of bees (natives and the introduced honey bee) as pollinators of crops ranged between $4.6 and $18.8 billion. Despite their well recognized economic and ecological value, we lack basic information on the global, regional, and local patterns of diversity and population trends of this species rich and ecologically important group. To begin to fill this gap, we have developed and tested a simple sampling protocol (http:\\online.sfsu.edu\~beeplot) that requires low cost equipment available worldwide. Our protocol is usable by scientists of many interests, as well as amateurs and school groups. Data generated using this protocol will be useful for 1) conservation planning and strategy development 2) local, regional and national assessments of species richness; and 3) evaluations of population trends in different habitat types (e.g. agricultural versus wilderness sites). This collaborative effort will allow us to detect differences in species richness and population trends among biomes, ecoregions, habitats, communities, and plots.

The diversity and distribution of Coleoptera in three different plant communities on Mt. Tangkubanparahu, West Java, Indonesia

A Linawati, TS Subahar
Kanazawa University International House R. 312, Ta 1-1 Kakuma Machi, Kanazawa 920-1192, Ishikawa, Japan; linawati @stu.kanazawa-u.ac.jp

Situated in Java Island, Indonesia, Mt.Tangkubanparahu possesses many interesting features, among others are floristic composition, elevation, and level of human disturbance, which undoubtedly affect the abundance and diversity of the fauna including those belong to the order Coleoptera. The study on diversity and spatial and temporal predominance of Coleoptera was conducted in three different plant communities namely Schima-Astronia forest(1600 m asl),pine plantation(1300 m asl) and agroforestry area (1200 m asl) using pitfall traps. The total abundance of Coleoptera in the three communities was 1284 individuals comprising 127 species from 22 families. The highest abundance was found in agricultural site (510 individuals) followed by in mixed forest (506 individuals) and in pine forest (268 individuals). The highest species richness was found in mixed forest (77 species) followed by in pine forest (55 species) and agricultural site (58 species). The index of diversity (H') was the highest in mixed forest (3.67) while that of pine forest and agricultural site were 3.30and 3.04 respectively. Coleoptera were found most abundant in mixed forest and in pine forest in November (161 and 94 individuals respectively) while in agricultural site in December (224 individuals). The highest temporal index of diversity in mixed forest and pine forest were found in November (H'= 3.21 and 3.10 respectively) while in agricultural site in December (H' = 2.99).

Colonisation of terrestrial bromeliads by insects in the Atlantic rain forest of Santa Catarina, Brazil

J Steiner, A Zillikens
"Dept. BEG, CCB, Federal University of Santa Catarina, 88.040-900 Florianópolis, SC, Brazil; steiner@mbox1.ufsc.br"

Bromeliads offer suitable environments for the reproduction of large numbers of animal species because their central leaf rosette forms small water bodies where aquatic insects live, while the lateral leaf axils hold decomposing organic material inhabited by terrestrial organisms. In order to better understand the dynamics of the animals that make use of bromeliads we performed a study on the colonization of *Aechmea lindenii* by terrestrial insects. Plants were manipulated by filling the central tank and the leaf axils with sterilized humus. For 10 months, a sample of 5 plants was collected every 4 weeks and all insects associated with them were recorded. 5 unmanipulated plants of the same species served as a control. During the same period, the soil fauna of patches close to the bromeliads was sampled by Winckler extraction. Both bromeliad groups contained about equal amounts of ants (75%). For the other arthropod groups, spiders and beetles dominated in manipulated bromeliads, while the controls contained about 50% aquatic beetles and flies. Our data suggest that the plants that were transformed into a more terrestrial habitat were successively colonized by a typical terrestrial arthropod fauna that presents similarities to the soil fauna as analyzed by the Winckler extraction.

The role of an adventitious mutualism and water stress in population outbreaks of scale insects

KL Abbott, PT Green, DJ O'Dowd
"School of Biological Sciences, Victoria University of Wellington, PO Box 600, Wellington, New Zealand; Kirsti.Abbott@vuw.ac.nz"

Outbreaks of pest insects are often preceded by stressful weather conditions, where stressed plants become susceptible to herbivores due to altered nutritional quality or defensive chemical concentrations. Some insect species also increase in abundance via beneficial interactions. We studied the explosions in density by the invasive yellow crazy ant, *Anoplolepis gracilipes*, on Christmas Island, which were concurrent with a rapid increase in populations of introduced/cryptogenic honeydew-producing scale insects. We tested the combined effect of plant water stress and attendance by *A. gracilipes* on the success of populations of the lac scale, *Tachardina aurantiaca*, on seedlings of rainforest species. Plant water stress had no significant effect on the abundance *T. aurantiaca* crawlers. Nor did stressed plants affect the abundance or establishment of adult females. However, the presence of *A. gracilipes* had a highly significant, positive effect on all life stages. After 2 months, densities of adult females increased 4-fold on seedlings with ants compared to those without ants. Our results suggest higher rates of crawler establishment and increased survival throughout development in association with an introduced ant mutualist, independent of plant water stress. Establishment of adventitious mutualisms following alien species introductions may play a pivotal role in accelerating population explosions and concomitant impacts of invasive insects.

Nightshade plants attract aphid vectors and harbor potato viruses

JM Alvarez, R Srinivasan, NA Bosque-Perez , SD Eigenbrode, R Novy
University of Idaho, Aberdeen R&E Center, 1693 S 2700 W Aberdeen, ID 83210; jalvarez@uidaho.edu

Hairy nightshade, *Solanum sarrachoides* is a solanaceous weed abundantly distributed in potato ecosystems of Idaho, the largest potato producing state in the U.S. It is a preferred host for green peach aphid (GPA) *Myzus persicae*, considered the most effective vector of potato leafroll virus (PLRV). Our previous laboratory experiments confirmed that GPA can transmit PLRV to hairy nightshade and that non-viruliferous aphids can become viruliferous after feeding on infected nightshades. Six percent of field-collected nightshade plants in 2002 were found to carry PLRV and in few cases other viruses such as PVY and PVX. We investigated whether PLRV-infected nightshades would attract GPA and also how this attraction would compare with the one produced by infected potatoes. Field trials were conducted to study the role of *S. sarrachoides* on vector distribution and PLRV epidemiology. Aphid counts and disease progression were monitored at weekly intervals. Results revealed that plots with nightshades recorded an increased number of aphids and also had higher number of PLRV infected potato plants. A preference study revealed increased preference of winged GPA to PLRV-infected *S. sarrachoides*. Our findings thereby suggest that *S. sarrachoides* might play a major role in the epidemiology of PLRV in the potato ecosystem.

Annual cycle of the African rice gall midge in southwestern Burkina Faso: host-plant relationships

NM Ba, D Dakouo, S Nacro, PA Ouedraogo
Institut de l'Environnement et de Recherches Agricoles (INERA), CREAF de Kamboinsé, 01 B.P. 476 Ouagadougou, Burkina Faso (West Africa); baniango@yahoo.fr

The African rice gall midge, *Orseolia oryzivora*, is a major pest in Burkina Faso. The present study was carried out during 4 consecutive crop seasons from 1999 to 2001 in three rice irrigated schemes in the southern part of the country. It aimed at monitoring the pest damage and its immature stage populations through observations on growing rice in farmer fields, on rice ratoons after harvest and on wild rice around rice fields. The pest survival in absence of rice was due to rice ratoons and wild rice, *Oryza longistaminata*. However, rice crop was the preferred host plant as over 15 % of galls were observed during wet seasons while damages and larval populations were very low in dry seasons. These results are important steps for the development of IPM for the pest control with regard to its host plant relationships.

Acridids as a model system for investigating plant nutrient-secondary metabolite interactions and herbivore foraging behaviour

ST Behmer, D Raubenheimer, SJ Simpson
Department of Zoology, University of Oxford, South Parks Road, Oxford, OX1 3PS, UK spencer.behmer@zoology.oxford.ac.uk

Insect herbivores forage to acquire nutrients, but they rarely encounter plants that contain nutrients in optimal ratios. Additionally, many plants contain secondary metabolites (PSMs) that are toxic or reduce food utilisation. Thus the challenge insect herbivores regularly face is one of meeting their nutritional requirements while simultaneously limiting the intake of detrimental compounds. Locusts have proven to be a useful model organism for investigating nutrient regulation under a number of different scenarios, and they are now being used to disentangle the influence of PSMs and nutrients on insect herbivore foraging behaviour. In this talk I present results from a series of experiments that examine feeding responses by locusts to foods containing different nutrient compositions and various levels of carbon- (tannic acid) or nitrogen-based (gramine) PSMs. The results demonstrate that the mode of action for a particular PSM can vary depending on a foods nutritional profile, and that an herbivore's response to a PSM can be modified depending on the chemical composition of the foods that are available. I conclude the talk by discussing the broader implications of these findings, specifically how they relate to plant defence theory and models of foraging behaviour.

Insect herbivore learning: what can grasshoppers teach us?

ST Behmer, CE Belt, L Pompilio, MS Shapiro
Department of Zoology, University of Oxford, South Parks Road, Oxford, OX1 3PS, UK, spencer.behmer@zoology.oxford.ac.uk

Numerous examples exist of insect herbivores developing learned aversions towards particular foods. In contrast, little is known about the extent to which insect herbivores learn about their foods following positive experiences. Grasshoppers are ideal subjects for such questions because of their biology and amenability to laboratory conditions. In this talk I present a novel protocol, based on a Y-maze, which is specifically designed for studying learning and choice behaviour in grasshoppers (*Schistocerca gregaria*, the desert locust is used in this study). Results from the first three experiments using this system demonstrate that *S. gregaria* can readily learn to associate colours and odours paired with the larger of two food rewards, and that it reaches the larger reward option faster. In the last experiment, the same protocol was used to examine choice rules related to foraging decisions. Results here suggest that feeding decisions were not exclusively based on the intrinsic properties of the options. Rather, they show that locusts preferred options that had a history of yielding higher fitness gain. I conclude the talk by discussing the benefit insect herbivores gain through forming positive learned associations, and the enormous potential of using grasshoppers as a model system for investigating learning in general.

Temporal variation in nectar production in two sympatric species of *Schefflera* (Araliaceae) – A strategy to overcome competition for pollinators?

VV Belavadi, Chandrappa, MK Honnabyraiah, B Raju
"Zonal Agricultural Research Station & College of Horticulture, Mudigere 577 132 University of Agricultural Sciences, Bangalore, India
vvbel@rediffmail.com"

During our studies on the flowering phenology of shade plants in coffee plantations, we came across two sympatric species of *Schefflera* (Araliaceae), viz., *S. venulosa* and *S. wallichiana* in the Western Ghats of India. These two species flower synchronously in the month of May and attract a large number of insects including honey bees. Of the bee species visiting *Schefflera* flowers, the Indian hive bee, *Apis cerana* was predominant (53%) followed by the stingless bee *Trigona* irridipennis (15%). Inflorescences of *S. wallichiana* were significantly larger with more number of flowers ($x = 4160.5 \pm 2169$; $n = 40$) compared to that in *S. venulosa* ($x = 2075 \pm 216$; $n = 40$). *Schefflera wallichiana* flowers secreted significantly higher quantities of nectar compared to those of *S. venulosa.* The two species of *Schefflera* exhibited a clear temporal segregation in nectar production, there by attracting pollinators in different times of the day. In *S. venulosa* nectar production was in the morning hours (between 0830 and 1130 hrs), while that in *S. wallichiana* it was during the afternoon hours (between 1300 and 1600 hrs), which resulted in shifting of the pollinators from *venulosa* flowers in the morning to *wallichiana* flowers in the afternoons.

Do herbivore arthropods benefit from vectoring plant-viruses?

B Belliure, A Janssen, P C Maris, D Peters and M W Sabelis
IBED, Institute for Biodiversity and Ecosystem Dynamics, Section Population Biology, University of Amsterdam, Postbus 94084 1090 GB Amsterdam, The Netherlands

Although much study has been devoted to mechanisms by which plant pathogens become vector-borne, it is still unclear why herbivorous arthropods should vector the pathogen. To address this question, we use a system consisting of *Tomato spotted wilt virus*, its thrips vector (*Frankliniella occidentalis*) and pepper plants. We apply a combination of plant and vector treatments to discriminate between indirect (*i.e.* through the shared host plant) and direct effects of virus infection on the thrips vector. The main positive effect of the virus on the vector is indirect. The attack of plants by the vector results in a reduction of plant quality for the vector, but virus infection of plants alleviates these effects of vector-induced plant defenses. Hence, it is advantageous for the vector to infect plants with virus or to develop on infected plants. Mechanical inoculations allow for testing the effect of the virus without herbivory, indicating a positive effect of virus infection of the plant further than overcoming induced plant defenses to herbivory. The benefit of virus infection for potential vector's performance is regardless of their ability to transmit the virus. The consequences for the food web of the presence of the virus in the system are discussed.

How species influence ecosystem function: grasshoppers influencing rangelands

GE Belovsky, JB Slade
Box 369, Biological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA, Belovsky.1@nd.edu

Conservation of biodiversity is often justified with claims that particular species are critical for maintaining ecosystem processes, such as nutrient cycling and net primary production (NPP), i.e., ecosystem structure controls function. Experiments in western Montana (USA) rangelands indicate that grasshoppers can accelerate nutrient cycling and thereby increase NPP by as much as 20% in some areas, or decelerate nutrient cycling and thereby decrease NPP by as much as 10% in other areas. In some areas one grasshopper species can increase NPP, while another grasshopper species decreases NPP. However, in other nearby areas at the same elevation and with the same plant species, the same two grasshoppers can have reverse effects on NPP. These observations ultimately rely on grasshopper feeding behavior. When grasshoppers increase NPP, they preferentially feed on the plants producing slower decomposing litter. However, when grasshoppers decrease NPP, they preferentially feed on plants producing faster decomposing litter. Each grasshopper's feeding preferences can change as plant characteristics vary in relation to the grasshopper's physiology in each area. Finally, predation on herbivores is often thought to enhance NPP. Our results indicate that this is only true if herbivory diminishes NPP. However, predation will decrease NPP if herbivores increase NPP.

Multitrophic gene-family interactions: cytochrome P450 monoxygenases in the wild parsnip/parsnip webworm interaction

MR Berenbaum, AR Zangerl
Department of Entomology, University of Illinois at Urbana-Champaign, 320 Morrill Hall, 505 S. Goodwin, Urbana, IL 61801, USA, maybe@life.uiuc.edu

Genome sequencing has yielded an embarrassment of riches with respect to certain gene families; insect genomes, e.g., can contain in excess of 100 cytochrome P450 genes. Because these genes play a role in mediating interactions among organisms, understanding the evolution of P450s within a genome necessitates characterizing trophic interactions at the molecular level. The interaction between wild parsnip (*Pastinaca sativa*) and the parsnip webworm (*Depressaria pastinacella*) is mediated by furanocoumarins: both the detoxification of furanocoumarins by webworms and their biosynthesis by parsnips involve cytochrome P450-catalyzed reactions. Thus, observed phenotype matching between detoxification profiles in the insects and furanocoumarin production in the plants reflects underlying variation in, among others, P450 genes in both insect and plant. In an initial effort to characterize these gene-family interactions, four cDNAs were cloned from webworm midguts. One of these P450s, CYP6AB3, is inducible by furanocoumarins and baculovirus-mediated expression studies confirm its role in metabolizing these compounds. Structural superpositioning of molecular models of this P450 and two CYP6B furanocoumarin-metabolizing *Papilio* P450s reveals high spatial similarity of elements within the catalytic sites of these enzymes, suggesting convergence across the guild of insects specializing on furanocoumarin-containing plants. Characterization of promoter sequences in P450 genes reveals both unique elements that may promote specialization and more generalized elements that may allow insects to respond preemptively to plant defense. The existence of a significant third trophic level, in the form of a specialist encyrtid parasitoid, in some parts of the range of parsnips and webworms indicates that selection by and on yet another suite of P450 genes can influence coevolutionary responses in this interaction.

Investing in growth vs. defense by plants under attack in a multitrophic context.

A Biere
"NIOO-KNAW, PO Box 40, 6666 ZG Heteren, The Netherlands, a.biere@nioo.knaw.nl "

Plants are faced with a limited amount of resources to invest in different functions such as growth, reproduction and defense. This often results in trade-offs between investment in defense and other fitness-enhancing traits. Optimal investment in secondary metabolites involved in direct chemical defense therefore depends on the costs and benefits associated with different levels of these defense compounds. Costs of both constitutive and induced defense have been documented in numerous systems. But clearly, in order to understand optimal levels of direct chemical defense compounds in natural plant populations, the magnitude of costs and benefits should be considered in a multitrophic context, because direct chemical defense may show compatible or conflicting associations with indirect defense (attraction and efficacy of natural enemies of herbivores). First, direct chemical defense can have cascading effects, affecting availability and quality of insect herbivores to their parasitoids and predators. Second, positive or negative genetic associations between direct and indirect defense may arise from shared biochemical pathways of allelochemicals and volatiles involved in parasitoid attraction, requiring insight into the underlying mechanisms. I review some of the interactions between direct and indirect defense and its potential consequences for selection on defense in natural plant populations.

Effect of transgenic resistance to *Barley yellow dwarf* luteovirus in wheat on virus-vector relationships

NA Bosque-Pérez, ES Jiménez-Martínez
Department of Plant, Soil and Entomological Sciences, University of Idaho, PO Box 442339 Moscow, Idaho, USA 83844-2339, nbosque@uidaho.edu

The life history of the bird cherry-oat aphid, *Rhopalosiphum padi* (L.), was examined on plants of a transgenic genotype and an untransformed wheat variety infected with *Barley yellow dwarf luteovirus* (BYDV), or non infected. Transgenic plants expressed the coat protein gene from BYDV-PAV and showed moderate resistance to the virus. Based on nymphal development period, length of reproductive period, total fecundity, and intrinsic rate of increase, virus-infected transgenic plants were inferior hosts for *R. padi* compared to virus-infected untransformed plants. However, non-infected transgenic plants were superior hosts for *R. padi* than non-infected untransformed plants. The effects of different acquisition access periods (AAP) on the transmission efficiency of BYDV by *R. padi* following feeding on transgenic or untransformed wheat, were also examined. Transmission efficiency increased with an increase in AAP in both, transgenic and untransformed wheat. However, aphids were less efficient vectors following feeding on virus-infected plants of the transgenic genotype compared to the untransformed variety. Our results show that transgenic virus resistance in wheat can indirectly influence *R. padi* life history and virus transmission efficiency.

Flower visitor assemblages associated with rainforest trees

SL Boulter, RL Kitching, BG Howlett
Cooperative Research Centre for Tropical Rainforest Ecology and Management, Australian School of Environmental Studies, Griffith University, Nathan, Qld 4111

The assemblages of insects which visit particular flower species within an ecosystem may reflect a predictable, organised, perhaps co-evolved, set that is responding to the particular inflorescence based on the colour, morphology, phenology or chemistry of the plant concerned. Alternatively the assemblage may represent a set that is assembled more or less by chance from the overall canopy fauna. Testing the specificity of flower visitors may be carried out in one of two ways; first, by monitoring the changes in visitors to a species across a number of seasons; and, second, by comparing visitor assemblages to co-flowering species within a population. Using several independent methods we have studied the visitor assemblages associated with ten different canopy plant species within the lowland rainforest of North Queensland. Even an analysis at the ordinal level shows that there are substantial, statistically significant differences across plant species. It seems likely that visitor assemblages represent a predictable response to particular plant species in most cases. We did however find evidence that the visitors to a number of plant species' flowers reflected general canopy insect 'traffic'. Uncertainty remains about the levels of host specificity involved, and the underlying variability in assemblage structure both within and between years.

Responses of grasshoppers to livestock grazing: habitat manipulation by mammalian herbivores

DH Branson
"USDA-Agricultural Research Service, 1500 N. Central Ave., Sidney, MT 59270, USA, dbranson@sidney.ars.usda.gov"

Little experimental work has examined the ecological interactions between livestock and grasshopper herbivores, and the effects of differing patterns of herbivory by livestock on grasshopper population dynamics have not been fully examined in western US rangelands. Grasshopper habitat manipulation in the form of livestock herbivory has been shown to impact grasshopper population dynamics. Mammalian herbivory can modify factors important for grasshoppers such as plant species composition, host plant quantity or quality, plant cover and microhabitat conditions. A multi-year cage experiment was conducted to examine how the presence, timing and intensity of sheep herbivory affected grasshopper population dynamics and vegetation. There were few initial treatment differences in grasshopper densities between the timing and intensity of sheep grazing, although grazing affected the biomass and quality of vegetation available for grasshoppers. Grasshopper population densities and community composition were assessed in pasture scale livestock grazing experiments. The results from the pasture scale studies indicate that differences in livestock grazing can affect grasshopper population dynamics, but treatment differences may not be apparent when grasshopper population densities are very low. In addition, habitat differences resulting from livestock herbivory may not occur within a single season.

Insect views on plant structural complexity

J Casas, M Aluja, C Godin
"Institut de Recherches sur la Biologie de l'Insecte, IRBI UMR CNRS 6035, Université de Tours, 37200 Tours, France, casas@univ-tours.fr, http://www.univ-tours.fr/irbi/"

What are the relative impacts of plant architecture and resource distribution on the movement and searching efficiency of males searching for females, of herbivores searching for oviposition sites, and of predator searching for prey in plant canopies? How far is movement function of the architecture and stimuli stemming from the resource? How shall we deal with canopy-to-canopy architectural variations? All these questions require quantification of (i) the architecture of the environment, (ii) the distribution of resources within it and (iii) the intrinsic rules of movement. The appropriate analytical framework is based on random walks in random environments. Using a large data set of the apple fruitfly *Rhagoletis pomonella* foraging in apple trees, we built a foraging model that considers the effect of canopy structure and the presence of fruits for oviposition. We then estimated the sphere of attraction of a single fruit by comparing predicted and paths. Finally, we present the latest computational advances required in modelling realistic canopy architecture using growth units and multi-scale structures. These techniques offer the prospect of dealing efficiently with the difficult problems of comparing and simulating canopy architectures, both in topological and in three dimensional geometrical terms.

Foliar nutrients and induced susceptibility: genetic mechanisms of Douglas-fir resistance to western spruce budworm defoliation.

KM Clancy, Z Chen, TE Kolb
Rocky Mountain Research Station, 2500 South Pine Knoll Drive, Flagstaff, AZ 86001-6381 USA, kclancy@fs.fed.us

We conducted greenhouse defoliation experiments with clones of Douglas-fir over three years to assess the role of foliar nutrients as a resistance mechanism to western spruce budworm defoliation. The grafted clones were derived from mature trees (i.e., ortets) that showed resistance or susceptibility to budworm defoliation in the forest. Current-year foliage was analyzed for concentrations of nitrogen, sugars, and eight minerals. We computed rank correlations between foliar nutrient levels in the ortets and their corresponding clones to test the null hypothesis that foliar chemistry does not have a genetic basis. Foliar concentrations of sugars and phosphorus were under genetic control to some degree, but concentrations of other nutrients were not. We used analysis of variance to test the null hypotheses that foliar chemistry does not change in response to budworm defoliation. We rejected the hypothesis for sugars, P, potassium, manganese, and zinc; defoliation by the budworm changed levels of these nutrients, and had divergent effects on concentrations of P, K and Zn in resistant compared to susceptible clones. We concluded that induced susceptibility, whereby defoliation alters foliar nutrients to make trees more favorable for insect feeding, appears to be an important determinant of Douglas-fir resistance to the western spruce budworm.

Influence of diet chemistry, anatomy, and biomechanical properties on Australian plague locust performance

FJ Clissold, GD Sanson, J Read
School of Biological Sciences, Monash University, Victoria, 3800. fiona.clissold@sci.monash.edu.au

The majority of locust nutritional physiology studies have been undertaken using artificial diets. Comparison of dietary utilisation and growth and development of the Australian plague locust on two contrasting grasses showed that existing models could not be used to predict locust performance. Following rain, Australian plague locusts develop in Mitchell grasslands which are dominated by perennial Mitchell grass and annual Button grass. Both grasses were similar in terms of the major chemical constituents. However, they differed anatomically, with Button grass having *c.* twice the specific leaf area and water per unit dry matter. Plant anatomy not only affected diet digestibility and post-digestive processing costs, but also influenced the rate of nutrient assimilation. When the barrier effect of the indigestible cell wall was removed by grinding, diet digestibility doubled, resulting in increased dry matter assimilation. This, together with reduced metabolic costs of converting these nutrients to biomass, increased growth. Early instars were able to digest and grow on either diet equally, but the later instars consuming Mitchell grass experienced reduced growth and increased instar durations. This appeared to be due to reduced consumption resulting from slower nutrient assimilation rather than lowered diet digestibility or increased metabolic costs associated with food processing.

Visual/Mechanosensory interactions and the evolution of insect behavior

CM Comer
"Biological Neurosciences (MC 067), University of Illinois, 840 W. Taylor, Chicago, IL USA, ccomer@uic.edu"

A major goal of neurobiology is to understand the design principles of cells and circuits that control behavior. Orthopteroid Insects provide ideal models for understanding the principles underlying the design of uniquely identifiable brain cells related to orienting behavior. Specific brain cells ("DMIs") of cockroaches trigger evasive turns in response to touch [abrupt antennal contact] from predators. The antennae of cockroaches are under visual guidance, apparently in part by other specific brain cells ("DCMDs") that were originally described in locusts. Our preliminary evidence suggests that cockroaches, crickets, locusts and mantids all possess a DMI / DCMD ensemble, and that these two interneuron systems operate in a coordinated way to control directional motor behaviors specific to each species. Comparative analyses on the four orthopterod species mentioned suggest the hypothesis that across these species, the sensory encoding properties of these interneurons have been conserved, but that their role in behavior has been adaptively altered by localized cellular changes in motor outflow organization at cerebral and/or thoracic levels of the CNS.

Developing novel resistance to *Helicoverpa* spp. in chickpeas

SC Cotter, HC Sharma, J Ridsdill-Smith, OR Edwards
"CSIRO Entomology, Private Bag 5, PO Wembley, WA 6913, Australia Sheena.Cotter@csiro.au"

Helicoverpa species are highly polyphagous, and are highly damaging pests of most agriculturally important crop plants. The development of cultivars with resistance to these pests is an economically and ecologically promising solution, but the low levels of genetic resistance in many crop species has led to the examination of wild relatives as possible sources of resistance to this insect. Screening of several wild *Cicer* accessions has led to the identification of putative resistant germplasm that could be crossed into cultivated chickpea varieties. In addition, an understanding of the genetic basis of host plant selection by these polyphagous pests may lead to novel approaches to control them in the future. We investigated the quantitative genetics of adult preference and larval performance on different chickpea genotypes, at different life stages, as well as the genetic correlations between traits. We found high levels of additive genetic variation in the population for its ability to feed on both susceptible and moderately resistant chickpea genotypes. Furthermore, we found significantly higher levels of variation in neonates than in the older larvae. The implications of these findings are discussed in relation to the potential of *Helicoverpa* to overcome host plant resistance in agriculturally important crops.

Life-history differences in the genus *Lipara* (Diptera) on their common hostplant, the grass *Phragmites australis*

L De Bruyn, J Scheirs
Department of Biology, University of Antwerp, Groenenborgerlaan 171, 2020 Antwerp, Belgium and Institute of Nature Conservation, 1070 Brussels, Belgium, luc.de.bruyn@instnat.be

The flies of the genus *Lipara* (Diptera; Chloropidae) are strict monophagous gall formers on the common reed, *Phragmites australis* (Poaceae). Some species induce clearly defined gall chambers while other do not. The *Lipara* species are not homogenously distributed in their common habitat. Each species' larval survival and populations are uniquely correlated with reed shoot diameter (a measure of plant vigor). The ovipositing females are able to discriminate between shoots of different quality. The different species also support different parasitoid guilds. At least one species acts as a kleptoparasite in the galls of other *Lipara* species. Kleptoparasitism in this system is mediated by the host plant and by the principal parasitoid. During the evolution of the genus *Lipara* a trade-off between obtaining the necessary food supply and growth dependent host plant resistance has been a major force in structuring the life cycle strategies.

Spatial heterogeneity in monoterpene concentrations of native pine as a driver of insect herbivore distribution and abundance

P Dennis, J Stockan, V Thoss, G Iason, J Lennon, J Beaton
Macaulay Institute, Craigiebuckler, Aberdeen, AB15 8QH, Scotland, UK, p.dennis@macaulay.ac.uk

We investigated whether the genetic diversity of structural species in native ecosystems can control the diversity of other taxa. This study focused on insect herbivores associated with Scot's pine (*Pinus sylvestris*) and tested hypotheses that variations in the monoterpene chemistry of individual pine trees will affect herbivore diversity and performance, and the quality of litter fall available to soil organisms.
Three methods were used;
Funnel collectors to sample litter fall from the crowns of 45 pine trees, selected to represent monoterpene variability across the forest.
A bioassay measured growth rates and survival of pine looper moth caterpillars, using net enclosures in the crowns of 30 pine trees.
Measurements of the numbers of ants climbing pine trees and the plant and arthropod material they transported to the ground.
Numbers of phytophages were related to the concentration of certain monoterpenes and tree structure and location. The growth of pine looper caterpillars was related more to chemistry than physical parameters. Ants transported significant material from pine crown to ground and removed phytophages other than aphids from the crowns. We discuss the contribution of genetic diversity for phytophage diversity and the broader ecological consequences.

Induced plant defences – using *Arabidopsis* as model for linking ecology with molecular biology.

M Dicke, RMP van Poecke, JG de Boer
Laboratory of Entomology, Wageningen University, PO Box 8031, NL-6700 EH Wageningen, The Netherlands, Marcel.Dicke@wur.nl

In their defence against pathogens, herbivorous insects and mites, plants employ many induced responses. One of these responses is the induced emission of volatiles upon herbivory. These volatiles can guide predators or parasitoids to their herbivorous prey, and thus benefit both plant and carnivore. This use of carnivores by plants is termed indirect defence and has been reported for many plant species, including elm, pine, maize, lima bean, cotton, cucumber, tobacco, tomato, cabbage and *Arabidopsis thaliana*. Herbivory activates an intricate signalling web and finally results in defence responses such as increased production of volatiles. Several components of this signalling web are known, such as the plant hormones jasmonic acid, salicylic acid and ethylene. Information on the molecular genetics as well as the phenotypic changes that are induced by herbivory can be exploited to design experiments that aim at assessing the effects of plant traits on the interactions with members of the food web in a multitrophic context.

Latex: mode of action, efficacy, and insect response

DE Dussourd
Department of Biology, University of Central Arkansas, Conway, Arkansas, USA 72035 dussourd@uca.edu

Over 5% of all plant species possess latex canals. The plants sequester adhesives and poisons within these pressurized delivery systems that release liquid latex immediately upon injury. Herbivores biting a leaf have their mouthparts coated instantly with noxious exudates that often become increasingly sticky before eventually hardening. Limitations of latex defenses include a vulnerability to herbivores capable of rupturing canals before feeding distal to the cuts in an area of reduced exudation. Insects sever canals with vein-cutting, trenching, and girdling behaviors that have evolved repeatedly in diverse insect groups. I will discuss how latex defenses affect insect foraging behaviors, herbivore distribution on individual plants, and host range. These studies document that latex exudation can harm both mandibulate and haustellate herbivores, as well as the natural enemies that prey upon them.

Bioprospecting with a caterpillar probe: identification of trenching stimulants

DE Dussourd
Department of Biology, University of Central Arkansas, Conway, Arkansas, USA 72035 dussourd@mail.uca.edu

Over 100 insect species sever veins or cut trenches in leaves before feeding beyond the cuts. The insects thereby depressurize defensive canal systems and prevent exudation of latex, resin, or other fluids during feeding. Whether the cuts function to reduce insect exposure to noxious chemicals in exudates, to adhesives, or both has been debated. Using a trenching bioassay with cabbage loopers, *Trichoplusia ni*, I have identified three compounds that elicit trenching: lactucin from lettuce latex, myristicin from parsley, and lobeline from cardinal flower. All three compounds affect the nervous system of mammals. Other neuroactive chemicals, including some neurotransmitters, insecticides and drugs also trigger trenching. The known toxicity of many of these compounds supports the hypothesis that cabbage loopers trench specifically to reduce their ingestion of noxious exudate constituents. Trenching assays thus have potential for directing the isolation of novel plant compounds with insecticidal properties and potential applications in pest management or pharmacy.

Aphid dispersal patterns from point sources: implications for the introduction and spread of viruses in crops

OR Edwards, KR Hopper, B Coutts, R Jones
"CSIRO Entomology, Private Bag 5, Wembly, WA 6913 Australia, Owain.Edwards@csiro.au"

The epidemiology of plant virus outbreaks is driven by the behaviour of the vector and the magnitude and disposition of the virus source. Controlling the damage caused by insect-transmitted viruses in annual cropping systems is greatly assisted by an understanding of the movement patterns of the vectors. In this paper, we describe field experiments designed to monitor the short-distance dispersal patterns from point sources of two species of cereal aphids. These experiments showed that most aphids disperse only a short distance (<5-10m) from their source. The relative probability of dispersal to host plants outside this range does not decrease greatly for distances up to 200m, if one factors out the dilution effects caused by increases in dispersal area. Our first year of experiments using anti-feeding pesticide barriers on the edge of fields indicated that a 25m-width barrier was insufficient to affect aphid immigration rates. Independent experiments examined the effectiveness of non-host barriers at diminishing virus introductions into crops by thrips and aphid vectors. Future experiments will combine these approaches, monitoring virus-infected aphid dispersal and population increase while also monitoring virus spread into the affected crop.

Response of aphid vectors of plant viruses to volatiles from virus-infected plants

SD Eigenbrode, JM Alvarez, NA Bosque-Pérez, TM Mowry, ES Jiménez-Martínez, BJ Werner, R Srinivasan
Division of Entomology, University of Idaho, Moscow ID, 83844-2339, USA, sanforde@uidaho.edu

During host selection, insect herbivores potentially respond to intraspecific variation in host plant quality, including that resulting from infection by disease–causing organisms. For example, virus-infected plants sometimes are superior and preferred hosts for the aphids that vector the infecting viruses. We have shown that virus-induced changes in headspace volatiles (VIVs) of infected plants influence host selection behavior by two aphid species in three pathosystems. The green peach aphid, *Myzus persicae*, is more strongly arrested by VIVs from *Potato leafroll virus*-infected cultivated potato, *Solanum tuberosum*, or wild *S. sarrachoides,* than by the headspace volatiles from virus-free plants of these species. The bird-cherry oat aphid, *Rhopalosiphon padi*, responds similarly to VIVs from wheat plants infected with *Barley yellow dwarf virus.* Response to VIVs not only is beneficial to the aphids, which are aided in locating superior hosts, but also potentially increases the rate of spread of the viruses. In such an apparently mutualistic relationship, the signals and responses to them potentially are shaped by natural selection to optimize accrued benefits. With this general hypothesis in mind, we examine the variation in VIV production and aphid responses to this variation throughout the disease cycle in the Potato-PLRV-*M. persicae* pathosystem.

Plant morphology at different spatial scales and insect-plant interactions

SD Eigenbrode
Division of Entomology, University of Idaho, Moscow ID, 83844-2339, USA, sanforde@uidaho.edu

The physical form of plants influences insect-plant interactions at several spatial scales. At relatively small scales, plant morphological features such as trichomes and surface waxes influence the ability of phytophagous and carnivorous insects to cling to and move over plant surfaces. The requirement to cling successfully to plants has been met through modifications of the attachment devices and behavior. These include variation in the anatomy of pretarsal claws and legs, the form and extent of adhesive pads and setae, the ability and propensity to construct silken platforms for resting, and behavioral accommodations for walking on plant surfaces. Adaptations evidently have also occurred in the ability of insects to obtain adhesive or frictional attachment to leaf surfaces, although these are as yet little understood. At larger scales, the plant soma presents a complex three-dimensional environment that insects must negotiate to find resources. Foraging in the plant canopy requires effective movement rules for finding resources efficiently. Potential effects of plant architecture on insect-plant interactions include multitrophic and coevolutionary interactions. In the talks that follow in this symposium, we will hear from scientists examining the effect of plant physical features at different spatial scales on insect-plant interactions. As we hear these talks, let us also consider how plant morphology at different spatial scales might interact to influence insects and shape the adaptive syndrome of insects foraging on plants. The influence of plant structure on insect ecology perhaps can be better understood through such a multi-scaled perspective.

Insect feeding behaviour and the transmission of plant viruses

A Fereres
"CSIC, Centro de Ciencias Medioambientales, Serrano 115 dpdo, 28006 Madrid, Spain, afereres@ccma.csic.es"

In the last years significant progress has been made on the specific feeding behaviour events associated to the acquisition and inoculation of plant viruses by their insect vectors. Most efforts have concentrated on aphid-transmitted viruses and particular behavioural processes leading to the transmission of non-circulative and circulative viruses have been identified. This paper will review on how viruses and other plant pathogens have adapted to exploit particular feeding habits of their insect vectors to spread from plant to plant. In particular, some phloem-restricted viruses (e.g. Luteoviridae and Begomovirus) use phloem feeders such as aphids or whiteflies for dispersal after circulation through the insect's hemocoel and excretion through the saliva. Others (e.g. Closteroviridae) are also acquired from the phloem but remain attached to the mouthparts of the vector until subsequent feeding on the phloem tissue of a healthy plant. Xylem-restricted bacteria are vectored by some Cicadellidae that penetrate the plant tissue intracellularly to feed in the xylem vessels. Other viruses (e.g. Caulimoviruses) are transmitted after several intracellular stylet punctures before starting phloem salivation or feeding. On the other side, there are viruses (e.g. Potyvirus) that have a very ephemeral interaction with their vector and are transmitted to the epidermis after single intracellular stylet punctures and are lost well before the vector reaches the vascular tissues.

Transmission of *Cauliflower mosaic virus*: **behavioural events associated to the inoculation process**

A Moreno, I Palacios, S Blanc and A Fereres
Centro de Ciencias Medioambientales, CSIC, Serrano 115 dpdo, 28006 Madrid, Spain, afereres@ccma.csic.es

"The transmission efficiency of *Cauliflower mosaic virus* is highest when the virus is acquired from the phloem, but information on the relationship between the different behavioural events associated to the inoculation phase is lacking. For a better understanding of the transmission mechanism of CaMV, we used the electrical penetration graph (EPG) technique to assess aphid feeding behaviour during the inoculation of CaMV by *Brevicoryne brassicae* L. and *Myzus persicae* Sulzer. to *Brassica rapa* (cv. Just Right) plants. After 8 hours of acquisition on CaMV infected plants, aphids were placed on test plants and removed immediately after specific behavioural events were recorded, and then transferred to a second test plant. Aphids transmitted CaMV with higher efficiency when five or more intracellular punctures were recorded or when they probed for five minutes on the test plants than when a single intracellular puncture was produced. No increase in the transmission rate of CaMV was observed when aphids reached the phloem phase. Interspecific differences were found in the retention and persistence of CaMV in its vectors. *B. brassicae* could retain the virus after several intracellular punctures were recorded whereas *M.persicae* lost the virus after performing the same number of punctures.

Intra- and inter-population correlations between growth rate, survival, and nutritional indices of *Melanoplus sanguinipes* (Orthoptera: Acrididae) on low quality diets.

DJ Fielding
USDA/ARS, P.O. Box 757200, Fairbanks, AK 99775, USA, ffdjf1@uaf.edu

Growth, survival, food consumption and assimilation were examined in grasshoppers from two different populations. One from Idaho (ID) and the other from Alaska (AK) where summers are cool and moist. When reared on a lettuce/bran diet, the ID grasshoppers develop more slowly and with greater variance in growth rates than the AK grasshoppers. For the experiment, grasshoppers were reared through the 4th and 5th instars on one of two artificial diets containing 0.7 or 2.6%N. The ID grasshoppers were split into two groups, those that attained 4th-instar in 15 to 17 days (ID-Fast) and those that required more than 19 days to reach 4th-instar (ID-Slow). The AK grasshoppers reached 4th-instar in 13 to 15 days. No individuals of the AK or ID-Fast groups survived to adult stage on the 0.7%N diet, whereas 58% of ID-Slow survived. On the 2.6%N diet, 47% of the AK survived to adult stage, and all individuals of both ID groups survived. Relative consumption rates of ID-Slow were greater than the AK grasshoppers. Assimilation rates in the ID-Slow were greater than for ID-Fast and AK grasshoppers. It appears that individuals that grow more slowly under optimal conditions, are better able to tolerate a poor quality diet through greater consumption and assimilation of food.

Silk production in the Hemiptera

MJ Fletcher, DS Kent, GM Gurr, JC Chang, B Gilbert and H Löcker
"Orange Agricultural Institute, Forest Rd, Orange, 2800 NSW, Australia, murray.fletcher@agric.nsw.gov.au"

Research on leafhoppers, *Kahaono montana* Evans (Cicadellidae: Typhlocybinae: Dikraneurini), living under silken shelters on the vertical leaves of species of *Eucalyptus* (Myrtaceae) has shown that these shelters are produced by the leafhoppers themselves. The silk has some chemical similarities to spider silk but very different physical properties. Feeding damage by the leafhoppers is limited to the area covered by the shelters. Liquid excrement expelled by the leafhoppers accumulates on the fibres and blackens through the growth of sooty moulds. Evidence will be presented suggesting that these shelters function to trap and retain heat to protect leafhoppers living in cooler regions of Australia. There are indications that at least one other species of Dikraneurini also produces silk.

Creating habitat for native bee pollinators in highly modified landscapes

GW Frankie, SB Vinson, J Hernandez
"University of California, Berkeley, 201 Wellman Hall #3112, Berkeley, California 94720-3112, frankie@nature.berkeley.edu"

The publication of "Forgotten Pollinators" in 1996 by Buchmann and Nabhan has raised much awareness about the decline of pollinators worldwide. Numerous papers that provide evidence for decline have been increasing yearly as biologists and others begin to carefully examine the evidence and appropriate responses to the phenomenon. Various countries and organizations have responded by developing initiatives to address the wide range of issues surrounding the loss of pollinators. These range from focusing on new biological research to environmental education to political outreach. One of the issues frequently mentioned concerns restoring pollinators to areas that once supported them under natural or near natural conditions. In this paper, case history information on restoring native bee pollinators to disturbed tropical dry forest in Costa Rica is presented. The work is proving to be a challenge because of the necessity to develop considerable ecological information on bees and their new relationships to plants in disturbed environments. Finding appropriate monitoring methods for assessing trends in bee populations through time has also proved to be challenging. Finally, social and political issues, especially regarding bee habitat and land tenure, require attention that place biologists in new and unfamiliar outreach roles.

Domination of ground cover by a single invasive plant species does not provide a habitat inferior to a native cover mosaic in terms of invertebrate assemblages.

TN Fuessel, CH Wild
Tania Fuessel, School of Environmental and Applied Science, Griffith University Gold Coast Campus, PMB 50 Gold Coast Mail Centre, Queensland 9726, t.fuessel@griffith.edu.au

Habitat disturbance to remnant melaleuca bushland at Coombabah Wetland Reserve has promoted the dominance of invasive plant species at ground level. Ground cover at the reserve comprises large stands very strongly dominated by either blady grass (*Imperata cyclindrica* var. *major*: Poaceae) or bracken fern (*Pteridium esculentum*: Dennstaedtiaceae) interspersed with smaller patches consisting of a mosaic of native plant species. Epigeal invertebrate communities were monitored within each of these three ground cover types using continuous pitfall trapping over 22 weeks to investigate quality of the habitat in terms of providing niches to support invertebrate species. Diversity assessment suggested that the habitats dominated by invasive plants were not inferior to native cover mosaic in terms of species abundance, richness and evenness. High levels of similarity (75% species shared) in terms of actual invertebrate species present, and the rank abundance of these species occurred within the three ground cover types. Ordination suggests that invertebrate community structure within native cover mosaic was the intermediate between the bracken and blady grass communities. Several species are blady grass specialists and a few are bracken specialists, whereas no species specialise in the native cover mosaic habitat. On the basis of this study, there is no evidence to support the theory that a greater level of plant ground cover diversity supports a superior invertebrate community in terms of either overall diversity or composition.

Resistance to multiple aphid species has been identified in a single *Medicago truncatula* cultivar: resistance involves both salicylic and jasmonic acid signaling pathways

LL Gao, R Horbury, J Klingler, RM Nair, OR Edwards, KB Singh
CSIRO Plant Industry and CSIRO Entomology, Private Bag 5, Wembley, WA 6913, Australia; lingling.gao@csiro.au

Aphids are serious pests of legumes and other crops worldwide. In contrast to plant-pathogen interactions, very little is known about molecular mechanisms underlying plant resistance to aphids. Australian breeders have introgressed *Acyrthosiphon kondoi* (bluegreen aphid) resistance into three popular cultivars and generated three pairs of resistant and susceptible near-isogenic lines in the model legume *M. truncatula*. Further characterization showed that each resistance line operates against a number of major legume aphid species. However, the magnitude of resistance varied depending on the *M. truncatula* line and/or aphid species. We have focused on one pair of near isogenic lines, A17 (susceptible) and Jester (resistant) in which a single dominant gene conditions resistance to bluegreen aphid. Jester also exhibits, to different degree, resistance to pea aphid, spotted alfalfa aphid and spotted clover aphid. Analysis of the transcriptional changes in defence related genes representing various signaling pathways suggest that both salicylic acid and jasmonic acid pathways are involved in the resistance of Jester to bluegreen aphid. We are currently taking high throughput approaches to analyse gene expression patterns during various compatible and incompatible aphid interactions in order to further understand this important plant-insect interaction.

Effect of chemistry of plant waxes on insect attachment

E Gorb, S Gorb, V Kastner, S Eigenbrode
Evolutionary Biomaterials Group, Mpi For Metals Research, Heisenbergstr. 3, D-70569 Stuttgart, Germany, o.gorb@mf.mpg.de

Insect ability to attach to epicuticular waxes of plants must depend on the structural, mechanical, and chemical properties of the plant surfaces. In order to test the effect of the chemistry of the surface on insect attachment, we measured the surface energy (SE) of several selected compounds of plant waxes (C18-C22 hydrocarbons, primary alcohols, and n-alkanoic acids) and the traction force generated by ladybird beetles *Harmonia axyridis* (Coccinellidae) on these surfaces. Our results demonstrated that the water contact angle differs greatly between different surfaces; however, the total surface energy of selected substances slightly depends on the chain length and not on the presence of active groups. No significant difference in traction force was detected on different wax surfaces. This result can be explained by the ability of attachment pads to generate a lipid-containing secretion. Since total SE does not differ very much between surfaces, only it's polar and dispersion components vary, the nonpolar secretory fluid aids in generating strong attractive forces on surfaces with different contact angles of water.

How suitable is this climate for an invasive insect? Using a phenology model for landscape-wide assessments of risk of establishment.

DR Gray
"Natural Resources Canada, Canadian Forest Service, PO Box 4000, Fredericton, NB E3B5P7 Canada, david.gray@nrcan.gc.ca"

One of the basic requirements of an invading insect is that the climatic conditions in the invaded location satisfy its seasonal requirements. For a holometabolous, phytophagous insect invading a temperate location this implies that eggs will hatch coincidentally with the emergence of suitable host material, that the cold-hardy stage will coincide with winter, and that these events will coincide sufficiently each year for the continual survival of the population. A multi-generational phenology model can directly assess this criterion of the risk of establishment (ROE) by quantifying the likelihood that temperature regimes in the invaded location will consistently produce seasonal development. Landscape-wide estimates of the ROE require a geographically robust phenology model – one that produces equally reliable simulations of phenological development regardless of the location. A geographically robust model of European gypsy moth phenology has been used for a North American-wide assessment of the ROE. Modifications to the model to assess ROE of the Asian gypsy moth in New Zealand, and preliminary results will be described.

Modeling insect behaviour in a constrained universe: caterpillar foraging on 3D virtual plants.

J Hanan, M Zalucki
"Advanced Computational Modelling Centre, University of Queensland, Brisbane, Queensland, Australia 4072, jim@cpai.uq.edu.au"

Models of insect-plant systems have traditionally been expressed using general-purpose programming languages, and more recently with plant modelling languages such as L-systems. Creation of special-purpose languages for expressing behavioural models that operate within a virtual plant environment will make the behavioural modelling job a lot easier. The basic requirements of such a system, such as expression of insect sensory capabilities, actions and "decision-making" processes, will be discussed, and a prototype language described. Individual-based models of caterpillars moving in a field of plants will be compared with models defined on a stochastic basis previously in the literature.

Decisions, decisions – host-plant assessment by adult generalist and specialist aphids with the same genotype

J Hardie, G Powell, CR Tosh
Imperial College London, Aphid Biology Group, Department of Biological Sciences, Silwood Park Campus, Ascot, Berks UK, j.hardie@imperial.ac.uk

Winged summer virginoparae (long-day, crowd induced) and the winged autumn gynoparae (short-day induced) are asexual forms of the black bean aphid, *Aphis fabae*. When reared from the same clone, they have identical genotypes, similar morphology but distinct behavioural and reproductive phenotypes. With regard to plant preference they differ in that the *generalist* summer form will accept and reproduce on many different host plants while the *specialist* autumn form preferentially accepts and reproduces on the spindle tree, *Euonymus europaeus*. A number of host-acceptance parameters were examined to distinguish between the decision-making mechanisms of these insects. Time from plant contact and from stylet penetration to the start of reproduction, time from plant contact and from stylet penetration duration prior to first phloem recognition, time from phloem recognition and number of phloem entries to phloem acceptance (>15 min access) as well as the incidences of phloem acceptance were assessed. One host common to both aphid forms, spindle, and four herbaceous hosts of the summer form, three of which they had not encountered previously, were used. It was hypothesised that the *specialist* autumn form would make more rapid, efficient decisions on plant suitability than would the *generalist* summer form. The results indicate that the decision criteria differ as much between the summer form on different hosts as between the summer and autumn forms on the single, common host.

Oviposition behavior of the Hessian fly and consequences for offspring growth and survival

MO Harris
"Department of Entomology, 202 Hultz Hall, North Dakota State University, Fargo, North Dakota 58105 USA; Marion.Harris@ndsu.nodak.edu"

The Hessian fly-grass interaction is characterized by plant defense via *R* genes and insect adaptation via *avr* genes. Although Hessian fly adaptation to plant *R* genes occurs only during the larval stage, the ovipositing female initiates the plant-insect interaction. Hessian fly larvae can move within the plant but cannot move to another plant. The mated female has a relatively short time (ca. 4-6 hours) to find homes for the 200-300 eggs she carries and is constantly in motion during the oviposition phase, flying from plant to plant, examining leaf surfaces, and ovipositing eggs. During these behaviors, the female is exposed to a variety of visual, chemical and tactile stimuli. Based on these stimuli, as well as endogenous stimuli, the female makes decisions about her flight direction, and locations where landing, examining behaviors, and oviposition will occur. Many of the decisions made by the ovipositing female benefit the growth and survival of offspring, but some do not. I will discuss the constraints placed on the female by time, as well as her sensory systems and mobility. Oviposition behavior also will be discussed within the context of the co-adapted system of *R* gene plant defense and *avr* gene Hessian fly adaptation.

Host mediated impacts on the population structure of oak gall wasp communities

A Hayward, GN Stone
ICAPB, University of Edinburgh, Edinburgh, EH9 3JT, Scotland, UK, a.hayward@ed.ac.uk

Oak gall wasps (Hymenoptera: Cynipidae, Cynipini) are very selective about the oak section and species upon which they induce their galls for reasons that remain unclear. Here I present data on Iberian and central European oak gall wasp populations apparently structured by host oak species. The extent to which similar population structures exist in an obligate chalcid parasitoid is then examined to determine if this specificity is expressed in further trophic levels. The Palaearctic oak gall wasps *Andricus kollari* and *A. quercustozae* show a population divide just north of the Pyrenees mountains in southern France, marked by a switch in distribution of their sexual generation host from the eastern European Turkey oak *(Quercus cerris*) to the Iberian cork oak (*Q. suber*). This pattern is compatible with the existence of long-lived oak-specific ecotypes within each species, supporting the conclusion from existing interspecific analyses that oak shifts are extremely rare in gall wasps. In contrast, population structure of the parasitoid *Megastigmus stigmatizans* does not show a clear break in the same location suggesting that unlike their gall wasp hosts, these enemies are not oak specific. This finding has major implications for contrasts in the population structure of different trophic levels within oak gall communities.

Smart-autoinoculation system attributes to consider in using insects as vectors of mycoherbicides against weeds.

AKW Hee, DM Suckling, A Stewart, G Bourdôt, E Jones, EG Brockerhoff, N Waipara, RL Hill, E Yamoah, SL Wee
National Centre For Advanced Bio-Protection Technologies, C/O Hortresearch, Canterbury Research Centre, Gerald Street, PO Box 51, Lincoln, New Zealand, ahee@hortresearch.co.nz

Biological control of weeds has been traditionally centred on the use of insects and microbial pathogens as biocontrol agents. Each of these approaches has brought considerable success in weed control, but an understanding of the tripartite interaction between insect-weed host-pathogen might lead to synergism and further improve current control measures. Here, we propose the development of a smart-autoinoculation system based on a tripartite model, using insects as deliberate and enhanced vectors of plant pathogens as a novel weed control strategy. This approach proposes using pheromone-based systems to attract insects to the pathogen inoculum and thereafter infecting the weed ("lure-and-infect"). However, the potential for deliberately using insects to deliver plant pathogens to weed hosts could only be realized if a wide range of hypothetical tripartite system conditions is met. Each of the three components is ecologically and biologically complex, and understanding of these factors is crucial. This research will gather information to examine the feasibility of available system options i.e. full benefits and risks of these components. Hence, a strategic approach will be to examine the specificity of interactions between the insect, pathogen and weed. The objective of this paper is to identify a suitable model system(s) with minimal complexity and having components that are clearly defined.

Studying tritrophic interactions by manipulating the release of terpenoid volatiles with molecular techniques

C Schnee, T Koellner, M Held, T Turlings, J Gershenzon, J Degenhardt
Laboratoire d'Ecologie Animale et d'Entomologie, Rue Emile-Argand 11, Université de Neuchâtel, CH-2007 Neuchâtel, Switzerland;
matthias.held@unine.ch

Parasitoids of herbivorous insects make use of odours emitted by herbivore-infested plants in order to locate their hosts. The odours are made up of blends of volatile organic compounds (VOCs) that show many similarities among plant families and can be roughly divided in "green leaf volatiles" (C6 aldehydes, alcohols and derivatives), terpenoids and aromatic substances. Maize (*Zea mays*) reacts strongly to *Spodoptera littoralis* caterpillar feeding. The resulting odour is highly attractive to females of the parasitic wasp *Cotesia marginiventris* but it remains unclear which are the key compounds mediating the attraction. The application of molecular techniques to this system has allowed modification of the pattern of released terpenoids by manipulating genes involved in terpenoid synthesis. In olfactometer assays we tested the attractiveness of maize knockout-mutants with reduced ability to produce specific terpenoid compounds and transgenic *Arabidopsis thaliana* plants expressing maize terpene synthases. The combination of molecular tools, analytical chemistry and behavioural studies provided new insights in the relative importance of terpenoid VOCs for the attraction of parasitoids.

Characterising mechanisms of resistance to defoliation in *Eucalyptus grandis*

ML Henery, C Stone, WJ Foley
"School of Botany and Zoology, Australian National University, Canberra, ACT 0200, Australia, martin.henery@anu.edu.au"

Leaf chewing beetles, mainly Chrysomelids (*Chrysophtharta cloelia* and *Paropis atomaria*) and Christmas beetles (*Anoplognathus* spp.), are major eucalypt defoliators and commonly cause significant defoliation of plantations of commercially important eucalypt species. The presence of eucalypt genotypes resistant to particular insect herbivores has been recognized for some time and chemical factors have been the focus of most studies (e.g. Christmas beetles). In this study State Forest genetic field trials of *Eucalyptus grandis* were assessed for canopy damage, predominantly derived from *Paropsis atomaria* activity, to identify open pollinated families (OPFs) resistant and susceptible to defoliation. Three selected resistant and susceptible OPFs and additional clonal resistant material were then tested via multiple bioassays to assess key parameters such as relative growth rate, consumption rate, mortality rate, efficiency of consumption, oviposition preference and adult feeding preference of leaf material. The results of these bioassays will determine whether consistent quantifiable differences exist in physical or chemical attributes between resistant and susceptible OPFs and whether these factors affect both larval performance and adult host selection conjointly. We also demonstrate if cross-resistance exists for *Anoplognathus spp.* and Chrysomelids in resistant *E. grandis* individuals.

Functional genomics identifies candidate virulence proteins of phytoplasmas, pathogens of insects and plants.

X Bai, V Correa, J Zhang, M Goodin, S Kamoun, SA Hogenhout
Department of Entomology, Ohio State University, 1680 Madison Avenue, Wooster, OH 44691, USA, hogenhout.1@osu.edu

Phytoplasmas belong to the Class Mollicutes and are non-culturable intra- and extracellular bacterial pathogens of insects and plants. Various computer algorithms were employed to mine the near complete genome sequence of phytoplasma strain AY-WB for genes encoding potential virulence factors. So far, 56 candidate virulence proteins were selected for functional analysis. To determine whether these proteins affect plants, corresponding genes were cloned into the binary potato virus X expression vector, pGR106, and expressed in tomato and *Nicotiana benthamiana* via *Agrobacterium*-mediated inoculation. This revealed 16 phytoplasma proteins that induced morphological aberrations in plants. Interestingly, five of the 16 proteins contain nuclear localization signals. Localization studies using yellow fluorescence protein fusions showed that two of the five proteins target plant cell nuclei. Transcripts of genes of these two proteins were detected in plants during AY-WB infection. To allow immunolocalization of these AY-WB proteins in the leafhopper vector and plant hosts, genes were expressed in *Escherichia coli* for subsequent antibody synthesis.

Relaxation of induced indirect defenses of acacias following exclusion of mammalian herbivores

M Huntzinger, R Karban, TP Young, TM Palmer
"Department of ENH, University of California, Davis, CA 95616, USA, pmhuntzinger@ucdavis.edu "

Many plants offer rewards to attract ants that provide indirect defense against herbivores. These rewards include nectar and swollen thorn domatia, and their production can be inducible. *Acacia drepanolobium* trees in East Africa house ant defenders that reduce feeding by goats and juvenile giraffes. Theory predicts that costly rewards should be relaxed if the risk of herbivory is reduced, although this has not been previously demonstrated. We compared the rewards offered by trees experimentally protected from mammalian browsing for seven years with those offered by unprotected trees. Protected trees produced 25% fewer nectaries per leaf and 25% fewer swollen thorns than trees in browsed plots. Relaxation of indirect defenses when trees are protected from herbivores is consistent with the dual hypotheses that inducible defenses are dynamic and that plants can save costs by relaxing these defenses when they are not needed. Among trees exposed to mammalian herbivores, trees that were browsed within roughly the past year provided similar rewards for ants as did trees exposed to herbivores but not browsed within the past year. This result suggests that relaxation of indirect defenses only occurs following more than one year of protection from mammalian herbivory.

Insects as vectors of plant diseases - an introduction

ME Irwin
"Department of Natural Resources and Environmental Sciences, University of Illinois. 1101 W. Peabody Drive, Urbana, ILLINOIS, USA,
meirwin@uiuc.edu"

Viruses are among the most devastating of organisms inflicting plant diseases. In many cases virus diseases become epidemic, progressing rapidly through a field and severely reducing harvestable yields. What is more, once the epidemic has begun, it is extremely difficult to control and can lead to plowing down the field and ceasing to grow that particular crop in that area in the future. The vast majority of plant-debilitating viruses are difficult to control because they are vectored by insects. This symposium examines interactions between viruses and their insect vectors as well as the feeding and movement behaviors of vectors in an attempt to uncover new ways to manage epidemics. Remarkable progress is being made in discovering, developing, and deploying such management tools.

Complex interactions between bottom-up and top-down control of grasshopper (Acrididae) performance

A Joern
Division of Biology, Kansas State University, Manhattan, KS, USA 66506, jjoern1@unlnotes.unl.edu

Grasshopper species from North American high plains grasslands experience highly variable environments, especially with respect to climate and the nutritional landscapes that vary within and among years. Long-term studies of the most common grasshopper species indicate corresponding variability in grasshopper population abundances. Strong evidence of density-dependence suggests the importance of biotic influences on responses in addition to extrinsic climatic effects. I will discuss underlying interactions between 'bottom-up' (food plant resources) and 'top-down' (natural enemies) factors that affect individual grasshopper performance in *Ageneotettix deorum* (Scudder), a common grasshoppers in Nebraska sandhills prairie. Relationships between bottom-up and top-down forces to grasshopper populations are important, subtle and complex. I will summarize our understanding of these interactions to date, emphasizing the importance of host plant quality for understanding the impact of natural enemies. Key points include evidence for strong indirect, trait-mediated responses by grasshoppers in the presence of spiders, density-mediated compensatory effects between predation and food quality, and possible threshold responses affecting population densities among years.

Behavioural changes in lepidopteran larvae on crop plants.

M-L Johnson, MP Zalucki
Queensland Department of Primary Industries, Zoology and Entomology Department, University of Queensland, St Lucia, Qld, 4072, Australia.
mjohnson@zen.uq.edu.au

Helicoverpa armigera Hübner (Lepidoptera: Noctuidae) or heliothis is a highly polyphagous major pest of crops world wide. Larvae cause direct damage primarily to reproductive parts of plants and to leaves. The influence of plant architecture (stage and crop type) on foraging by this species is not well known. This is particularly true for early instar larvae which are the key stage targeted for control. We show how foraging behaviour (movement and feeding) changes with crop type. Two crops *Vigna radiata* (L.) R. Wilczek (Leguminosae) (mungbean) and *Cajanus cajan* (L.) Millisp. (Fabaceae) (pigeon pea) were compared at the seedling and flowering/early fruiting stage. Mungbeans are short, large leaved and hairy compared to the more slender glabrous pigeon pea. Experimental conditions reflected Australian summertime temperatures. The amount of time allocated to key activities such as feeding and searching were determined from observations of newly hatched neonate larvae on whole plants over 8 hours. In addition the frequency and duration of a single bout and where larvae spent most time on each crop type were recorded as were the location and type of plant part most frequently fed on. Results show differences occur between seedling and flowering plants and crop type.

How the clover root weevil finds white clover roots in the soil

SN Johnson, PJ Gregory, X Zhang
"School of Human & Environmental Sciences, Department of Soil Science, PO Box 233, University of Reading, Reading RG6 6DW, United Kingdom.
S.N.Johnson@reading.ac.uk"

The clover root weevil, *Sitona lepidus*, is a destructive pest of white clover. The adult weevil feeds on leaves above-ground whereas the soil-dwelling larvae attack the root system. Larvae initially feed on root nodules that house symbiotic N_2 fixing Rhizobia bacteria, before moving onto progressively larger roots. Studying such small soil insects *in situ* is difficult, but the development of X-ray microtomography has allowed us to non-invasively track the movement of larvae towards roots in the soil. Using X-ray microtomography and other techniques, we have shown that newly hatched *S. lepidus* can recognise white clover roots in the soil from 6cm away and distinguish them from non-host plant roots such as subterranean, strawberry clover and perennial ryegrass. Using these empirical results, an individual-based lattice Boltzmann model has been developed to simulate the movement of *S. lepidus* in the rhizosphere of white clover.

Interspecific competition between the native and the exotic dandelion mediated by pollinators

I Kandori, T Hirao, E Katakami
Naka-machi, Nara, 631-8505, Japan, kandori@nara.kindai.ac.jp

In Japan, especially in the suburbs, the native species of dandelion has been replaced by the exotic one for the past few decades. This phenomenon is called "Dandelion Wars". The widely accepted hypothesis to explain this replacement is, that there is a habitat segregation between the two, i.e., the native prefers stable while the exotic prefers destructive, labile environment, which is spreading in the suburbs, and that there is no interspecific competition between the two. Is this true ? At least, we often find mixed population in the field, which means that there is not a clear habitat segregation. Here we propose another hypothesis, that is, there must be some indirect interspecific competition mediated by pollinators in such mixed population. The results of this study supported this hypothesis in three-holds. 1. The exotic flowers attracted twice or more the flower visitors than did native ones in the field. 2. Seed-set of the native species is 10 – 20 % higher in the single-species population than in the mixed population. 3. (omitted). The above results showed for the first time that the pollination of the native dandelion is interfered by the exotic one as the latter spreads its habitat.

Host-specificity and evolution of the genus ***Bruchidius sl.*** **(Coleoptera: Bruchidae).**

GJ Kergoat, A Delobel, G Fédière, B Le Rü and JF Silvain.
IRD-PGE, avenue de la Terrasse, 91198 Gif-sur-Yvette, France, kergoat@pge.cnrs-gif.fr

The understanding of the mechanisms explaining the diversification of phytophagous insects is a stimulating topic and numerous studies have followed one another since Erhlich and Raven's (1964) seminal paper was published. Within the superfamily Chrysomeloidea, the family Bruchidae exhibits a strong host-specificity that strengthen their usefulness in evolutionary studies. Seed sampling in the field and monitoring of adult emergences give the opportunity to identify insect-plant associations accurately. By using molecular phylogenetics, we have investigated the relation between host-plant preferences and bruchid phylogeny in order to highlight possible evolutionary patterns. We have studied European and African members of the genus *Bruchidius sl.* separately, with the inclusion of additional data on the nature of seed secondary compounds for the later. Our results indicate that phylogenetically related bruchids are generally associated with phylogenetically related host-plants. However, for European species, the insect-host plant pattern does not follow the host-plant phylogeny recently proposed by Wink & Mohamed (2003). Morevover, for African species, it appears that host-plants phylogeny alone cannot explain the observed patterns. Interestingly, the nature of the seed secondary compounds appears to be the major factor explaining the diversification of *Bruchidius sl.* that specialized on Caesalpinioideae and Mimosoideae superfamilies.

Development of an *in vitro* feeding system for root-feeding Hemiptera

KB Kingston, KS Powell, P Cooper
Primary Industries Research Victoria - Rutherglen, Department of Primary Industries, RMB 1145 Chiltern Valley Road, Rutherglen, Vic 3685, Australia, kim.kingston@dpi.vic.gov.au

Limited published data exists on artificial diets for root-feeding Hemiptera. Using Grape Phylloxera, *Daktulosphaira vitifoliae* Fitch (Hemiptera: Phylloxeridae) as a model insect, an artificial feeding system was developed. Phylloxera is classified as viticulture's worst insect pest due to damage caused to the root system of the commercial grapevine, *Vitis vinifera* L. Phylloxera feeds on non-vascular cells, inducing the development of a 'nutrient sink' and root galls, leading to a decline in vine health and eventual death. The development of an artificial feeding system for phylloxera required special chamber design due to the size of the insect (1 mm adult length). Specific requirements included allowing for diet renewal without insect disturbance, and reducing condensation levels on the diet membrane while maintaining a sufficient humidity level. Limited probing activity and survival of 1st and 3rd instar insects has been recorded for up to eight days. Diets containing amino acids improve feeding rates due to the insects natural diet of the high protein content of non-vascular cells. Optimising an artificial diet for phylloxera will determine of the essential nutrients for survival and development, and provide a medium for the rapid testing of potential control agents. The system developed in this study could be modified for other root-feeding Hemiptera.

Genetic analysis of aphid resistance in a plant model system

J Klingler, R Creasy, LL Gao, RM Nair, H Spafford-Jacob, OR Edwards, KB Singh
CSIRO Entomology and CSIRO Plant Industry, Private Bag 5, Wembley, WA 6913, Australia, kli026@csiro.au

Medicago truncatula Gaertn. (barrel medic) is grown as forage in Australia, where plant breeders have identified aphid resistant *M. truncatula* germplasm. The status of *M. truncatula* as a model legume provides the opportunity to study defence against aphids at physiological, biochemical and molecular levels. Aphid resistance has been backcrossed into susceptible cultivars to create pairs of resistant and susceptible near-isogenic *M. truncatula* lines. We are focusing on the near-isogenic lines Jemalong (susceptible) and Jester (resistant) to identify mechanisms of defence against *Acyrthosiphon kondoi* Shinji (bluegreen aphid). We have identified three modes of resistance to *A. kondoi* in Jester: antixenosis (non-preference by the aphid); antibiosis (negative impact on aphid biology); and tolerance (little plant damage under aphid infestation). Molecular-genetic analysis of the trait is underway to isolate and characterize the dominant aphid resistance gene, *AKR* (*Acyrthosiphon kondoi* resistance). This gene is tightly flanked by resistance gene analogs of the NBS-LRR gene family, which confer resistance to a broad range of agricultural pests including microbial pathogens and phloem feeding insects. Our results suggest *AKR* may also be a member of this gene family. The advantages of studying this trait in a model system will be discussed.

Induction reduces performance of a specialist herbivore on one host plant species but not another

J Landosky, D Karowe
"Department of Biological Sciences, 3425Wood Hall, Western Michigan University, 1903 W. Michigan Avenue, Kalamazoo, MI 49008-5410 USA, j.landosky@wmich.edu"

Induced resistance to herbivory is often thought to be more effective against generalist and semi-specialist herbivores than specialists. However, we found that even for specialists, the effect of induced resistance on herbivore performance may depend on host plant species. Collard (*Brassica oleracae*) and mustard (*Brassica nigra*) were grown in outdoor chambers; half of the plants were mechanically damaged to simulate herbivory. Induced resistance in collard decreased the performance of *P. rapae. P. rapae* feeding on induced collard had more difficulty digesting leaf material and grew more slowly. Conversely, induced black mustard resistance did not affect the performance of *P. rapae*. *P. rapae* feeding on induced black mustard had greater conversion efficiency of food to biomass and lower consumption rates, but their growth rates were unaffected. In an effort to determine how host plant characteristics changed following damage, and what characteristics correlate with *P. rapae* performance, concentrations of sinigrin in black mustard and the relatively complex suite of seven common glucosinolates in collard were also measured. Glucosinolate concentrations will be discussed considering the proposed value of induction to increase the variability of the host plant.

Impact of Pea leaf and stipule morphological variation on Pea aphid predators

AI Legrand
Department of Plant Science, U-67, 1376 Storrs Rd. University of Connecticut, Storrs, CT 06269 United States. alegrand@canr.uconn.edu

It has been suggested that plants could be modified to enhance the activity of natural enemies of herbivores. Among the plant characteristics that could be modified are physical features such as plant morphology. We have been able to test hypotheses regarding the effect of plant morphology variation on the effectiveness and intraguild interactions of pea aphid predators by using near-isogenic lines of peas *Pisum sativum* L. These lines exhibit single gene mutations that drastically alter the shape of leaves and stipules. Increased leaf morphological complexity was found to be detrimental to the predation efficacy and plant surface search efficiency of *Coccinella septempunctata* L. adults and larvae. However, the efficacy of *Chrysoperla rufilabris* (Burmeister) larvae was unaffected by increases in complexity. This difference in predator responses was also observed in recent work on the effect of pea afila leaf and reduced stipule traits on the efficacy of these two predators. Predation by the chrysopid was enhanced only when afila leaf occurred together with reduced stipules. In addition to influencing the efficacy of predation on aphids, variation in plant morphology can legislate the occurrence of intraguild predation among the aforementioned predators. Results from work on this topic will be presented.

Induced resistance and susceptibility of brassica plants to diamondback moth

SS Liu, YQ Liu, MJ Furlong, MP Zalucki
"^{1}Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Road, Hangzhou 310029, China. shshliu@zju.edu.cn"

Correlations between induction response and constitutive resistance in plants to herbivores have been speculated for a number of years. In laboratory and field experiments we compared the effects of exogenous jasmonate treatment to two closely related cabbage species on the host-searching and oviposition preference of the diamondback moth, *Plutella xylostella*. Jasmonate-treated Chinese cabbage (*Brassica campestris*) was less attractive than untreated Chinese cabbage to ovipositing *P. xylostella*, while jasmonate treatment of common cabbage (*B. oleracea*) made plants more attractive for oviposition by this insect. Similar effects were observed when plants of the two species were damaged by *P. xylostella* larvae. In the absence of insect-feeding, or jasmonate application, Chinese cabbage is much more attractive to *P. xylostella* than common cabbage. Inducible resistance therefore appears to occur in a more susceptible plant and induced susceptibility appears to occur in a more resistant plant, suggesting a possible balance mechanism between constitutive and inducible defences to a specialist herbivore. A further study, that uses a range of wild crucifer plant species exhibiting low through to high degrees of constitutive resistance, is underway to test this hypothesis.

European honeybees and Australian grevilleas: cross-cultural attraction

SM Lloyd, D Ayre, R Whelan
School of Biological Sciences, University of Wollongong, Wollongong, NSW, Australia, 2522. sml95@uow.edu.au

European honeybees, like most pollinators, are expected to visit attractive plants more frequently, and consequently these plants may achieve greater fitness. Many Australian plants species are very attractive to honeybees (eg. large floral display), but facilitate pollination by birds and mammals (eg. Proteaceae). The floral structures of these plants mean that honeybee foraging behaviour may not transfer pollen. Thus, investment in reproductive effort comes at a high price. Few Australian studies have tested the response of honeybees to variation in plant reproductive effort and the consequences for reproductive output. *Grevillea macleayana* **was used to (1) identify interplant variation in honeybee foraging behaviour (2) determine whether variation in plant reproductive effort (eg. inflorescence production) explained the interplant variation in honeybee foraging and (3) determine whether interplant variation in reproductive output could be explained by variation in honeybee foraging. Honeybee visitation was observed at 16 plants, at three sites in Jervis Bay (NSW), over 6 days. Significant interplant variation was found in rates of honeybee visitation. Significant positive relationships were found between rates of honeybee visitation per plant and both inflorescence number and plant size. However, thus far, no relationship has been found between plant seed production and rates of honeybee visitation.**

Depauperate pollinator and seed disperser assemblages provide adequate ecological services to an entomophilous and myrmecochorous shrub in restored habitat

B Lomov, DF Hochuli, DA Keith
Building A08, School of Biological Sciences, The University of Sydney, NSW 2006, Australia. blomov@bio.usyd.,edu.au

Concern over the loss of natural ecosystems to urban development has triggered many restoration projects. However, the effectiveness of various techniques used to restore biodiversity and associated ecological functions remains largely unassessed. We evaluated the success of a restoration project by comparing pollination and seed dispersal in an entomophilous and myrmecochorous shrub *Dillwynia sieberi* in revegetated pasture and remnant Cumberland Plain Woodland, Sydney, Australia. Flower visitation data from revegetated areas suggests a negative interaction between introduced Honey Bee and native bee species on *D. sieberi* flowers. This interaction was not pronounced in forest remnants due to the lower flower densities. Plants in restored areas had higher flower densities, while forest remnant plants had a higher flower-to-fruit ratio. Rates of *D. sieberi* seed removal by ants in revegetated and forest areas were similar, although species richness of seed-removing ants in revegetated areas was lower and their composition was different from that in forest remnants. Our data suggests that, although habitat restoration can take decades, recovery of certain processes occurs at the early stages of restoration due to the ability of certain species to expand their role in the ecosystem.

Density dependent effects of aphids on defense expression in milkweeds and aphids

SB Malcolm, JW Martel
Department of Biological Sciences, Western Michigan University, 1903 West Michigan Ave., Kalamazoo, Michigan 49008-5410, U.S.A.;
steve.malcolm@wmich.edu

Density effects of the specialized sucking herbivore, *Aphis nerii*, on cardenolide expression were measured in a milkweed host plant with high constitutive defence expression. We found that host cardenolides were reduced at low aphid density and as density increased cardenolides were induced to levels above aphid-free controls. The cardenolide response was strongest in leaves with aphids, but a similar, less pronounced response also occurred in adjacent leaves. We could find no effect of cardenolides on aphid performance and there was no effect of time of exposure or the interaction between herbivore density and feeding time. *A. nerii* sequesters cardenolides for defensive use against its natural enemies, and seems capable of effectively handling significant increases in cardenolide concentration with little adverse effect on colony density and biomass. Cardenolide reduction and induction host plants may therefore influence the effectiveness of sequestered chemical defense against natural enemies in the third trophic level according to herbivore density. We explore the predicted implications of such dynamic shifts in plant response for both herbivore and natural enemy trophic levels.

Captures of Mexican fruit fly in orange baited traps, in Yautepec, Morelos, México

MJ García-Ramírez, V López-Martínez, CM Acosta-Durán
Av. Universidad 1001, Col Chamilpa, 62210, Cuernavaca, Morelos, México. vilomar74@yahoo.com.mx

The Mexican fruit Fly is one of the most serious pests of fruit crops in México and many other tropical and subtropical regions. Historically, the principal capture system is integrated by McPhail traps baited with commercial protein, use of host volatiles to bait traps is recent. The objective of this research was to compare capture rates of Mexican fruit flies in traps baited with commercial protein bait (Captor 300®), and in traps baited with orange fruit. From early february to late march, field experiments were conducted in a 14-ha mango orchard. The following treatments were conducted (1) orange pulp, (2) orange skin, (3) orange with pulp and skin, and (4) commercial protein. There were 4 replicates of each treatment and the position of trap was rotated every week. All captured counts were made weekly, all specimens were preserved in 70% ethyl alcohol. Fruit fly capture data for each treatment were subjected to a repeated-measures ANOVA using weekly counts ad repeated measures, and treatment means were compared using the LSD test. Data were transformed by log (x+1) to stabilize variances before analysis. In field tests traps baited with orange complete were more effective for capturing fruit flies than others baited traps (proportion 1.68:1 versus commercial bait, 2.95:1 versus pulp alone, and 1:1.55 versus orange skin). Results from this study indicate that use fruit odors as attractants in commercial orchards will improve the number of flies captured.

Behaviour of first instar *Helicoverpa armigera* (Hübner) (Lepidoptera: Noctuidae): Does starting position make a difference?

AG Manners, ML Johnson, MP Zalucki
"Zoology and Entomology, Goddard Building University of Queensland, St. Lucia, Qld 4072, s349967@student.uq.edu.au "

The effect of oviposition site on consequent behaviour of first instar *Helicoverpa armigera* (Hübner) was investigated on cotton plants. Larvae were observed from egghatch for three hours starting from three positions: upper leaf, square, and boll. Of the following behaviours quantified using Noldus observer: feeding, crawling, resting, dropoff (falling from the plant on a silk strand) feeding on the eggshell, waving down, waving up, and unknown, significant differences in the total amount of time spent feeding, crawling, resting and dropoff were found among treatments. Larvae that started from the upper leaf rested most and crawled least. Larvae that started from squares fed most and dropped off least. Larvae that started from bolls crawled most and fed and rested least. Further study is needed in order to discover the mechanism for the behavioural differences and to determine if the behaviour of larvae from different oviposition sites differs over longer time scales. Implications of oviposition sites on the foraging behaviour of first instar larvae and its relevance to the management of *H. armigera* in the field are discussed.

Pollination of a high latitude, dioecious plant, the cloudberry (*Rubus chamaemorus* L.): a generalized or specialized interaction?

A Brown, JN McNeil
Department of Biology, University of Western Ontario, London, ON, Canada N6A 5B7 jmcneil2@uwo.ca

Recent articles on the latitudinal trends in plant-pollinator specialization have questioned the long held notion that proportionally fewer specialized interspecific interactions occur at higher latitudes. We conducted a study to examine the pollinator guild of cloudberry (*Rubus chamaemorus* L.), dioecious, perrenial herb in subarctic bogs. We recorded 43 different insect Families as visitors, suggesting generalization in this pollination system. yet the Apidae, Halictidae, Muscidae, and Syrphidae represented 87% of all visitors. Controlled pollination experiments revealed that the halictids and syrphid were the most effective pollinators although the mass and seed set of the fruit actually produced did not differ between the four Families. Based on pollinator importance, a product of relative abundance and effectiveness, showed syrphids and muscids were of paramount importance to cloudberry as these Diptera were physically excluded from accessing nutritional rewards from competing Ericaceae flowers and consequently obligate visitors to cloudberry. Thus, there is moderate pollinator specialization with cloudberry offering small but significant rewards to attract small Diptera.

The ecology of inquilinism in communally parasitic *Tamalia* gall aphids

DG Miller III
Department of Biological Sciences, California State University-Chico, Chico, CA 95929 USA, dgmiller@csuchico.edu

Tamalia aphids occupy galls on *Arctostaphylos* spp. shrubs in Western North America. A gall-inducing species, *Tamalia coweni*, exhibits facultatively communal behavior in that multiple female foundresses may share galls. A second species, *Tamalia inquilina*, obligately invades galls of *T. coweni*, singly or in groups, although no apparent agonistic interactions have been observed between the two species. Although total reproductive output of adult offspring is similar between galls containing *T. coweni* alone and galls with both species, the allocation of brood is significantly skewed toward that of the inquiline; hence, *T. inquilina* is a parasite of *T. coweni*. The presence of *T. inquilina* has no significant effect on survivorship of *T. coweni* in mixed-species galls. *Tamalia inquilina* can successfully reproduce in open galls abandoned by *T. coweni* and under these circumstances may be characterized as commensal rather than parasitic. To the author's knowledge, this is the first example of communal parasitism in galling aphids.

"Toxicity of pellitorine, an amide isolated from *Piper tuberculatum* Jacq. (Piperaceae) to the pollinator *Apis mellifera* L. (Hymenoptera: Apidae) "

JE Miranda, HMD Navickiene, RH Nogueira-Couto, SA De Bortoli, M Furlan, V da S Bolzani, MJ Kato
Embrapa Algodão, CP 714, 74001-970 Goiânia, GO, BRAZIL, miranda@cnpa.embrapa.br

Pellitorine, an amide isolated from *Piper tuberculatum* (Piperaceae), has been studied as a biopesticide against agricultural pests in Brazil. In order to investigate their impact on non-target organisms, particularly pollinator insects, researchs were performed to evaluate the acute toxicity action of the compound on larvae and newly emerged adults of honeybee *Apis mellifera* by means of contact and ingestion bioassays. Workers in the larval and adult phase were separated in groups, which received pellitorine in different concentrations. The larvae were maintained in their own original cells, receiving feeding and normal care from the nurses. The adults were confined in wooden cages with screens, receiving artificial diet made up of sugar and water (1:1). The concentrations of 40, 200, 1000, 5000 and 25000 ng a.i./individual were obtained diluting pellitorine in 98% ethanol. LD_{10} values of 39.14, 36.16 and 13.79 ng a.i./insect were determined for larvae, for adults by ingestion and adults by contact, respectively. The honeybee larvae were shown to be highly susceptible to the amide pellitorine. The amide pellitorine was shown to be more active when its absorption took place via dermal contact (by topical application).

A dynamic brain is the key to become a tospovirus vector

G Moritz, S Kumm, LA Mound
"Martin-Luther-University of Halle-Wittenberg, Domplatz 4,D-06099 Halle, Germany. moritz@zoologie.uni-halle.de"

Although tospoviruses are transmitted only by thrips, it is not possible for an adult to acquire then transmit one of these plant diseases. An individual thrips can acquire a tospovirus only by feeding on an infected plant during its first or early second larval instar, the virus then moving from the gut lumen to the salivary glands from where it can subsequently be re-injected into a plant. Much of the research by tospovirus workers has concentrated on how the virus enters the gut cells, but the translocation of the virus through the insect body has been given rather less attention. Studies on the developmental morphology of the early instars of *Frankliniella occidentalis*, the western flower thrips, have demonstrated a well defined period during which there is a temporary association between the mid-gut, the visceral muscles and the salivary glands. This association occurs because during the first and early second instars the brain is displaced into the prothoracic region by the large cibarial muscles. With increasing body size, the brain moves into the head and the close association is lost between the salivary glands and gut wall. Subsequently, there is a strong input of virus into the malpighian tubules from the haemocoel.

Host plant use by polyphagous grasshopper and the defense traits of the plants related with it

K Miura
"Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan miura@kais.kyoto-u.ac.jp"

Most of herbivorous insect species are oligophagous although the benefits to expand the host plant range were reported. That suggests that polyphagous insects have more cost in host plant use than oligophagous ones do. The one of the causes is considered that they have to defeat various plant defenses of family-specific. When they feed on unrelated plant species with common defense traits, such feeding habits could contribute to less cost in host plant use than ones with uncommon. However, a few studies examined the use of host plants growing in the habitat and the defense traits with them. Because most of grasshoppers were polyphagous at an individual, they have the feeding habits and mechanisms for decreasing such cost. Host use pattern by nymphs of polyphagous grasshopper, *Parapodisma subastris* Huang was examined, and the results were as following:1. Out of 19 plant species growing in the habitat, the plants with tough leaves or dense trichome ranged over family, and showed higher intrinsic quality. 2. When nymphs fed on several lethal plant species, they improved their survivorship greatly. Above the characteristics of host plants and the feeding habits were useful to decrease cost of expanding host plant over families.

Integrity of pollinator communities in restored habitats in Mauritius.

CB Müller, CN Kaiser, DM Hansen
Institute of Environmental Sciences, University of Zürich, Winterthurerstrasse 190, 8057 Zürich, Switzerland. cbm@winst.unizh.ch

Island habitats normally show high degrees of endemism but are often affected negatively by exotic invaders and species extinctions. The aim of our study is to assess the management success for the restoration of a native, original plant community in terms of essential ecosystem services, such as pollination and seed dispersal. We use quantified interaction webs of the pollinator community to contrast the quantified network between plants and pollinators in restored and unrestored plant communities. Restoration is achieved by regular weeding of invasive, exotic plant species, resulting in higher disturbance levels than in unrestored habitats. We show that abundance and diversity patterns of the pollinator interactions differ between restored and unrestored plant communities and that the resulting seed sets of endemic plants are affected by management. Experimental field studies are used to validate the predictions of strong influences of exotic invasive plant species on the pollination services to endemic plant species.

Endophytic fungi and their impact of insect food webs.

CB Müller, S Härri, J Krauss
"Institute of Environmental Sciences, University of Zürich, Winterthurerstrasse 190, 8057 Zürich, Switzerland cbm@winst.unizh.ch"

Many fungal microorganisms live in symbiosis with terrestrial grasses. They affect both the quantity and quality of resources and thus, the energy supply to invertebrate consumers at higher levels in the food chain. Plants infected by endophytic fungi are chemically protected against herbivore consumption. However, the influence of this fungus-plant association on multi-trophic interactions remains largely unexplored. We show effects of fungal endophytes on insect food webs that reflect limited energy transfer to consumers as a result of low plant quality, rather than productivity. We use quantified herbivore-parasitoid webs on endophyte-free and endophyte-infected grasses to show enhanced insect abundance at alternate trophic levels, higher rates of parasitism, and increased dominance by a few trophic links on uninfected plants. These results mirror predicted effects of elevated productivity on food-web dynamics. Experimental analysis of the underlying mechanism indicate life-history effects for different species of herbivorous aphids and negative effects of endophyte presence on aphidophagous insects.

"Role of pseudomonad induced resistance in tomato *Lycopersicon esculentum* against leafminer, *Liriomyza trifolii*"

"M Murugan, N Dhandapani, R Samiyappan"
Centre for Plant Protection Studies, Tamil Nadu Agricultrural Univeristy, Coimbatore 641 003, India. Present address: Regional Research Station, Paiyur 635 112, India. email:entomurugan@rediffmail.com

"Tomato is an important vegetable crop of India and it is frequently infested by the leafminer, *Liriomyza trifolii* resulting in yield loss. Insecticides offer less impact in its management and genetic resistance iS minimum in commercial cultivars. Induced resistance is found to be a source of pest reduction in crops like tomato. Hence, an attempt was made to induce the resistance in tomato using biological and chemical inducers. *Pseudomonas fluorescens* (strain Pf1) was used to treat the seeds, seedlings and was applied to soil and foliage. The incidence of *L. trifolii* was significantly reduced on plant basis (29.7%) and leaflet basis (19.9%), when compared to check (53.7 and 31.9% respectively). The induced plants showed non-preference for feeding and egg laying to female flies. Antibiosis was observed in larval growth and development. Egg to adult period was increased by 3.2d. The larval parasitism by *Chrysaonotomyia rexia* was 34.7% more on the induced plants. Leafminer infestation resulted in enhanced expression of the pathogenesis related (PR) proteins and defense enzymes *viz.,* peroxidase, polyphenol oxidase, phenylalanine ammonia lyase, 1-3 glucanase, proteinase inhibitors and chitinase. The defense chemicals *viz.,* total phenols, tannins and acylsugars were also high in the induced plants. Compatibility of induced resistance was also noticed with the neem products under field condition.
"

Neural processing underlying taste-mediated behaviour in locusts

PL Newland
School of Biological Sciences, University of Southampton, Bassett Crescent East, Southampton SO16 7PX, England. pln@soton.ac.uk

The decision an insect makes to accept or reject food is largely a consequence of the information it receives from its taste receptors. These taste receptors, or contact chemoreceptors, are distributed over the body and mouthparts. How then is the chemosensory information provided by these receptors encoded within the central nervous system? Recent advances in our understanding of taste perception in insects shows that there is a very close anatomical and physiological relationship between chemosensory and mechanosensory processing. The destinations of chemosensory neurons in the central nervous system is determined not by the type of chemical that they respond to, but rather to the spatial location of the chemosensory receptors on the leg. Our recent studies show that local interneurons within the thoracic nervous system are responsible for much of the processing of chemosensory information from contact chemoreceptors on a leg. Chemosensory coding by these interneurons appears to be for a single quality, that of aversiveness, which is a product of both chemical identity and concentration. Moreover, the strength of the chemosensory responses in interneurons and leg motor neurons is strongly correlated with the behavioural aversiveness of a chemical stimulus.

What good are syndromes? A review of pollination systems in New Zealand.

LE Newstrom, AW Robertson
"Landcare Research, PO Box 69, Lincoln 8152, New Zealand. newstroml@landcareresearch.co.nz"

The concept of pollination syndromes, originally designed to describe a combination of floral traits that frequently occur together in association with particular groups of pollinators, has recently been criticised. Determining the most effective pollen transfer vectors (either in quality or quantity) is context dependent and often fails to match predictions based on the syndrome concept. We review pollination systems in New Zealand to assess the usefulness of the syndrome concept. The low diversity in native and exotic pollinator assemblages, extremely high seasonal and daily microclimate variability, and easy access to pollen and nectar in most flower types in New Zealand is thought to promote generalist and mixed pollination systems. The majority of native insect pollinators in New Zealand (e.g., small bees and flies) do not manipulate flowers with precise or complex behaviours. Therefore the syndrome concept as a predictive tool has been considered less appropriate than for North Temperate and Tropical regions (e.g., large bee and hawkmoth). However, differential floral attraction, floral preferences, and temporal resource partitioning need to be considered. Used correctly, the syndrome concept still has an important role in understanding and predicting the nature of pollination systems in New Zealand.

Effects of trait variation and weather on herbivore survival and on the strength of trophic interactions in a food chain

O Ovadia
Department of Life Sciences, Ben-Gurion University of the Negev, POB 653, Beer Sheva, 84105 Israel, oferovad@bgumail.bgu.ac.il

Classical theory in community ecology assumes that smaller-scale details such as individual traits can be abstracted and that community dynamics can be characterized in terms of net changes in population densities. I explore the effect of body size variation among herbivores on community dynamics using a computational model which consists of a three-level food chain. I illustrate that survival of herbivores is negatively correlated with variation in their body size and that predicting herbivore population dynamics requires incorporating frequency-dependence. At the community-level, however, it is the proportion of surviving herbivores rather than their population density that determines plant abundance, i.e., plant dynamics can be predicted from the initial body size distribution of herbivores in combination with their body size-survival curve. I then present empirical evidence, for the relationship between net food web effects and variation in herbivore body size, from an old-field community, consisting of spider predators, grasshopper herbivores, and grass and herb plants. I show qualitative congruence between results of the simulation and field experiments. Decreased grasshopper survival not only reduces the damage inflicted on plants, it weakens the strength of indirect effects of spiders on grass and herb plants. Grasshopper survival, however, is also sensitive to intra- and inter-annual weather variability. Small changes in the distribution or duration of rainfall events result in changes of up to several orders of magnitude in the mortality rate of grasshoppers. I thus conclude that in this system both body size distribution of grasshoppers and weather should be incorporated in a time-series model whose goal is to predict community dynamics.

The plant signal cis-jasmone - genetics to applied ecology

M Matthes, JA Napier, JA Pickett, LJ Wadhams
"Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom; john.pickett@bbsrc.ac.uk"

In many cases, volatiles produced by plant defensive mechanisms during herbivory act directly to repel insect attack, and may have indirect effects by attracting predators and parasitoids of the pest insect. *cis*-Jasmone occurs as a component of flower volatiles, but can also be produced by damaged vegetative tissues. In an olfactometer bioassay, *cis*-jasmone was repellent to alatae of the grain aphid, *Sitobion avenae*. Methyl jasmonate, a catabolite of jasmonic acid biosynthesised from linolenic acid during herbivory, can induce defensive metabolism in various plants. The biosynthetically related *cis*-jasmone is also a catabolite of the stress-produced jasmonic acid, but had previously been considered only as a biological sink for the jasmonate pathway. However, bean plants, *Vicia faba*, exposed to *cis*-jasmone vapour were more attractive to the parasitoid *Aphidius ervi*. This was associated with a more persistent effect than found with methyl jasmonate, including induced production of (*E*)-ocimene, a parasitoid foraging cue. The molecular mechanism by which *cis*-jasmone influences plant gene expression is being studied in *Arabidopsis thaliana*, with about 30 genes upregulated. These studies will potentiate development of *cis*-jasmone as a plant activator for crop protection, as well as allowing "switching on" of other useful genes and traits. Already, in a series of small-plot experiments conducted over four years, *cis*-jasmone applications have been shown to reduce cereal aphid populations infesting wheat in the field.

Can molecular tools be used to improve proximate and adaptive understanding of tritrophic interactions?

GM Poppy
"School of Biological Sciences, University of Southampton, Southhampton, SO16 7PX, UK; gmp@soton.ac.uk"

There are increasing opportunities to use molecular tools which can allow further understanding of the mechanisms involved in herbivore-induced plant signalling to higher trophic levels. However, this should not lead to further segregation between the reductionist and holistic approaches to tritrophic interaction research. The use of transgenic/mutant plants and genomic tools such as microarrays should allow mechanisms to be explored at the same time as answering questions about the ecological and evolutionary roles of herbivore-induced changes in plant chemistry. Arabidopsis is proving a useful model-plant for exploring tritrophic interactions involving both aphids and lepidopteran larvae and their parasitoids. Using GM and mutant Arabidopsis, the role of specific chemical/physical traits has been explored, including herbivore/parasitoid behavioural responses to "novel" secondary compounds. Other studies are focussing on wild populations of *Brassica oleracea* using genomic tools being developed for Arabidopsis. Two populations of *B. oleracea*, which differ in aliphatic glucosinolate composition, are being currently investigated at the genomic, chemical, behavioural and ecological level. This is an example of how molecular tools can help develop our proximate and adaptive understanding of herbivore-induced plant defence systems.

Aphid-plant interactions during stylet penetration of the apoplast and symplast

G Powell
Imperial College London, Wye Campus, Ashford TN25 5AH, UK, g.powell@imperial.ac.uk

Aphids alter plant physiology via mechanical stylet penetration, injection of gelling and watery saliva, removal of photosynthates, and transmission of plant viruses. Incorporating insect and plant in an electrical (EPG) circuit allows monitoring of stylet activities during these processes. The DC-EPG system uniquely differentiates intracellular (symplastic) and extracellular (apoplastic) stylet tip positions. Although the stylets follow an apoplastic pathway, the maxillae regularly puncture cells with important consequences for host selection and virus transmission. I will consider evidence for plant defences against aphids in both apoplast and symplast:

- Apoplastic defences. Stylet avancement may be restricted by mechanical properties of cell walls. Video recording of labial retraction is being used to investigate relationships between the rate of stylet advancement and different 'pathway' activities.
- Symplastic defences. Stylet puncture of a phloem sieve element may be followed by injection of watery saliva and uptake of phloem sap. Components of aphid saliva injected immediately after phloem puncture probably inhibit normal sieve tube responses to damage (particularly P-protein gellation) and enable sap uptake without phloem sealing. Comparisons of insect responses to nearly-isogenic resistant and susceptible plants suggest that resistance factors are expressed in the phloem and may involve modified sealing mechanisms.

Non-persistent virus transmission by aphids: new evidence for the ingestion-salivation hypothesis

G Powell
Imperial College London, Wye Campus, Ashford TN25 5AH, UK, g.powell@imperial.ac.uk

Approximately 75% of aphid-vectored viruses are transmitted in a non-persistent (non-circulative, stylet-borne) manner. The non-persistent transmission mechanism has therefore been the focus of extensive research. Electrical recording of stylet penetration activities (EPG technique) reveals that aphids show three successive intracellular activities (sub-phases II-1, II-2 and II-3) during maxillary puncture of the epidermal plasma membrane. Sub-phase II-3 is linked with virus acquisition and therefore represents uptake of virions to their retention site within the maxillary food canal. Sub-phase II-1 is associated with release of virions into an inoculated cell. The 'ingestion-salivation' hypothesis speculates that inoculation occurs via salivary release of virions from the common food-salivary duct at the tips of the maxillary stylets (Martin et al., 1997, *Journal of General Virology* 78: 2701-05). I will report recent EPG experiments using inoculation of circulatively-transmitted pea enation mosaic virus as a marker for intracellular salivation during epidermal cell punctures. The results confirm that inoculation of non-persistent viruses (sub-phase II-1) is associated with injection of saliva directly into the cytoplasm.

Gall-inducing species adaptive radiation, biogeography and biodiversity

PW Price
"Department Of Biological Sciences, Northern Arizona University, Flagstaff, Arizona 86011-5640, USA. Peter.Price@Nau.Edu"

The local richness of gall-inducing insect faunas reaches a peak in Mediterranean latitudes, and their altitudinal equivalents in the tropics. The validity of this pattern and the mechanisms that result in this pattern are debated, just as the adaptive significance of the galling habit itself is controversial. Such discussion of patterns and mechanisms stimulates many new studies, with encouraging expansion of research in the tropics. Adaptive radiation of gall-inducing lineages appears to be opportunistic rather than coevolved or cospeciated with host plant taxa, with some galling families radiating into many adaptive zones represented by different plant resources. Radiation on herbs, shrubs and trees is influenced by plant architecture, although the specifics depend on the particular host plant and insect herbivore interaction. The large genera and the many sibling species of some gall-inducing taxa suggest rapid speciation and adaptive radiation without much genetic differentiation, with more new species complexes uncovered each year. Studies on gall-inducing taxa will continue to illuminate many areas of ecology and evolutionary biology, although much research is required to fully understand these intriguing insects.

Herbivory modifies the genetic structure of birch populations

K Prittinen, J Pusenius, J Tahvanainen, M Rousi, J Heinonen, H Roininen
Department of Biology, University of Joensuu, P.O. Box 111, FI-80101 Joensuu, Finland, kaarina.prittinen@joensuu.fi

We studied the effects of selective herbivory on genotypic diversity in seedling populations of silver birch (*Betula pendula*), a light demanding pioneer tree species. The study covered the first two growing seasons, during which considerable thinning occurred within the experimental populations. Mortality resulted in decreased diversity compared to a control simulating random mortality. When insect and vole herbivory and nutrient enrichment treatments were compared, taking into account differences in mortality, vole herbivory resulted in increased diversity in the canopy layer. This is noteworthy, since the canopy layer includes the seedlings with best prospects of surviving in competition for light. The 2-yr natural insect exposure had no effect on diversity when mortality was accounted for, but cluster analysis showed that insect herbivory changed the genetic structure of the experimental populations.

The transmission of the bacterium *Xylella fastidiosa* by sharpshooters

A Purcell
"University of California, 201 Wellman MC 3112, Berkeley, CA 94720-3112, USA. purcell@nature.berkeley.edu"

The vector transmission of the bacterial plant pathogen *Xylella fastidiosa* (*Xf*) is deceptively simple. Virtually any xylem sap-feeding insect can be a vector, with no required latent period and molting arresting vector transmission. The simplest model for transmission is that the feeding-acquired bacteria attach to the foregut, and some bacteria detach during later feeding on other plants. The precise location(s) within the foregut from which *Xf* is transmitted is unknown, but < 200 live cells of *Xf* per insect are needed for efficient transmission, suggesting that the transmission-critical area of the foregut is very small. Colonies of *Xf* can "carpet" the vector's precibarium, but this does not increase transmission efficiency. *Xf* cells attach to the foregut cuticle most often where fluid flow is most rapid (5 to over 50 cm/sec). *Xf* mutants of genes for fimbriae (attachment filaments) and cell-cell signaling lack normal surface-attachment abilities and vector transmissibility. Anomalies that are not explained by a simple attachment-detachment model are (i) lack of transmission by vectors that acquire large numbers of cultured *Xf* from in vitro suspensions in sterile xylem sap, and (ii) the lack of transmission by non-xylem specialist leafhoppers that acquire *Xf* from feeding on plants.

The possible role of aphids' cuticular proteins in binding potyviral helper component

B Raccah, A Dombrovsky, H Huet, N Chejanovosky
Department of Virology and Entomology, The Volcani Center, ARO, Israel braccah@volcani.agri.gov.il

Transmission of potyviruses by aphids requires the presence of the viral *helper component* (HC) protein. Apparently, the HC serves as a bridge between virions and the aphid stylet. Potyviruses were seen attached within the stylet's food canal. The stylet is made of epicuticle and composed of cuticular proteins (CuPs) and waxes. Herein, we test the hypothesis that CuPs bind to the HC, and thus, indirectly, bind to the virions. CuPs are insoluble after hardening. Therefore, several chemicals were used to extract cuticular proteins from whole aphids: 8M Urea, 1% Calcofluor, 1% Congo red or 5% Sodium dodecyl sulfate (SDS). The extracted proteins were separated by electrophoresis, electroblotted onto a nitrocellulose paper and exposed to a recombinant HC tagged with 7 histidine residues. Bound HC was visualized using a commercial monoclonal antibody to the His-tag. This procedure allows determining that CuPs bands of 31 and 33 kDa that were extracted with either 1% Congo Red or 1% Calcofluor to react with the HC. This is the first report for an affinity between the potyviral HC and the aphid CuPs. A biologically inactive HC did not bind to extracted CuP. The significance of this finding and future work will be discussed.

Parthenium hysterophorus (Asteraceae): the host plant for the gall moth *Epiblema strenuana* (Lepidoptera: Tortricidae) and the gall weevil *Conotrachelus albocinereus* (Coleoptera: Curculionidae)

A Raman, K Dhileepan, SK Florentine
"The University of Sydney, PO Box 883, Orange, NSW 2800, Australia araman@orange.usyd.edu.au"

The gall moth *Epiblema strenuana* and the gall weevil *Conotrachelus albocinereus* have been introduced into the state of Queensland (Australia) as an initiative to biologically control the invasive weed *Parthenium hysterophorus*. Both the moth and the weevil infest and induce galls on *P. hysterophorus*, but only the gall moth is established in the weeded natural areas. Both insects attack the shoot axes of *P. hysterophorus* and induce fusiform galls, although *C. albocinereus* usually restrict their attacks to the main stems and rarely occur on the terminal and lateral meristems. All developmental stages of *P. hysterophorus*, viz., rosette, pre-flowering, and flowering stages, respond to *E. strenuana* by developing galls, though of subtly different morphologies, whereas only the younger, viz., the rosette and pre-flowering stages of *P. hysterophorus* respond to *C. albocinereus* with galls. *E. strenuana* damages the growth point, phloem, and associated parenchyma tissue, and reduces plant vigour; on the other hand, *C. albocinereus* damages xylem tissue in particular, which results in stress arising out of water inundation and consequent anoxia.

"Does feeding by autumn gum moth larvae induce changes in *Eucalyptus globulus* leaf chemistry?"

LP Rapley, GR Allen, BM Potts
CRC for Sustainable Production Forestry, Private Bag 12, Hobart, Tasmania, 7001, Australia, Luke.Rapley@ffp.csiro.au

We empirically tested whether branch defoliation (artificial and larval) of 2-year-old *Eucalyptus globulus* Labill. altered the abundance of specific plant secondary metabolites immediately and 8 months after the cessation of larval feeding. The abundance of even carbon length foliar wax benzyl alkanoates and in particular benzyl n-tetracosanoate, was of foremost interest as high levels of these compounds have previously been reported to be associated with reduced *E. globulus* defoliation caused by autumn gum moth (*Mnesampela privata*) larvae. We found no evidence that benzyl n-tetracosanoate was induced by defoliation, consistent with its operation as a constitutive resistance mechanism. Other *E. globulus* plant secondary metabolites, including essential oils, polyphenolic groups and additional foliar wax compounds, were assayed and in all cases their abundance was not significantly altered by defoliation. However, the level of foliar tannins immediately after cessation of larval feeding did display a trend that suggested elevated levels as the result of defoliation, though this trend was not evident 8 months later, indicating that, if real, the response was a rapid and not a delayed induced response. The level of foliar tannins was also negatively correlated to both average larval survival and average percentage branch defoliation, suggesting that foliar tannins may operate as toxins to *M. privata* larval feeding.

Fiji disease virus levels in populations of the sugarcane planthopper - role of host-plant virus titre, percentage gall area and plant morphology

AW Ridley, GH Walter, K Dhileepan, BJ Croft
School of life sciences, University of Queensland, QLD, 4072, Australia, a.ridley@mailbox.uq.edu.au

Fiji disease virus (FDV) causes Fiji leaf gall (FLG), one of the most important diseases of sugarcane in Australia. The acquisition of FDV by its Australian vector, *Perkinsiella saccharicida,* varies with the sugarcane cultivar on which the vectors were raised. Vector populations raised on tolerant and resistant cultivars have a lower incidence of FDV infection compared to populations raised on a moderately susceptible cultivar. However, the features of the infected host plants in determining hopper acquisition levels remain unknown. Cultivars of known resistance to FLG were propagated using infected planting material. Virus free hoppers were allowed to lay eggs on each of them and the resulting populations of vectors were sampled and processed for FDV infection. Host plant virus titre was obtained with real time RT-PCR. Leaf areas and the areas infected with FLG galls were calculated using image analysis software.

Gustatory processing in the central nervous system of the locust

SM Rogers, PL Newland
Zoology Department, Cambridge University, Cambridge, U.K. CB2 3EJ smr34@cam.ac.uk

Chemosensory sensilla on the legs of locusts contain four chemosensory and one mechanosensory neurone. These sensory neurones project to their local thoracic ganglion somatotopically, such that the location of the sensilla on the leg is preserved in the relative location of the neurones' arborisations in the central nervous system. Both mechanosensory and chemosensory neurones project to the same region of neuropil, and no modality or sensitivity specific segregation could be observed. A behavioural assay established that the probability of a locust withdrawing its leg from a droplet of a chemical solution applied to the hind leg increased with chemical concentration. All tested chemicals, even nutrients, could elicit withdrawal responses but critically the concentration at which different stimuli became effective at eliciting the behaviour varied over several orders of magnitude. Chemosensory neurones make monosynaptic connections onto the same spiking local interneurones that receive mechanosensory sensory inputs from the leg. The relative responses of local interneurones to these same solutions, as well as their outputs onto leg motorneurones, closely correlated with the probability of eliciting a withdrawal response. We suggest that chemosensory processing in the thoracic ganglia directly assesses a chemosensory quality, that of aversiveness, rather than individual chemical identities and concentrations.

The guilds of sawfly gallers on willow (*Salix* spp.) species

H Roininen, A Zinovjev, T Nyman
"Vantaa Research Centre, PO Box 18, 01301 Vantaa, Finland, Heikki.Roininen@metla.fi"

We studied the guilds of galling sawflies (Hymenoptera: Tenthredinidae) living on 138 Eurasian willow species in order to investigate whether the numbers of different galler guilds found on individual willow species depend on various ecological characteristics of the hosts (growth form, mean height, habitat type, local patchiness, role in plant communities, geographical area of distribution, size of distribution area, section in taxonomy, and tendency to hybridise). A total of 308 galler species in nine guilds of galls were found. Leaf folders (*Phyllocolpa* and *Pontania* spp.) were found on 88, leaf gallers (*Pontania* and *Eupontania* spp.) on 176, and stem, petiole, or bud gallers (*Euura* spp.) on 44 willow species. The numbers of sawfly species per willow species correlated positively among galler guilds. The following ecological traits of the willows explained a significant amount of variation in the total number of guilds per host species: size of distribution area, geographical area of distribution, role in the community, local patchiness, growth form, mean height, and habitat type. The size of the distribution area explained ca. 40% of the variation in numbers of galler guilds per host species, which shows the overwhelming role of the size of the geographic range in explaining probabilities of colonisation by gallers.

Plant waxes, insect attachment and aphid predators

CE Rutledge, SD Eigenbrode
"Department of Entomology, Smith Hall, 901 W. State. St. W. Lafayette, IN 47907-2089 clairer@entm.purdue.edu"

Abstract: The surface of plants can greatly affect the ability of predators to locate and capture their prey. All aerial, terrestrial plant surfaces are covered in epicutlicular wax, which varies among, and within, plant species in composition, quantity and morphology. We worked with two cultivars of peas, one with a normal wax bloom, a thick crystalline layer of wax, and one with a severely reduced wax bloom. The reduced wax bloom cultivar supported lower pea aphid populations in the field. Pea aphids had the same intrinsic rate of increase on both pea phenotypes showing that the reduced wax peas were not by themselves resistant to pea aphids. In fieldwork using exclusion cages, we showed that the apparent resistance of reduced wax peas to aphids was due to the presence of predators. In the laboratory, we showed that *Hippodamia convergens*, the major predator of pea aphids in Idaho, was more efficient at capturing pea aphids on reduced wax peas than on normal wax peas due to the increased attachment of the predators to the surface of reduced wax peas. In addition, we studied the interaction of predators on plants with and without the wax bloom.

Environmental consequences of the introduction of *Bombus terrestris* (Linnaeus) (Hymenoptera: Apidae) in Chile.

D Tapia, L Ruz
Laboratorio de Zoología, Pontificia Universidad Católica de Valparaíso. Casilla 4059. Brasil 2950. Valparaíso. Chile. lruz@ucv.cl

Three major environmental consequences of the introduction of *Bombus terrestris* have been reported: displacement of native bees, pollination of invasive exotic plants and the introduction of parasites. This work is focused on the first two consequences in Viña del Mar (V Región). To determine modifications on the foraging behavior of native bees by *B. terrestris*, the correlations in visiting frequencies to the *Psoralea glandulosa* (Fabaceae) were estimated. Visiting frequencies of native bees, *Apis mellifera* and *B. terrestris* to the invasive weed, *Galega officinalis* (Fabaceae), were measured and preliminary quantitative comparisons of pollen carrying were performed. A significant negative correlation of visiting frequencies of *B. terrestris* and native bees was obtained for one period of the day. On *G. officinalis* patterns of visitation were variable in time. *A. mellifera* was more frequent, although an interaction between day time and bee species was involved in the differences of visiting frequencies. Finally, *B. terrestris* carries twice the amount of pollen than *A. mellifera*. The results are discussed on the basis of bibliographical antecedents of *B. terrestris* introductions, and predictions of further experiments.

Pollination and pollinator mediated selection in Australian sexually deceptive orchids

F Schiestl, J Mant
Geobotanical Institute ETH Zürich, Zollikerstrasse 107, CH-8008 Zürich, Switzerland. florian.schiestl@env.ethz.ch

Sexually deceptive orchids mimic sex pheromones and appearance of female insects and thus attract only male insects which pollinate the flowers in an attempted mating. Male mating behavior is crucial for pollination and pollinator attraction is highly specific. 1) In *Chiloglottis trapeziformis*, one compound, named Chiloglottone, was identified to attract the males of the Thynnine wasp *Neozeleboria cryptoides* (Hymenoptera: Tiphiidae) as pollinators. To examine selection imposed on the orchids by pollinators, we used synthetic Chiloglottone on artificial dummies to study the male mate-choice behavior in the pollinator of *C. trapeziformis*. 2) When males of the pollinator were given the choice between two dummies of different sizes, they preferentially attempted to copulate with middle size dummies over small size dummies. 3) When given the choice between two dummies with different amounts of pheromone, males preferred the larger amount of pheromone. Larger amounts of pheromone generally attracted more males than smaller amounts. 4) Orchid flower labella, the mimic of a female body, were significantly longer and broader than female bodies. Flowers also produced on average ten times more Chiloglottone than females. Under pollination limitation, the evolution and maintenance of these exaggerated mating signals is likely to be mediated by the here demonstrated male pollinator behavior.

Negative effect of purple loosestrife and reed canary grass on the diversity of wetland plant and moth communities.

SS Schooler, PB McEvoy, EC Coombs
CSIRO Entomology, 120 Meiers Road, Indooroopilly, QLD, 4068 shon.schooler@csiro.au

Invasive plants have the potential to reduce the diversity of species in plant and animal communities. We examined the negative effect of two invasive wetland plants, purple loosestrife and reed canary grass, on the species richness and diversity of plant and moth communities within 24 wetland study sites in the Pacific Northwest. We hypothesized that as the cover of the invasive species increased, the diversity of the local plant and moth community would decrease. Increasing cover of purple loosestrife and reed canary grass was associated with reduction in the diversity of wetland plant communities irrespective of the diversity measure examined. Moth species richness was positively correlated with plant species richness. Wetland hydrology, soil characteristics, and topography were measured to control for potentially covarying and confounding influences on plant diversity. Temperature, ambient light, and surrounding land-use were measured to control for potentially covarying and confounding influences on moth sampling and diversity. None of these variables was significantly associated with invasive species abundance. This strengthens the conclusion that the invasive species are the cause of the decline in biotic diversity.

Sites of oviposition and initiation influence structure and associated community complexity in *Diplolepis* (Hymenoptera: Cynipidae) galls on wild roses

"JD Shorthouse, JJ Leggo, M Sliva"
Department of Biology, Laurentian University, Sudbury, Ontario, P3E 2C6, Canada, jshorthouse@laurentian.ca

Cynipid wasps of the genus *Diplolepis* are restricted to inducing galls on various organ systems of wild roses. Most species oviposit into unopened leaf buds or the tissues in close proximity to them. Leaf gallers such as *Diplolepis polita* and *D. ignota* deposit eggs on the surface of folded leaflets whereas stem gallers such as *D. nodulosa*, *D. triforma* and *D. spinosa* embed their eggs within the stem tissues between immature leaves. Unlike most stem gallers, *D. fusiformans* deposits its eggs onto the young, current year stems. Multi-chambered stem galls are more structurally complex than single-chambered leaf and stem galls. Inducers within single-chambered galls suffer greater mortality due to inquilines and parasitoids than do inducers of multi-chambered galls. Examination of gall structures and complexity of associated insect communities reveal patterns that help explain relationships among species of the *Diplolepis* complex.

Evolutionary relationships between swallowtail butterflies (tribe Troidini) and their pipevine host plants

KL Silva, VN Solferini
Pós-graduação em Ecologia; Dept. de Genética e Evolução – Instituto de Biologia, Universidade Estadual de Campinas - Unicamp. Campinas, SP, Brazil. Cep 13083-970 klucas@unicamp.br

Butterflies of the tribe Troidini (Papilionidae: Papilionini) use exclusively host plants in the genus *Aristolochia* (Aristolochiaceae). Each Troidini species also has a preferred *Aristolochia* species, possibly due to the plant chemical compounds. This close association between Troidini/*Aristolochia* is an adequate model for insect-plant relationships and coevolutionary studies. Seeking to test the hypothesis of close evolutionary relationships between them, we have sequenced three genes (COI, COII, and EF-1α) of tropical Troidini, and two genes (matK and a non-coding region (*trn*L-*trn*F)) of the *Aristolochia* species used by those butterflies. The phylogenetic analyses were performed with PAUP, using Maximum Likelihood on the combined data (3285 nucleotides of butterflies and 2173 of plants). We did not find a perfect match between the phylogenies of butterflies and their host plants. Using data on the presence/absence of aristolochic acids in *Aristolochia* we were able to infer that independence of these compounds appeared twice in Troidini evolution. The sister species *Parides zacynthus/P. neophilus* (bootstrap = 100%), use species with and without those compounds, respectively. The next step is to identify which patterns have evolutionary origins and which are obtained by ecological interactions.

Will trichome-based resistance of *Lycopersicon* impair IPM?

AT Simmons, GM Gurr, D McGrath and PM Martin
"PO Box 883, Orange, NSW, 2800, Australia, asimmons@orange.usyd.edu.au"

The Australian tomato (*Lycopersicon esculentum*) industry used pesticides to achieve production estimated at $225.3 million dollars in 2000-2001. Pesticides are still widely used in the industry and can contribute to the degradation of environmental, and human, health. The introduction of trichome-based host plant resistance of wild *Lycopersicon* species into the cultivated tomato has the potential to reduce the use of pesticides and the negative effects associated with their use. The effect of trichome-based host plant resistance on arthropod pests is well documented, though insufficient research has focussed on sub-lethal effects on natural enemies and compatibility with IPM. Natural enemies that are used, or have the potential to be used, in Australian tomato production were exposed to the wild species *L. pennellii, L. hirsutum* and *L. cheesmanii*, and mortality, entrapment and predation/parasitism recorded. Multiple regression analysis was used to determine whether trichomes played a role in mediating observed effects. The implications of trichome-based resistance on IPM will be discussed.

Locusts as model systems: from neurones to swarms to human obesity

SJ Simpson, D Raubenheimer
Department of Zoology, University of Oxford, South Parks Road, Oxford OX1 3PS, UK. stephen.simpson@zoo.ox.ac.uk

Over recent years the study of locusts has made important contributions to a diversity of areas within the field of insect-plant relationships – and more generally within the biological sciences. Some examples include contributions to the study of the neural bases of behaviour, phenotypic plasticity, nutrient balancing, learning, nutrient-allelochemical interactions, evolution of host plant range, optimal foraging and resource allocation theory, individual-based models of population dynamics, ecological stoichiometry and community ecology. State-space models of nutrition that arose from work on locusts have also provided fundamental breakthroughs in the study of human obesity and in the optimal design of diets for farmed animals. In this talk we survey a selection of these and set the scene for other speakers in the symposium.

Of mites and movement: the effect of plant canopy connectedness on biological control

DJ Skirvin, JS Fenlon
"Horticulture Research International, Wellesbourne, Warwick CV35 9EF, UK, david.skirvin@hri.ac.uk"

Successful biological control in ornamental crops in the UK relies on preventing the establishment of pests within the crop. This means that predators have to locate sparsely distributed prey within the crop. The structure of the plant canopy, in terms of both spatial complexity and connectedness will therefore have a major impact on the ability of a predator to locate prey, and this will influence the effectiveness of biological control. Impact of these factors on the ability of a randomly searching predator to locate prey has been investigated using virtual plant software that simulates a range of canopy structures. The results show that both connectedness and spatial complexity play important roles in determining the time to prey location, along with an effect of the number of plants in the canopy. The more connected the crop, the shorter the time to locate prey, but as crop canopy complexity increases, then the time to locate prey increases. This has important implications for the way in which biological control agents are introduced into the crop, and suggest that plant canopy architecture should be taken into consideration when developing biological control strategies.

Host plant-associated genetic differentiation in the snakeweed grasshopper, *Hesperotettix viridis* (Acrididae: Melanoplinae)

GA Sword, A Joern, LB Senior
United States Department of Agriculture, Agricultural Research Service, Northern Plains Agricultural Research Laboratory, 1500 N. Central Ave., Sidney, Montana, 59270, USA, gsword@sidney.ars.usda.gov

Studies of herbivorous insects have played a major role in understanding how ecological divergence can facilitate genetic differentiation. In contrast to the majority of herbivorous insects, grasshoppers as a group are largely polyphagous. Due to the relative lack of intimate grasshopper-plant associations, grasshopper-plant systems have not played a large part in the study of host-associated genetic differentiation. The oligophagous grasshopper, *Hesperotettix viridis* (Thomas), is endemic to North America and feeds on composites (Asteraceae) within the tribe Astercae. Previous work has shown both preference and performance differences between *H. viridis* individuals feeding on either *Solidago mollis* or *Gutierrezia sarothrae.* We examined the genetic relationships among 38 *H. viridis* individuals feeding on these plants both in sympatry and allopatry using 222 AFLP markers. Neighbor-joining analysis resulted in two distinct host-associated clades with 71% bootstrap support for host–associated monophyly. Analyses of molecular variation (AMOVA) revealed significant genetic structuring with host plant accounting for 20% of the total genetic variance while locality accounted for 0%. Significant genetic differentiation was detected between *S. mollis*-feeders and *G. sarothrae*-feeders even when the two were present in sympatry. These results suggest that *H. viridis* as a species is comprised of at least two distinct host plant-associated lineages.

Gene expression in bean plants induced by spider mites

J Takabayashi, R Ozawa, G Arimura, S Kugimiya
"Center for Ecological Research, Kyoto University, Otsu, 520-2113, Japan, junji@ecology.kyoto-u.ac.jp"

When infested by herbivorous arthropods, plants start emitting a blend of volatiles called herbivore-induced plant volatiles (HIPV). One of the ecological functions of HIPV is to attract the carnivorous natual enemies of herbivores. In addition, HIPV can mediate interactions between plants, and between plants ans herbivores. HIPV are knwo to be specific in terms of plant species, herbivore species, developmental stage of herbivores etc., and such specificity can result in the attraction of carnivorous natural enemies of the herbivores. An intriguing question is how plants produce and emit such specific blends of HIPV. To date, several signaling pathways, such as jasmonic acid-, ethylene-, and salicylic acid-related signaling pathway are know to be involved in the production of HIPV. In addition, post-transcriptional regulation may be involved. In this paper, we use a system composed of two bean plants [*Phaseolus lunatus* (lima bean plant) and *Lotus japonicus* (a mdel regume plant)] infested by two spotted spider mites (*Tetranuchus urticae*) to investigate the above question.

The effects of self-pollination on plant defense against insects

JD Tindle, MD Eubanks, DE Carr
"Department of Entomology & Plant Pathology, 301 Funchess Hall, Auburn University, AL 36849, tindljd@auburn.edu"

Self pollination is prevalent among plant species. Self pollination provides plants with reproductive assurance when pollinators are limited and provides a 50% gene transmission advantage. However, self pollination reduces genetic variation, increases the expression of deleterious alleles, and typically results in reduced fitness. This fitness reduction is called inbreeding depression. Understanding factors that increase or decrease the intensity of inbreeding depression is a major objective of plant evolutionary biology. We propose to investigate the effects of inbreeding on anti-herbivore defense in plants. Plants defend themselves through tolerance of and resistance to herbivory. We tested the hypothesis that inbreeding decreases tolerance in the yellow monkeyflower (*Mimulus guttatus*) and that plants compensate for this loss of tolerance by increasing resistance traits such as trichome production. To do this, we conducted experiments that quantified the tolerance and resistance of monkeyflowers to herbivores. Resistance and tolerance tradeoffs are thought to be widespread in plants, but few studies have demonstrated these trade-offs. This study found a significant effect of inbreeding on defense. This effect varied among families. There was also a significant negative correlation between defense traits and herbivore performance.

Flower Visitors of *Annona* spp. in Japan

M Tsukada, H Higuchi, T Furukawa, Y Kato, T Ninomiya, N Suzaki, M Inoue
Faculty of Bioresources, Mie Univ, Mie 514-8507, Japan, tsukada@bio.mie-u.ac.jp

" Bees are commonly used for pollination of agricultural plants. However, for quite a few plants species, they are not available. Annonaceous fruit trees such as cherimoya and atemoya are included to these plants. We surveyed flower visitors of cherimoya and atemoya in Japan to find out potential candidates of pollination agents. The field survey was conducted from 1998 to 2003 at five study sites in Wakayama, Mie and Okinawa prefecture. We found more than 40 species of arthropods most of which were beetles. They were; *Cortinicara gibbosa* (Corticariidae), *Haptoncus luteolus, H. ocularis, Carpophilus marginallus* (Nitidulidae), *Mimemodes monstrosus* (Rhizophagidae), two unknown species of the family Stephylinidae, and others. In addition to beetles, thrips and true bugs were occasionally found. However, no bees or butterflies were found. Flower visitor communities were diverse at family level among the study sites. Total number of individuals were mostly the same for families Corticariidae, Ntitidulidae and Stephylinidae. Number of species was largest in Nitidulidae. The index of diversity H' varied from 0.83 to 1.77, and 1-D from 0.3 to 0.78. The index of similarity of communities, Morishita's C-ramda, ranged between 0.001 to 0.756. The flower visitor communities seemed to reflect communities of surrounding areas.
"

Gene flow risk assessments: laboratory studies of the potential impact of host plant quality and an 'escaped' *Bt* gene from GM oilseed rape on *Pieris brassicae* and *Cotesia glomerata*.

KL Turner, CC Payne, GM Poppy, MJ Wilkinson
"School of Plant Sciences, The University of Reading, Earley Gate, Reading, Berkshire, RG6 6AT, United Kingdom. k.l.turner@reading.ac.uk"

Gene flow from *B. napus* to its wild relative *B. rapa* is the best model system for studying transgene movement between GM and native Brassicas. To accurately assess the potential risks of this scenario, both the effect of plant hybridisation resulting in a change in host plant quality and the direct effect of an 'escaped' gene need to be addressed. Host plant quality can have significant effects on herbivores and their parasitoids. Using commercial oilseed rape *(Brassica napus)*, a wild *B. rapa* population and their hybrid, the biological and behavioural effects on *Pieris brassicae* and *Cotesia glomerata* of host plant variation, have been examined. The main findings indicate that herbivore development varies significantly on the three host plants. No significant effects of host plant were noted during studies of parasitoid biology. The effects resulting from a simulated escape of a *Bacillus thuringiensis (Bt)* toxin were also investigated using interspecies hybrids generated by a *Bt- B.napus* x *B.rapa* cross, as well as fully introgressed offspring. Results showed that the *Bt* gene expressed in these plants had a significant impact on the biology of both the herbivore and parasitoid when compared with control plants in which the gene was not expressed.

Crucifer specialists - clever manipulation of the major host plant defense

H Vogel, U Wittstock, A Ratzka, J Kroymann, J Gershenzon & T Mitchell-Olds
Max Planck Institute for Chemical Ecology, Hans-Knöll-Strasse 8, 07745 Jena, Germany, hvogel@ice.mpg.de

Most known biochemical mechanisms used by insects to overcome plant chemical defenses involve the detoxification of secondary plant products. However, a two-component defense such as the glucosinolate-myrosinase system of cruciferous plants appears to offer additional targets for herbivore interference. In *Plutella xylostella* (diamondback moth, Lepidoptera: Plutellidae) a glucosinolate sulfatase (GSS) in the larval gut prevents the formation of toxic hydrolysis products. In contrast, larvae of *Pieris rapae* (cabbage white butterfly, Lepidoptera: Pieridae), another crucifer specialist, utilize a gut protein designated nitrile-specifier protein (NSP) to redirect the hydrolysis reaction towards the formation of nitriles instead of toxic isothiocyanates. GSS in *P. xylostella* and NSP in *P. rapae* appear to be the key biochemical counteradaptations that allow these insects to feed with impunity on plants containing glucosinolates and myrosinases. This finding sheds light on ecology and evolution of plant-insect interactions and suggests novel, highly selective pest management strategies.

Host plant location: correlating electrophysiology with behaviour

J van den Berg, MA Birkett, K Chamberlain, ZR Khan, JA Pickett, T Toshova, LJ Wadhams, CM Woodcock
"Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom; lester.wadhams@bbsrc.ac.uk"

To understand the mechanism by which the lepidopteran stemborers *Chilo partellus* and *Busseola fusca* are controlled by a "push-pull" strategy in cereal production, chemical signals (semiochemicals), released by the highly attractive trap crops Napier grass, *Pennisetum purpureum*, and blue thatching grass, *Hyparrhenia tamba*, and by maize and sorghum crops, were isolated from the air above the plants using entrainment into a porous polymer. The volatiles collected were analysed by gas chromatography (GC) coupled to electrophysiological preparations from the antennae of the stemborers. Active compounds were identified by GC-mass spectrometry. Significant qualitative and quantitative differences in production were observed between the host plant species and between day and night periods, and could be related to differential attraction of gravid stemborers. These studies are providing understanding of the roles of key semiochemicals in mediating host location by stemborers.

Feeding behavior of whitefly nymphs

G.P Walker, YX Jiang
Department of Entomology, University of California, Riverside, California 92521, USA walker@citrus.ucr.edu

Electrical Penetration Graph (EPG) studies have identified several waveforms produced by nymphs of silverleaf whitefly, *Bemisia argentifolii* Bellows & Perring. One waveform, waveform C, is produced during the stylet pathway from the plant surface to the phloem sieve element. It is similar to the analogous waveform C of adult whiteflies. Three waveforms, J, H, and L are produced after the stylets penetrate a sieve element. Waveform J is the first waveform to appear after penetration of a sieve element; it lasts usually less than a minute and doesn't appear again. After waveform J, waveforms H and L alternate with each other over and over. Waveform H was correlated with honeydew production indicating that waveform H is produced during ingestion. Waveform L is probably correlated with salivation into the sieve element. The transparent nature of silverleaf whitefly nymphs allows observation of muscles operating the stylets, cibarial pump, and salivary pump. Contraction of these muscles was correlated with specific EPG waveform components by using a split-screen video technique where microscopic images of the muscle contractions were recorded on the same video tape with the EPG waveforms that were being simultaneously produced.

Contrasting plant-insect responses in wild and agricultural systems: Unintended influences of crop domestication

SC Welter, Y Chen, S Rao, J Rosenthal
201 Wellman Hall, Berkeley, CA, 94720, USA, welters@nature.berkeley.edu

Multi-trophic studies looking at expected and unexpected changes in plant-insect interactions have revealed both direct effects and indirect system effects. Direct effects from changes in plant resource allocation patterns have altered both plant responses to herbivory through alterations in plant tolerance to damage or decreased plasticity in response to herbivory. Enhanced tolerance to herbivory has been associated with increased allocation to non-reproductive structures in tomato and maize such that optimization of allocation patterns will depend on projected cropping system type and expected damage levels. Similarly, interactions between allocation patterns and changes in photosynthetic potential have interacted to shape the relationships between allocation to plant reproduction and tolerance. Unexpected negative effects of crop domestication on natural enemies via production of physical refugia or changes in semiochemical signatures have been demonstrated in both direct contrasts of wild and domesticated sunflowers or in high-yield strawberry phenotypes. Effects of domestication were dependent on system traits, e.g. nitrogen, such that the conclusions are contextually dependent. Failure to consider fully all three trophic levels in the domestication process appears to have resulted in the failure of native co-evolved natural enemies to regulate their native herbivore host.

Host plant volatiles for the strawberry blossom weevil

A Wibe, H Bichão, J Rohloff, AH Steen, AK Borg-Karlson
"Norwegian Centre for Ecological Agriculture, N-6630 Tingvoll, Norway, atle.wibe@norsok.no"

The strawberry blossom weevil (*Anthonomus rubi*) may cause serious damage on strawberry crops (*Fragaria ananassa*) by cutting the stalk of the flower bud. In order to develop new protection methods for strawberry against insect damage this study aims at identifying plant produced volatiles, detected and used in host location by the strawberry blossom weevil. Plant volatiles of cut green plant parts were extracted on Porapak-Q and analysed by gas chromatography-mass spectrometry. The green leaf volatiles were dominated by hexanol- and hexenyl-type alcohols and esters. Various monoterpenes, sesquiterpenes and aromatic compounds were also identified. When analysing intact leaves by the use of headspace solid-phase microextraction coupled with GC-MS, mainly monoterpenes, sesquiterpenes, aldehydes and long-chain organic acids were detected. Changes in plant volatile, especially by the relese of sesquiterpenes were observed due to mechanical injury in strawberry leaves and flower buds. By the use of gas chromatography linked to electrophysiological recordings the insect antennae have been screened for sensitivity to plant volatiles. The experiments showed sensitivity of the antenna to 18 different compounds, identified as aliphatic ketones, aldehydes and esters, aromatic alcohols and mono- and sesquiterpenes. The behavioural effect to these compounds is now studied in laboratory assay and in the field.

Direct effect of frugivorous invertebrates on seed viability of host plants

AJ Wilson
"School of Natural Resource Sciences, Queensland University of Technology, GPO Box 2434 Brisbane, Qld, Australia 4001.
a36.wilson@student.qut.edu.au"

Frugivorous invertebrates, such as fruit flies, are often assumed to have a negative ecological impact on host plants, in part as a result of the economic loss they cause to cultivated crops. However, this lacks empirical testing. Germination trials were used to quantify the direct effect that *Bactrocera tryoni* (Froggatt) (Diptera: Tephritidae) has on seed production and viability of three host plants from the family *Solanaceae*. Tomato, capsicum and eggplant were selected as host plants to challenge the movement and proximity of larvae to seeds with their different spatial arrangements between seeds and flesh. Successful germination of infested and control fruits was compared for the proportion of the total crop of fruits infested and the proportion of individual fruits infested. Results suggest that *Bactrocera tryoni* are not detrimental to seed viability and do not reduce seed number in these hosts. Although the plants used in these trials do not have an evolutionary history with *B. tryoni*, the results suggest economic damage cannot be equated to reduced fitness in these hosts and evolutionary interactions between fruit flies and their larval host plants need to be reassessed.

Differences in species richness of galling aphids on *Pistacia*: selection of hosts or selection by hosts?

D Wool
"Department of Zoology, Tel Aviv University, Tel Aviv 69978, Israel, davidw@tauex.tau.ac.il"

Three species of *Pistacia* (Anacardiaceae) are common in Israel. *P. palaestina* and *P. atlantica* each host 6-9 host specific galling aphids (Homoptera; Pemphigidae: Fordinae). In contrast, *P. lentiscus* is colonized by only one species, *Aploneura lentisci*. Selection of hosts: The colonizing sexuparae do not distinguish between species of *Pistacia* and frequently land on the wrong host. The reddish color of the new foliage may distinguish the deciduous *P. palaestina* and *P. atlantica* from the evergreen *P. lentiscus* in the spring. Selection by hosts: Different response of the host plant to stimulation by fundatrices of different aphid species is possible. Resin in the phloem of *Pistacia* may be a barrier for the phloem-feeding Fordinae. *P. lentiscus* in particular produces commercially-exploitable quantities of resin. *A. lentisci* may have evolved a unique mechanism to exploit this host. Phylogeny. The phylogeny of the Fordinae suggests several host shifts during their evolution. None of these shifts involved *P. lentiscus*, which belongs taxonomically to a different group of *Pistacia*. It is possible that the difference in species richness is a phylogenetic trait.

Host range and life history strategy of *Asphondylia sphaera* Monzen (Diptera: Cecidomyiidae): utilization of *Rhus* species (Anacardiaceae) as momentary side hosts besides main annual hosts, *Ligustrum* species (Oleaceae)

J Yukawa, N Uechi
Entomological Laboratory, Faculty of Agriculture, Kyushu University, Fukuoka 812-8581, Japan, JZS02305@nifty.ne.jp

The majority of *Asphondylia sphaera* (Diptera: Cecidomyiidae) individuals are univoltine and oligophagous, inducing fruit galls on *Ligustrum obtusifolium*, *L. japonicum*, *L. lucidum*, and *L. ovalifolium* (Oleaceae) in Japan. However, some emergent early spring individuals have two generations a year, utilizing flower buds of *L. japonicum* for the first generation from May to June and fruit for the second from June to the following May. The current field surveys and DNA sequence data revealed that the emergent early spring individuals also utilized, for galling, the flower buds of *Rhus succedanea* and *R. sylvestris* (Anacardiaceae) from May to June. Adults emerged from the flower-bud galls on *Rhus* were considered to return to *Ligustrum* and to join the univoltine or bivoltine individuals of *A. sphaera* inhabiting fruit galls on *Ligustrum* spp. Thus, *A. sphaera* is regarded as a polyphagous species, galling on plant species belonging to different botanical families, Oleaceae and Anacardiaceae. However, the polyphagy of *A. sphaera* is neither seasonal host alternation as has been noted for other *Asphondylia* species nor simultaneous utilization of plural plant families throughout the year. *Asphondylia sphaera* exhibits 'momentary polyphagy', utilizing *Rhus* species only in early summer as momentary side host plants.

The face of furanocoumarin induction in wild parsnip

AR Zangerl
"Department of Entomology, University of Illinois at Urbana-Champaign, 320 Morrill Hall, 505 S. Goodwin, Urbana, IL 61801, USA.
azangerl@life.uiuc.edu"

Although most, if not all, plants possess some form of inducible defense, detailed knowledge of the causes and consequences of induction are known only for a few plants. Among those few is wild parsnip, in which genotoxic furanocoumarins are produced in all organs of the plant but are inducible only in a subset of them. Induction of furanocoumarins in leaves is particularly amenable to examination. A novel method of precisely mapping the spatial distribution of furanocoumarins in leaves reveals that furanocoumarin induction is limited to those injuries that disturb the integrity of furanocoumarin-bearing oil tubes. The consequences of furanocoumarin induction include benefits-deterrency and toxicity--as well as costs for synthesis and reduced photosynthesis and growth. The furanocoumarin defense is not effective against all folivores, but its mobilization appears to conform to classical optimal defense theory.

The conservation genetics of endangered mutualisms: increased genetic differentiation and reduced effective population sizes in specialist bees.

A Zayed, L Packer
Department of Biology, York University, Toronto ON, M3J 1P3, Canada, azayed@yorku.ca

Oligolectic bees collect pollen from one or a few closely related species of plants, while polylectic bees visit a variety of flowers. Because of their more restricted range of host plants, it may be expected that specialists exist in more isolated populations, with lower effective population sizes (Ne) than do generalists. We tested this hypothesis by examining levels of genetic variation in five phylogenetically independent oligolectic/polylectic species pairs. Within each pair, the oligolectic member had fewer polymorphic loci, lower allelic richness, and lower expected heterozygosity than its polylectic relative. The pattern of reduced genetic variation in specialists was statistically significant. We also tested the hypothesis of greater isolation of specialist populations by comparing levels of genetic differentiation in one species pair. Again, populations of the specialist species had significantly higher levels of genetic differentiation than those of the generalist over identical geographic distances. Our data support the hypothesis of greater isolation and lower Ne in specialist populations, making them more prone to extinction. We suggest that in instances where bee specialists are involved in mutually codependent relationships with their floral host, these mutualisms may be endangered for genetic and ecological reasons.

Insect feeding behavior as a marker to evaluate the compatibility of different elicitors of plant resistance

AJ Nichols, GW Zehnder
"Department of Entomology, 114 Long Hall, Clemson University, Clemson, SC, USA, zehnder@clemson.edu"

This work focused on interactions involving systemic acquired resistance (SAR) and induced systemic resistance (ISR). Laboratory experiments were done to compare the effects of plant growth promoting rhizobacteria (PGPR), an elicitor of ISR, and ActigardÔ, an elicitor of SAR, and combinations on feeding behavior of cucumber beetles and aphids. Results of cage experiments with cucumber indicated that cucumber beetle feeding was significantly greater on ActigardÔ-treated plants than on untreated control plants. However, the combination of PGPR plus ActigardÔ resulted in significantly lower feeding damage than occurred with ActigardÔ alone; suggesting that simultaneous induction of ISR by PGPR mitigated the stimulatory effect of ActigardÔ. Additional experiments to compare PGPR and ActigardÔ treatment effects on aphid feeding behavior were conducted using electronic monitoring of insect feeding (EMIF) techniques. Results of the EMIF experiments indicated that aphids feeding on cucumber plants where SAR was elicited by ActigardÔ exhibited an increased number of stylet probes and spent less time in phloem than aphids on untreated plants. As in the cucumber experiments, simultaneous induction of ISR by PGPR (in the combination treatments) mitigated this effect.

Analysis of quantitative trait loci for stem borer resistance in a DH rice mapping population

ZR Zhu, MB Cohen, A Romena, K Teng, JA Cheng
Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Lu, Hangzhou, Zhejiang, 310029, China. International Rice Research Institute, Los Banos, laguna, Philippines. zrzhu@zju.edu.cn

In order to better understand the genetic basis of rice stem borer [mainly *Chilo suppealis* (Walker)] resistance in rice, efforts to identify the quantitative trait loci (QTL) related to the stem borer resistance have been done. The phenotype trials of resistance to the stem borer were tested in 1 subtropical and 2 tropical environments (totally three seasons). We mapped the stem borer resistance in a doubled-haploid rice (*Oryza sativa* L.) population of 154 lines [CT9993-5-10-1-M (CT9993)/IR62266-42-6-2 (IR62266)]. A genetic linkage map with 315 DNA marker loci was applied. A mixed linear model approach was used to detect QTLs with main effects, QTLs involved in digenic epistatic interactions and QTL by environment interactions (QEs). Several main-effect quantitative trait loci (QTLs) that related to rice stem borer damage traits (dead heart (DH) and white head (WH)) were identified. Among them loci located in intervals G187 – ME2_11 - EM14_1 - RZ997 in Chromosome 8, RM219 - RG553 - EM14_6 in Chromosome 9, C813 – EM11_11 – RG109 – ME10_14 in Chromosome 1 were repeatedly identified main effect QTLs. Each trait normally has several pairs of epistatic loci, QEs, and additive * epistatic * environment interactions. These results are helpful for fine mapping the stem borer resistance QTLs in rice and marker assisted selection in the future.

EPG evidence for local suppression of induced resistance by aphids

The Entry of Whiteflies into Greenhouses – Distribution in Time and Space.

Dr D. Ben-Yakir, Dr M.J. Berlinger, Dr M. Teitel, M. Chen, M. Barak
P.O. Box 6, BET-DAGAN, 50250, ISRAEL, benyak@volcani.agri.gov.il

We determined the distribution of the sweet potato whitefly, *Bemisia tabaci*, outside and inside a greenhouse (inside area 1000m^2) equipped with side windows covered with 50-mesh screens and four open roof vents. The study was in the Northern Negev region of Israel during the fall season of three years. Outside the greenhouse significantly higher numbers of whiteflies were trapped on the down-wind side. Both outside and inside, 70% of the whiteflies were caught between 7:00 to 10:00 and 25% were caught between 10:00 to 13:00. Inside the greenhouse, most whiteflies were caught under the roof vents. The number of whiteflies caught under the roof vents and the number of tomato plants infected with TYLCV were significantly higher under roof vents at the down-wind side. Under our experimental conditions air was usually sucked into the greenhouse through vent located down-wind and exhausted through the vent located up-wind. Our results indicate that roof vents were the major port of entry of whiteflies in this greenhouse. It appears that the pattern of air movement through the roof vents determined the spatial distribution of the whiteflies in the greenhouse. This information may be used to reduce the risk of whiteflies entry and establishment.

Pollinator-mediated effects of leaf damage on plant fitness

S.Y. Strauss
Section of Evolution and Ecology, UC Davis, 2320 Storer Hall, One Shields Ave, Davis, CA 95616 USA email: systrauss@ucdavis.edu

The effects of herbivores on non-seedling plants are almost always non-lethal, but can still have large impacts on plant fitness via both direct and indirect pathways. When plants are attacked by herbivores, a cascade of responses typically ensues. Common plant reactions to foliar damage include altered allocation to root: shoot biomass, short-term increases in photosynthetic rate, and the induction of costly structural and chemical defenses in plant tissues. Less well documented, but perhaps more prevalent than originally thought, are changes in allocation to reproductive structures like floral size and rewards after damage. Moreover, induced chemical defenses are often systemic and may enter into floral traits and rewards. Changes in plant morphology and chemistry after damage, in turn, can modify the responses of pollinators to damaged plants. The ability of plants to recover seed production or to export pollen after damage may be hampered indirectly by pollinator limitation, as well as directly by resource limitation. In this chapter, I will review the literature and discuss some of my own experiments that point to pollinator-mediated effects of leaf damage on plant fitness. Such trait-mediated indirect effects of damage may be important sources of fitness costs to plants.

How aphid colonization indirectly affects early-and late-emerging herbivorous insects on the tall goldenrod

Y Ando, T Ohgushi
Center for Ecological Research, Kyoto University, Kamitanakami, Otsu, 520-2113, Japan; ando@ecology.kyoto-u.ac.jp

We investigated insect communities on a perennial forb *Solidago altissima* in Japan. The most dominant species was an aphid *Uroleucon nigrotuberculatum,* which mainly occurred from June to August. The aphid was tended by an ant *Formica japonica* for honeydew. Moreover, the aphid colonization induced rapid branching and increased the production of new leaves in October. Therefore, we hypothesized that the aphid colonization indirectly affected not only co-occurring herbivorous insects through removal behavior by the attending ants, but also temporally-separated insects in autumn. To test this hypothesis, we conducted an aphid exclusion experiment. The aphids negatively affected the abundance of caterpillars and leafhoppers by the excluding behavior of the attending ants in early season. On the other hand, the aphids also affected the abundance of temporally-separated insects, such as scale insects and grasshoppers, in late season. Prior sucking by the aphids decreased the density of scale insects. The decreased scale insects may be due to changes in plant quality by the feeding of aphids in early season. The decreased density of scale insects resulted in a reduction of density of the attending ants to scale insects. Therefore, the density of grasshoppers increased because of the low impacts of tending ants.

Ecological stress of aldicarb on soil arthropods associated with coffee plantations.

C.S. Bastos, M. C. Picanço, R. N. C. Guedes, C. A. Badjii, H. E. P. Martinez.
Rua São Paulo, no. 790, Primavera do leste, mt, Brazil, 78850-000; cristina@cnpa.embrapa.br

Soil arthropods have been considered by various authors as good indicators of environmental effect of pesticides. This study aimed to evaluate the impact of a systemic insecticide (aldicarb) on soil arthropods associated with coffee plantations. The experiment encompassed three treatments (control, 1 application – 10 g of Temik 150 (aldicarb)/plant applied in 12/16/1999 and two applications - 10 g/plant applied in 12/16/1999 and 10g/plant applied in 03/01/2000) and four blocks, evaluated once before insecticide application and at 13 different days after the insecticide application. It was measured the soil arthropod densities found in berleze traps and the data was submitted to multivariate techniques. The days of evaluation were considered as treatments replicates through time and the generated data set was analyzed by canonical correlation and redundancy analyses and multivariate repeated analysis. Aldicarb effect on the assemblage of soil arthropods was significant and the main group impacted was Acarinae: Galuminidae. As the variation on the abundance of the coffee soil arthropods community could not be explained by the variation in weather conditions, it is suggested that the insecticide was the major factor causing the effects described previously.

Two genetically distinct lines co-exist in populations of the endoparasitoid *Venturia canescens* **.**

HSL Roberts, A Reineke, O True, J Belatti and O Schmidt
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia; otto.schmidt@adelaide.edu.au

In a laboratory colony of the solitary endoparasitoid *Venturia canescens* (Hymenoptera: Ichneumonidae) two genetically distinct lines (named RP and RM) appear to coexist sympatrically. The two lines differ in a cluster of phenotypic characters, including ovarian morphology, parasitism behaviour and reproductive success. Controlled oviposition experiments showed that RM females produce fewer offspring under single egg parasitism but more under con-specific superparasitism, compared to RP wasps. Investigations of interlarval combat under *in vitro* conditions showed that the higher reproductive success of the RM line under conspecific superparasitism is due to a physiological difference between the newly hatched larvae of the two lines which results in an advantage to the RM larva independent of the order or time interval between ovipositions. Examination of field-derived wasps has found that wasps displaying the two phenotypic clusters occur in natural populations. A model, using an iterative approach with experimental data to predict the stable composition in a mixed population of wasps displaying RM and RP, suggests that the two lines will coexist sympatrically when overall rates of superparasitism are greater than 5 to 10%.

Effects of understorey diversity in pine plantations on pest Lepidoptera and their natural enemies

LA Berndt, EG Brockerhoff, H Jactel
Forest Research, PO Box 29 237, Fendalton, Christchurch, New Zealand; lisa.berndt@forestresearch.co.nz

Biodiversity in plantation forests is becoming more important to forest managers as government policy and foreign markets increasingly demand evidence of sustainable management of these forests. Protecting indigenous biodiversity not only assists in conservation efforts, but may also play a role in ecosystem functioning, leading to a reduction in the risk of pest outbreaks. In this study we investigate the effects of indigenous and exotic floral diversity in the understorey of a pine plantation in Canterbury, New Zealand, on pest Lepidoptera and their predators. Of particular interest is the native geometrid *Pseudocoremia suavis,* which has caused major defoliation in pine plantations in the past, and carabid beetles, which may prey on moth pupae. The data suggest that moths are more abundant where the understorey is less diverse, and that carabid diversity in pitfall traps is greater with increased understorey diversity. These results indicate a benefit of increased understorey diversity in plantations

Life cycles of some ground beetles (Coleoptera: Carabidae) in Kuban-Azov lowland (South Russia).

E Bokhovko,
Department of Entomology, Faculty of biology, Moscow State University Moscow, 119992 Russia; bokhovko@yahoo.com

We studied seasonal dynamics, spatial distribution, reproductive cycles of five widespread (*Harpalus (*s. str.*) rufipes* Deg., *H. tardus* Pz., *Brachinus elegans, Br. psophia* Dej., *Br. explodens* (Duft.)) and one endemic (*Carabus exaratus* Quens.) species of ground beetles in agrolandscape of Kuban-Azov lowland. Life cycles of *Br. elegans, Br. psophia* and *Br. explodens* are monovoltine (one year with overwintering imago). Life cycle of *C. exaratus* is supposed to be similar to those of the former species, however it also includes overwintering larvae of last ages. In this area, the life cycles of *H. rufipes* and *H. tardus* are realized as annual with two variants: summer reproduction and overwintering imago and summer-autumn reproduction and overwintering larvae. The life cycles of the later two species are supposed to be the more flexible in relation to environmental factors.

RECULTIVATION OF POST MINING AREAS WITH *QUERCUS RUBRA* – THE SUCCESSION OF GROUND BEETLE COMMUNITIES

I. BRUNK[1]*

[1] Dept. of General Ecology, Institute of Environmental Management, BTU Cottbus, PO Box 101344, 03013 Cottbus, Germany; E-mail address: brunkin@tu-cottbus.de

In the Lusatian mining area situated in the East of Germany, lignite mining has been practiced for nearly 150 years. An area of more than 80.000 ha, has been utilized so far for open cast mining. The investigated sites are found on acidic lignite rich tertiary sands characterized by extreme abiotic soil conditions (low soil pH). After dumping, amelioration and fertilisation, a large amount of spoils were claimed by afforestation. According to the extreme soil conditions, various tree species were put to the test for afforestation. Only little is known about the ground beetle communities of afforestations of alien plant species stands such as Red Oak (Kolbe 1992). In 1994, Red Oak stands (*Quercus rubra*) formed nearly 12 % of the recent tree distribution on post mining landscapes in the Lusatian mining area. The succession of ground beetle communities of afforested and Red Oak stands in the Lusatian mining area was studied using the chronosequence method. Mainly grass dominated (*Calamagrostis*, *Festuca*, *Poa*) afforestations are colonized in high species numbers and abundances. The species composition of the afforestations was mainly influenced by the species compositions of the surrounding areas. Xerobiontic to moderate xerophilous, heliophilous openland species, like *Calathus erratus* and *C. ambiguus* or *C. fuscipes* are dominating. With increasing age of the stands the ground beetle communities changed from typical openland communities to woodland communities. Species composition in the 20 to 30 year old Red Oak stands differs from those in afforestations. In these Red Oak stands are to be found the lowest activity densities and biomasses of the chronosequence. This corresponds to results of Kielhorn & Keplin (1999) and Vogel & Dunger (1991), carried out in studies on ground beetle communities of the Lusatian mining area. Possibly the combination of extreme site conditions (dryness, low pH of soil) with a very close canopy of Red Oaks (85 - 95 % of this strata), very reduced plant diversity of herbs, and very reduced cover of herbs (1 - 5 % of this strata) are difficult for colonisation of phytophagous insects and therefore also for the mainly zoophagous ground beetles. The species composition of nearly 40 year old Red Oak stands on reclaimed soils in comparison to the reference stands (ALT) differ in habitat and shade preferences, but is in accordance with the humidity preferences of a Oak stand on the reference sites. In the older stands of the chronosequence and at the reference sites numerous large ground beetles like *Pterostichus niger* and *Carabus spec.* were found to be dominant. Dunger (1997) and Wanner & Dunger (2002) found for some groups underdeveloped soil arthropod communities on reclaimed sites on the pyrite rich Lower Lusatian spoils low. The quantitative aspect is remarkable, especially in comparison to the Upper Lusatian Area. The body length of the ground beetles is also an important factor for preying, and it is adapted to size of preferred prey.Some small species with low dispersal abilities have not been found on the sites on reclaimed soils until now. Possibly they have not yet colonised these sites. *Dyschirius globosus* for example has a small dispersal ability. We found this species in Red Oak stands on at disturbed sites, but it is still missing in the chronosequence stands on former mining sites. Within 40 years after reclaiming and planting, we found ground beetle communities which are, according to species numbers and humidity preferences, comparable to communities on Red Oak stands on undisturbed soils. Activity densities and biomasses of ground beetle communities are after 40 years of colonisation lower than activity densities and biomass on undisturbed soils. There are also still differences within the shade preferences and main habitat types between communities on reclaimed and not disturbed land.

Predicting the potential distribution of *Sirex noctilio* (Hymenoptera: Siricidae), a significant exotic pest of *Pinus* plantations.

AJ Carnegie, M Matsuki, B Hurley, R Ahumada, DA Haugen, P Klasmer, Jianghua Sun
Research & Development Division, State Forests of NSW, PO Box 100, Beecroft, NSW, 2119, Australia; E-mail angusc@sf.nsw.gov.au

Sirex woodwasp (*Sirex noctilio*) is not considered an important pest in its native range, however, where it has become established in the Southern Hemisphere it has become a significant pest of exotic *Pinus* plantations. The potential distribution of *S. noctilio* in Australia, South America, Africa, North America and China was assessed from a study of the insect's potential distribution and host range using the climate-matching program CLIMEX. *Sirex noctilio* is predicted to be able to establish in the majority of commercial *Pinus* plantations in Australia, South America (Uruguay, Brazil, Argentina, Chile, Paraguay) and Africa (South Africa, Zimbabwe, Tanzania, Uganda and Ethiopa) over the next 25 years. In China, *S. noctilio* is predicted to be able to persist in many areas where large-scale afforestation of susceptible hosts has occurred and is planned. Restriction of movement of infested logs and the Sirex Management Strategy will help reduce the impact of *S. noctilio* in Australia, South America, Africa and China. *Sirex noctilio* is predicted to be able to persist in many areas in North America, where large tracts of land are occupied by susceptible hosts in native forests. Exclusion of *S. noctilio* is the only feasible approach in Northern America.

Bracon vulgaris Ashmead (Hymenoptera:Braconidae) parasitism avaliation in two pests in different parts of cotton plants in Ilha Solteira, São Paulo, Brazil.

SL Carvalho
Department of Biology and Zootecny, FEIS/UNESP, Av. Brasil 56, 15385-000 – Ilha Solteira/SP – Brazil; e-mail: sergicar@bio.feis.unesp.br

The objective of this work was to investigate ecological aspects of *Bracon vulgaris* Ashmead (Hymenoptera: Braconidae) an ectoparasite of both *Anthonomus grandis* Boheman, 1843 (Coleoptera: Curculionidae), the boll weevil, and Pectinophora *gossypiela* Saunders, 1843 (Lepidoptera: Gelechiidae), the pink bollworm, key pests of cotton culture, in several countries of the world, including Brazil. The investigations were conducted in 1996 and 1997 in an untreated area at the UNESP Farm in Ilha Solteira (São Paulo state). The samplings were made of weekly collections of reproductive structures of the cotton (cotton squares, flowers and cotton bolls), from the third superior, medium and inferior parts. These structures were examined using stereoscope in the laboratory for the presence of eggs, larvae, pupae or adults of the parasite. Parasite population fluctuated with the host population with tendency to increase in parasitism from the middle to the end of the crop cycle reaching a maximum of 61.5% in boll weevil larvae in the superior third and 22,2% in pink boll worm larvae in the medium third. The parasite, demonstrated to possess great conditions for contributing to Integrated Pest Control Management in cotton allowing for preservation of the natural environment.

Life Tables of the Parasitoid ***Aphidius gifuensis*** **Ashmead and its Host** ***Myzus persicae*** **(Sulzer)**

H Chi, HY Su.
PO Box 17-25, Taichung 40098, Taiwan; hsinchi@agon.nchu.edu.tw

The life history data for both the parasitoid *Aphidius gifuensis* Ashmead and its host *Myzus persicae* (Sulzer) were collected in the laboratory. To take both sexes and the variable developmental rate among individuals into consideration, the raw data were analysed based on the age-stage, two-sex life table. The intrinsic rate of increase for *A. gifuensis* is 0.246/day. The net reproductive rate is 46.1 offspring and the mean generation time is 15.6 days. To incorporate the parasitism rate with the two-sex life table, the daily parasitism rate of *A. gifuensis* was collected for individual female. The mean parasitism rate is 92.3 aphids/female. The intrinsic rate of increase for *M. persicae* is 0.233/day. The net reproductive rate is 29.4 offspring and the mean generation time is 14.5 days. The net parasitism rate for *A. gifuensis* on *M. persicae* is 46.2 aphids.

Spatial heterogeneity affects spider assemblages in a desert agroecosystem

E Gavish, Y Lubin, M Coll
Department of Entomology, The Hebrew University of Jerusalem, PO Box 12 Rehovot 76100 Israel, coll@agri.huji.ac.il.

Desert agroecosystems are characterized by extreme differences in productivity, microclimate and habitat structure between the managed fields and the surrounding natural habitats. These differences may affect crop colonization by potential natural enemies such as spiders. We collected spiders from winter wheat fields and the surrounding natural habitats in the Negev desert in southern Israel and used pitfall traps, emergence traps and visual searching to determine species composition and relative abundance of spiders in this agroecosystem. Data show that there are three dominant families in the fields during the growing season: Linyphiidae are residents in the fields, and Gnaphosidae and Theridiidae are migrants from surrounding natural habitats and must colonize the crops each growing season. Linyphiide spiders survive in the fallow fields between successive crops. Indeed, only species belong to this family complete a full life cycle, from eggs to reproducing adults, during a single growing season. Implications for the role of spiders as natural enemies in desert agroecosystems are discussed.

Population variability of leaf beetles in managed and natural willow stands

P Dalin, C Björkman, O Kindvall
Department of Entomology, Swedish University of Agricultural Sciences, P.O. Box 7044, S-750 07 Uppsala, Sweden; E-mail: Peter.Dalin@entom.slu.se

It is generally believed that insect outbreaks more frequently occur in managed systems, such as forest plantations and crop fields, than in natural and diverse systems. In this study we compare fluctuations in leaf beetle (*Phratora vulgatissima*) population density between willow (*Salix viminalis*) plantations and natural willow (*Salix cinerea*) stands. The primary aim was to test the diversity-stability hypothesis, assuming that plantations are less diverse than natural stands. Density of leaf beetles was measured in 20 willow plantations and in 22 natural willow stands for five years. Densities of main predators (e.g. omnivorous heteropterans) and two habitat diversity indices (plant species diversity and stand structural complexity) were estimated. Leaf beetle populations were, on average, as variable in managed willow plantations as in natural willow stands. Neither were there any significant relationships between habitat diversity and population stability of leaf beetles. The highest variability was found in some of the willow plantations where the leaf beetle went from relatively low density to high outbreak density within a few years. This pattern was not observed in any of the natural willow stands. Leaf beetle outbreaks were correlated with a low abundance of predators.

Temporal-spatial patterns of beetles and planthoppers across grass-heather mosaics in upland Scotland

P Dennis, K Beaton
Macaulay Institute, Craigiebuckler, Aberdeen, Ab15 8qh, Scotland, UK; P.Dennis@Macaulay.Ac.Uk

Grazing herbivores alter plant species composition and structure in upland indigenous biotopes. They do not uniformly forage and will typically select sheltered areas, feed in preferred patches and on favoured plant species within these. We are investigating how insects respond to the spatial heterogeneity of vegetation mosaics generated by domesticated sheep or wild red deer. We hypothesised that the size and structure of grass and heather patches would alter the distribution of insect species by affecting their rates of movement and ability to locate certain patches in the mosaic. We studied the distribution of small planthopper species, during their sedentary nymphal stage, on transects positioned across patch boundaries. The movement of large predatory ground beetles was recorded using a harmonic radar tracking system. The distribution of planthopper nymphs closely reflected the patterns of host plants, whether grasses or shrub species. The sinuosity of movement of predatory beetles did not differ between individual grass or heather patches but was significantly different across grass-heather mosaics of different grazing history. A trade-off was apparent for patch use by beetles between structural complexity and predation risk. We interpret these results to provide insight into the conservation of general insect diversity with grazing management.

Modelling the population dynamics of *Helicoverpa armigera* (Hübner) in Punjab, India

VK Dilawari, Baljinder Singh, Beant Singh, MP Zalucki
Department of Entomology, Punjab Agricultural University. Ludhiana-141004, Punjab, India; vkdil@yahoo.com

A simple population dynamics model was developed to predict the incidence of *Helicoverpa armigera* (Hübner) on cotton using DYMEX (CSIRO, 1999). It is a computer package that enables interactive modelling of fluctuating populations of organisms in changing environments and has been used to model the population dynamics of *H.armigera* species and to describe the environment in which organisms exist. The prevailing weather conditions (minimum and maximum temperatures, morning and evening humidity) during *Rabi* (y season) 2002-03 were found to be similar to *Rabi* 1993-94 ($p< 0.01$). Therefore, Dymex was run for 1993-94 and 2002-03 *Rabi* season. Observed peaks of *Helicoverpa* incidence in 1993-94 coincided with the peaks simulated using Dymex. The validity of the model was verified by comparing the expected and observed moth populations during *Rabi* 2002-03 seasons. The expected number of adults were statistically non-significant ($P=<0.01$) with that of observed ones. Assuming that the weather conditions during the rest of 2003 might follow trends similar to those in 1994, incidence of *Helicoverpa* was predicted for the *Kharif* (wet season) 2003 season using weather file of 1994. The model was later validated using weather file of 2003 *Kharif* season. The peaks of *Helicoverpa* incidence again coincided with simulated ones ($p < 0.01$).

Humidity and host-plant as important factors influencing the pre-imaginal development of fruit flies (Diptera: Tephritidae)

PF Duyck, P David, S Glénac, S Quilici
UMR « Peuplements végétaux et bio-agresseurs en milieu tropical », CIRAD Pôle de Protection des Plantes (3P), 7 Chemin de l'IRAT, 97410 Saint-Pierre (France) ; duyck@cirad.fr

In Reunion Island, four species of fruit flies (Diptera: Tephritidae) cause damages on fruit crops namely the Mascarenes fruit fly, *Ceratitis catoirii* (Guérin Mèneville), the Mediterranean fruit fly, *C. capitata* (Wiedemann), the Natal fruit fly, *C. rosa* Karsch and the recent invasive peach fruit fly, *Bactrocera zonata* (Saunders). The influence of four important host fruit (guava, *Psidium guava* L., strawberry guava, *Psidium cattleyanum* Sabine mango, *Mangifera indica* L. and Indian almond, *Terminalia catappa* L.) on larval development and of a range of relative humidity on pupal development and the influence have been studied in the laboratory. Larval host had strong effects on survival, developmental times and pupal sizes (that possibly have consequences on fecundity of the female in the same generation). Humidity, especially low levels (30 and 50 %RH), had very important effect on survival depending on the fruit fly species. Indeed, *C. capitata* and *B. zonata* showed a high tolerance to dryness contrary to *C. catoirii* and *C. rosa*. These fruit fly species live in different ecological niches that can overlap. Results of this study are discussed according to the current distribution of these four fruit flies species in Reunion Island. Predictions can be also made on the future distribution of the invasive peach fruit fly.

Diversity, structure and composition of flying insects captured in fragment and continuos forests in the high Andean forest on the South West Sabana de Bogotá (Colombia).

P Acero, G Fagua, J Pérez-Torres
Carrera 7ª No 43-82, Pontificia Universidad Javeriana, Edificio 53; Bogotá, Colombia, fagua@javeriana.edu.co

The structure and composition of flying insects in parcels of high Andean forest fragments and continuous was studied. A description of the morphotypes captured in omnidirectional and Malaisse traps was made. Species richness was measured (richness, estimators and Margaleff index) and Jaccard and Bray-Curtis similarity indexes were used to compare the composition by localities and traps; distribution models were used like structure descriptors. No differences were found between the insects collected in parcels of continuous forest (San Cayetano and La Selva) and those of fragmented forest (Miralejos and Silencio). The composition varied according to the used traps, thus being complementary methods, and the species richness differs between the four sites, being San Cayetano the site with the greater richness and La Selva the less. The richness estimators showed that the sampling was of low efficiency and logarithmic serial showed to be the most appropriated model. For Omnidirectional traps, Scolytidae (Coleoptera) was predominant, and for Malaisse Cecidomyiidae, Sciaridae and Phoridae (Diptera). The abundance of the community varied temporarily. One concludes that the communities partially reflect the differences attributable to the characteristics of the degree of conservation of forests and fragments.

Edge effect in the structure and composition of papilionoideos (Lepidoptera) of Andean forest at Sabana de Bogotá

Biol: S Tavera, s:_G Fagua, J Pérez-Torres.
Carrera 7ª No 43-82, Universidad Javeriana, Edificio 53; Bogotá, Colombia; fagua@javeriana.edu.co

The composition and structure of the butterfly community to different distances from the edge was studied in two areas of high mountain forest. Four transects were drew toward forest respect to the edge (-60 to 150m), with one sampling station each 30 m; a control transect was located to 300 m in the forest interior. Traps, net and visual observation (at a perpendicular transect of 50 m by station) were used. 54 species were obtained (n=1346) in an efficient sampling (80% Chao 1). The edge showed the nearest value richness to the expected. The composition and abundance were organized in three groups of stations (external, edge and internal) by Jaccard and Bray-Curtis index. The richness and the diversity was greater in the edge according to observations and captures, the traps don't have differences in the gradient. The distribution of abundances followed the geometric, logarithmic and broken-stick models (external stations, edge and interior respectively). For butterflies, the edge effect positively penetrates until 60 m like minimum, affecting the richness and diversity of the edge; the forest act like a source of species for the edge. Useful species were identified to evaluate the penetration of the edge effect in Andean Forest.

Life table and demographic parameters of the "lettuce aphid" *Nasonovia ribisnigri* Mosley

BM Díaz, A Fereres
Departamento de Protección Vegetal, Centro de Ciencias Medioambientales, CSIC. C/Serrano 115 dpdo. 28006 Maid, Spain; afereres@ccma.csic.es

The objective of this study was to evaluate the development, survivorship and fecundity of *Nasonovia ribisnigri* (Mosley) at seven constant temperatures (8, 12, 16, 20, 24, 26, 28ºC) under laboratory conditions. The results obtained show that the proportion of alatae increased with increasing temperatures (T), remaining below 7% at T£16ºC and increasing to 40-57% at T³20ºC. The highest developmental period of apterae was obtained at 8ºC (31.5 days) and the lowest was at 26ºC (6.2 days), while the developmental time of alatae was approximately one day longer than for apterae at each of the constant temperatures used in the study. The survivorship of immature stages was always above 90% at the temperature range of 12-26ºC. However, the survivorship decreased dramatically at 28ºC (15%). The largest intrinsic rate of natural increase, r_m occurred at 24ºC (0.329) and the lowest at 8ºC (0.070). Unexpectedly, no nymphs were produced by adult morphs at 28ºC. The highest gross reproductive rate (åmx) and net replacement rate (*R*o) of *N. ribisnigri* occurred at 20ºC.The minimum and maximum developmental thresholds for apterae and alatae were calculated to develop a degree-day based model for this aphid species.

Population dynamics of aphid species colonising lettuce crops in Central Spain and identification of their associated parasitoids

M Nebreda, JM Michelena and A Fereres
Departamento de Protección Vegetal, Centro de Ciencias Medioambientales (CSIC). C/ Serrano 115 Dpdo. 28006. Maid (Spain); afereres@ccma.csic.es

Aphid species colonising lettuce crops and their associated parasitoids were monitored during the spring and autumn growing seasons of 2001 and 2002 in Central Spain (Navalcarnero, Maid). Plants were sampled randomly following a zig-zag pattern by visual inspection at weekly intervals. The most abundant aphid species in both spring and autumn crops was *Nasonovia ribisnigri*, reaching the following peak densities at the end of each growing season: 80 individuals/plant in spring and 50 individuals/plant in autumn of 2001, and 132 individuals/plant in spring and 18 individuals/plant in autumn of 2002. The second major species present was *Macrosiphum euphorbiae*, reaching its peak density at the beginning of spring (2 and 0.3 individuals/plant in 2001 and 2002, respectively). In autumn, however, *Aulacorthum solani* was the second most abundant species reaching a peak density of 11 and 5 individuals/plant in 2001 and 2002, respectively. Three species of parasitic wasps (Hymenoptera: Aphidiinae) were identified from mummies of *N. ribisnigri* collected in lettuce crops: *Aphidius hieraciorum*, *Aphidius ervi* and *Aphidius colemani* . This is the first citation of *A. hieraciorum* acting as a parasitoid of *N. ribisigri* in Spain.

Ecological succession in bovine cattle dung pads - 60 years after Carl Mohr.

CAH Flechtmann, F Oikawa, W Mesquita Filho, RA Pereira,
Department of Plant Protection, FEIS/UNESP, Av. Brasil 56, 15385-000 - Ilha Solteira/SP – Brazil; e-mail:

The study of ecological succession in bovine dung pads is important for they are considered temporary microhabitats used by several insect species as ovipositing and feeding places. The objective of this research was to study the ecological succession occurring in dung pads from its excretion until they are not attractive to fimicolous insects anymore. Freshly excreted pads were placed in a pasture at 9:00 AM (F1), 9:00 PM (F2), 3:00 AM (F3) and 3:00 PM (F4), and insects were collected thereafter. More than 6,700 insects were collected and identified, mainly in Sepsidae, Sarcophagidae, Muscidae, Fanniidae and Chloropidae (Diptera), as well as Histeridae, Staphylinidae and Scarabaeidae (Coleoptera) plus Pteromalidae (Hymenoptera). The majority of the species visited the pads in higher numbers the first day after deposition. Paracoprids and endocoprids (Scarabaeidae) were mostly nocturnal; Sepsidae and Muscidae were most active in the morning and Sarcophagidae and Staphylinidae species in the afternoon. There were both diurnal and nocturnal Histeridae species. Muscidae and Staphylinidae were most abundant in F1 pads, paracoprids in F2 pads and Sepsidae in F3 pads; in endocoprids results varied. F3 pads took the longest (cerca 9 days) and F2 the shortest time (cerca 4 days) to be decomposed by Scarabaeidae.

Impact of the introduction of *Digitonthophagus gazella* (Diptera, Muscidae) on the native fauna of coprophagous Scarabaeidae in Brazil.

CAH Flechtmann
Department of Plant Protection, FEIS/UNESP, Av. Brasil 56, 15385-000 - Ilha Solteira/SP – Brazil; e-mail:

Dung pads are a food source to many insects, mainly Coleoptera, Diptera and Isoptera, including several nematodes and flies associated with cattle, especially the horn fly, *Haematobia irritans*, one of the main pests of Brazilian cattle. Coprophagous Scarabaeidae (CS) while burrowing pads improve nutrient cycling, soil structure and forage growth for cattle, besides acting as efficient biological control agents of flies and nematodes of veterinary importance. *Digitonthophagus gazella* (DG) is an exotic CS to Brazil, and it was first registered at the UNESP Farm in Selvíria (Mato Grosso do Sul state) in 1993. Since 1989 CS are being weekly collected in a light trap in order to evaluate the impact of DG on the native fauna of CS. The diversity of species dropped sharply after DG invaded the area, which increased slightly three years later. For the majority of paracoprid species there was a reduction in the population density after DG was detected, while for some endocoprid species it increased. Some paracoprid species, considered common before DG colonized the area, are either not trapped anymore or in only small numbers. Ten years after DG invaded the Farm, it is still not clear if a new equilibrium was reached.

Dispersal kernels, matrix and marsh fritillary

Z Fric, M Konvicka
School of Biological Sciences, University of South Bohemia, Branisovska 31, CZ-37005 Ceske Budejovice, Czech Republic; zdenek.fric@tix.bf.jcu.cz

Two different dispersal kernels most frequently used in research on insect movements are the Negative Exponential Function (NEF) and the Inverse Power Function (IPF). In both, dispersion decreases exponentially with distance, but IPF has a wider tail, allowing for active long-distance dispersal. Using data from a metapopulation of the endangered *Euphyyas aurinia* butterfly in the Czech Republic, we tested how robust are the functions against reductions of data set, e.g., due to variation in sampling effort. Random removal of individuals, days, and both showed that slopes of the IPFs did not change when as much as 3/4 of data were deleted. IPF is thus superior for quick mobility assessments. We also asked how do matrix and quality of patches affect inter-patch movements in the metapopulation. In both sexes, movements were positively associated with a high number of individuals in original patch and absence of barriers (hedgerows), and negatively with the distance between patches. In addition, males were attracted to patches with many conspecific males, and females to patches rich on larval host plant.

Relationships of vegetation and soil dwelling Diptera colonizing initial succession stages

J Frouz
Institute of Soil Biology, AS CR, Na Sádkách 7, Ceské Budejovice, CZ 37005, Czech Republic;

This contribution summarizes the results of several research projects dealing with the initial stages of secondary succession in old fields, and areas disturbed by industrial use, post fire succession and driven succession used for restoration of species rich meadows in various part of central Europe. Soil dwelling Diptera are frequently abundant in these situations, and in many cases they dominate the soil macro-fauna. Some Chironomida (*Smittia atterima*) and Tipulidae (*Tipula scripta* and *T. paludosa*) and some other species are often more abundant in disturbed places than in the surrounding undisturbed landscape. Sites with a high abundance of chironomid larvae usually had little cover of higher plants, although areas with sparse vegetation were often preferred over completely bare sites. Tipulidae prefer sites with annual or weeds. Food resource analyses indicated that the presence of attractive food sources such as terrestrial algae, in Chironomidae and young seedling in Tipulidae are the main reason for preferential use of these habitats. Colonization of these optimal habitat have large impact on colonization sub-optimal habitat in the same site. As cover of optimal habitat increase density in sub-optimal habitat increased as well. On the other hand sub-optimal habitat may by in some situation more resistant to seasonal drought population in theses sub-optimal habitat may be important to overcome adverse environmental fluctuation.

Propagation-status of the fungal symbiont of a woodwasp, *Urocerus japonicus* (Siricidae) inoculated in living tree in the wood of Japanese cedar after felling

H Fukuda, A Sano
Nihon Fukushi University, 475-0012, Higashihaemi-Cho 26-2, Handa, AICHI, Japan; fukuda@n-fukushi.ac.jp

Most woodwasps are symbiotically associated with *Amylostereum* fungi; female adults inoculate the fungi during their oviposition in host trees, and the larvae can digest wood with the aid of symbiosis. In earlier studies, we clarified females oviposit selectively in fresh felled trees that are presumed to be suitable for the fungus-propagation, and also clarified *U. japonicus* a fungus-carrying woodwasp can utilize the fungus which had already propagated in old felled trees. However, the inoculation-season in living trees suitable for the woodwasp-propagation has never been clarified. Thus, we conducted fungus-isolation to evaluate the symbiont-propagation status in inoculated trees. In July, we inoculated the fungus artificially in 6 living Japanese cedar trees (July-trees); 2 trees were felled in August and other 4 trees were done in November in the same year. Also in October, we inoculated the fungus in 2 living trees (October-trees), they were felled in November. In the next summer, fungi were isolated from all trees. In July-trees clear discoloration was recognized, while in October-trees little discoloration was done. In July-trees, the fungus propagated mainly within discoloration-areas, while in October-trees it propagated widely irrespective of discoloration-areas. These results indicate that trees inoculated in fall would be suitable for the woodwasp-propagation.

Sex ratio, stage distribution and larval interactions in *Chrysomya albiceps*

WAC Godoy, H Serra, GS Rosa, C Reigada, LDB Faria, R Castellucci
Departamento de Parasitologia –IB – UNESP – 18618-000 – Botucatu SP – Brazil; e-mail: wgodoy@ibb.unesp.br

Chrysomya albiceps is an exotic blowfly species, which differs from others in several aspects. It is a species with a naturally biased sex ratio and exhibits cannibalistic and predatory behavior over larval stage. In this study, we evaluated the impact of changes in sex ratio on the dynamic behavior of C. albiceps in a density-dependent mathematical model, analyzed the stage distribution by using the Leslie matrix model and investigated cannibalism and intraguild predation with functional response and interaction models. Bifurcation diagrams with periodicity windows between chaos regimes were found when sex ratio was evaluated. The stage distribution stooped changing after 40 generations, suggesting that the populations tend qualitatively towards stable stage distribution. No cannibalism occurred during the first and third larval instars of C. albiceps, but it was evident over the second instar. The functional response on second instar larvae tended to Holling type II. Investigating the intraguild predation, the flow of trajectories indicated the complete elimination of C. macellaria by C. albiceps and the coexistence between C. megacephala and C. albiceps.

Biology, dispersal and manner of damage by *Caryedon serratus* (Col.: Bruchidae) on *Prosopis cineraria* in Bushehr -Iran.

SR Golestaneh_& N Farrar, H Askary
Research center of Natural Resources and Animal affairs, Bushehr, Iran; golestaneh53@yahoo.com

Caryedon serratus is the most important pest on *Prosopis cineraria* because it causes the most damage in coastal areas from Kangan to Bandar-abbas. *C. serratus* has studied between (1997-1999) at Nature and Laboratory in Bushehr province. Significant damage was observed to seeds in June and November in nature. The damage was calculated at 20 to 30% on the seeds on the trees and 70 to 90% on the seeds under the trees on the ground. I observed oviposition to occur with mostly solitary eggs being laid and less frequently in a group (3-5 egg) on seeds and pod surfaces. After hatching, larva penetrated the seeds and destroyed them. Then, became pupa in the seeds and adults made exit holes on surface fruits. The eggs were elliptical and white by an 0.5 mm width and 1 mm length. the developed Larva were with 2 mm width and 6 mm length. Over wintering by larvae, pupae and adults was observed. over summering by adults on cover crop or under the sheath was observed. During the summer, these species were generated quickly and overlapping observed. *C. serratus* has 5 - 6 generations in a year. The life cycle was recorded 45 days at Laboratory (25úc-29úc) between June, July and August. This cycle was shorter in the Nature. *C. serratus* distribution was observed mostly at coastal lines in Bushehr province.

Potential indicators of biodiversity changes in a Mediterranean area subject to agriculture, forestry and livestock uses

MP Gurrea, J Martín, ML Munguira, JC Simón, AG Moreno, E de Juana, VJ Rico, J Serrano, F Fernández, O Viedma
Departamento de Biología, Universidad Autónoma de Maid, 28049 Maid, Spain; pilar.gurrea@uam.es

This work is part of the European Project "Biodiversity Assessment Tools" whose main objective is to assess changes in biodiversity. Butterflies, birds, carabids, springtails, soil macrofauna, plants and lichens were studied along a land use gradient. The study area was a typical Mediterranean with the natural vegetation comprising holm and cork oaks. The selection of the sites was made in the basis of information obtained on the area through remote sensing methods. Sampling was carried out in the Cabañeros National Park and its surroundings (Spain), during the years 2001 and 2002. For the land use gradient we selected six plots, with the natural forest in one side to the cultivated land on the other. The results are based on the analysis of 148000 specimens belonging to 1100 different taxa. The land use intensity affects the species richness and diversity in different ways in the different studied groups. The highest habitat diversity, typically found in areas with different land uses (agriculture, grazing, forestry) but without predominance of a particular one, favours the richness of birds, carabids and plants. Areas with natural forests show highest richness values of springtails, butterflies and lichens. Birds, plants and carabids would be adequate to assess the effect of agricultural or stock grazing uses. Butterflies, lichens and springtails are more relevant to assess the effect on biodiversity produced by forestry uses.

Genetic population structure of *Calathus erratus* (Carabidae) in postmining landscapes in Lower Lusatia (Germany)

M Güth, J Mrzljak & W Durka
Dept. of General Ecology, Institute of Environmental Management, BTU Cottbus, PO Box 101344, 03013 Cottbus, Germany; E-mail: gueth@tu-cottbus.de,

Colonization by arthropods of former coal mining areas of Lower Lusatia (Germany) was studied based on a comparative analysis of mining sites of different age and distance from undevastated areas including adjacent former military training areas. In the SUBICON project (www.subicon.de) investigations on the population structure of the carabid beetle *Calathus erratus* were carried out using AFLP method. We want to know whether the observed population differentiation was due to isolation by distance or different age of sampling sites. At the youngest sampling site (about 14 years after dumping), beetles were collected at different distances (1km, 5km) from the starting point. Further sampling sites comprise two older former coal mining sites (27 years, 5km and 56 years, 30km) as well as two former military training areas. First results with neutral molecular markers (AFLP) and AMOVA showed significant spatial genetic structure in that 98% of genetic variability resided within populations (only 2% among populations, global Fst=0.013). A Mantel test shows no correlation between genetic distances to geographic distances (Mantel test: p = 0.66). Colonization of devastated areas seems to take place rather quickly from surrounding biotopes. In fact we found at the youngest sampling sites 10% winged beetle individuals.

Characteristics of dipteran larvae infestations of marine turtle (*Caretta caretta, Chelonia mydas, Natator depressus*) nests and the impacts on reproductive success in central Queensland, Australia

SCB Hall, CJ Parmenter
School of Biological and Environmental Sciences, Central Queensland University, Rockhampton, Queensland, 4702, Australia; s.hall@cqu.edu.au

Dipteran larvae are known to infest marine turtle eggs, however, the few studies that have been conducted on this topic have presented conflicting conclusions as to the role of the larvae in the nest. This study will focus on the identification of the species of Diptera that infest green, flatback and loggerhead turtle nests in central Queensland, the role they play in the nest (detrimental, neutral or beneficial) and the subsequent consequences of that role on turtle hatch success. The three mutually exclusive roles listed above will have markedly different effects on the subsequent hatch success of affected marine turtle nests in central Queensland. If the larvae function in a detrimental role as predators, they will negatively affect hatch success. A neutral role would imply that they simply devour dead material accumulating in the nest. Lastly, the larvae could be functioning in a beneficial manner by removing decomposing material that might otherwise lead to fungal or bacterial infection within the nest, and thus they may positively affect hatch success. This study will provide useful information for the management of marine turtles in the central Queensland region.

Composition and structure of bark and wood-boring pest communities in Belgian beech (*Fagus sylvatica*) stands, in relation to dead wood stock.

JM Henin, P Lejeune, J Rondeux
Gembloux Agricultural University, Unit of Forest and Nature Management, Passage des Déportés, 2; 5030 Gembloux (Belgium); henin.jm@fsagx.ac.be

Because of economic reasons and of forest hygiene measures, dead wood and overmature trees (DWOT) are almost systematically removed from woodlands in Wallonia (Southern Belgium). Consequently, the average amount of dead wood in Walloon deciduous forests is less than 5 m^3/ha, whereas it would be of several tens of m^3 per ha if those forests were left unmanaged. There is nowadays growing awareness of the crucial roles that DWOT play in forest ecosystems and of the need to restore those habitats. Nevertheless, because of misunderstanding and lack of adequate information, they are often considered as pest sources and threats to timber production. Since complex relationships link xylophagous pests, their antagonists, saproxylic communities and DWOT, leaving a part of the latter in deciduous forests would however not necessarily imply a significant increase of xylophagous pest population levels. In this context and as part of a more global study, we present and discuss the composition and structure of xylophagous pest communities caught in 2002 in five beech (*Fagus sylvatica*) stand pairs (fauna surveyed with eight unbaited window-traps per stand). Each pair consists of a stand with few DWOT and another stand with similar characteristics but with high quantity of DWOT.

Patterns of population fluctuations of the mulberry tiger moth, *Lemyra Imparilis* (Butler): effect of predation by the specialist carabid predator, *Parena perforata* (Bates)

M Hondô
Ebie 1-11-2-601, Fukushima, Osaka 553-0001, Japan; hondomh@yahoo.co.jp

Population changes of the mulberry tiger moth, *Lemyra imparilis* (Butler) (Lepidoptera: Arctiidae) and its carabid predator, *Parena perforata* (Bates) (Coleoptera: Carabidae) were surveyed at two disjunct study sites on Kii Peninsula, western Japan, from 1989 to 2003. The population fluctuation of *L. imparilis* showed a pattern in which the density approaches peaks slowly but collapses rapidly. The analysis of population growth rates showed that delayed density-dependent factors act as important roles regulating *L. imparilis* populations. At one study site, the number of *P. perforata* per prey colony changed closely with the density of *L. imparilis*. During the decline phase of *L. imparilis*, *P. perforata* was observed in over 80% of the prey colonies and the predation effect acted strongly. At another site, however, the carabid beetles were very few. At this site, the peak shape of *L. imparilis* population change was flatter than that of another site having sharp and angular peak. In addition, the amplitude was ca. one-third that at another site. It was suggested that the predator-prey interaction constitutes an important factor in explaining the different behaviors of *L. imparilis* populations at different localities.

Spatio-temporal dynamics of dung beetle communities in pastures

O Imura, K Shi, N Morimoto
National Institute of Livestock and Grassland Science, Senbonmatsu 768, Nishinasuno, Tochigi, 329-2793 Japan; imurao@affrc.go.jp

Dung beetles (Coleoptera: Scarabaeidae) play an important role to decompose cattle droppings in pastures. The rate of the decomposition should depend on the dynamics of dung beetle community in the pastures. We surveyed dung beetles by a dug-bated trap in 17 pastures located in the basin of River Naka in Tochigi prefecture, Japan, once a month from May to October for three years to elucidate the dynamics of dung beetle communities. Twenty-five species were collected (21 were used to analyze). The community varied among pastures and years in terms of species richness, abundance and structure. We analyzed the data by principal component analysis (PCA) using a software ADE-4 (Thioulouse et al., 1997) to evaluate temporal and spatial dynamics of the communities. Ordinal PCA indicated that regional abundance and yearly change in abundance of the beetles mostly explained the variability of the communities. The spider graph representing variability of factor scores among pastures and years on Z1 - Z2 plane predicted that the former was larger than the latter. Further analyses by within- and between- groups PCA demonstrated that the spatial dynamics was much more important than the temporal one. Environmental and biological factors seemingly influenced the spatio-temporal dynamics of the communities.

Parasitoid's switching predation enhances persistence in two-host one-parasitoid experimental system

Y Ishii, M Shimada
Department of System Sciences (Biology), University of Tokyo, Meguro, Tokyo 153-8902, Japan, ishiij@dolohin.c.u-tokyo.ac.jp

Effect of predation on the persistence of competing prey species were examined by laboratory experiments. Two bruchid beetles, *Callosobrucus maculatus* and *C. chinensis* were used as the competing prey species, and the parasitoid of these beetles, *Anisopteromalus calanae* was introduced as its common predator. The currently existing theoretical models suggest that persistence of systems depends on foraging strategy of the predator; random or switching predation (Murdoch and Oaten 1975; Post et al. 2000). In this study, we aim to determine how the persistence and dynamics of this system are affected by predation. The time until extinction of either of prey species was observed by the long-term multi-generation experiment, and the foraging behaviour of *A. calanae* was also examined by short-term experiments. In all long-term experimental replications without wasp, *C.chinensis* was competitively excluded. On the other hand, significantly longer persistent time was observed in the presence of wasps, in which alternate population oscillations were observed in two prey species. The short-term experiments suggested that *A. calanae* learned hosts which they had oviposited and preferred it more when parasitising. This behaviour results in positive frequency-dependent predation, and causes persistence and the dynamics pattern in this system with parasitoid.

The significance and variability of predation of weed seeds in an agricultural landscape in Western Australia.

D Minkey, H Spafford Jacob, J Majer
School of Animal Biology (M085), University of Western Australia, 35 Stirling Hwy, Crawley, W.A. 6009, Australia; e-mail: hsjacob@agric.uwa.edu.au

Understanding the fate of weed seeds over summer in agricultural fields is not well understood, but is necessary in order to develop possible alternatives to weed control – particularly when considering the increasing failure rate to herbicides. It is widely accepted that granivory plays a role in regulating plant populations and is a major contributor to seed loss in natural ecosystems. Despite this, the relationship has not been thoroughly researched or proven to significantly reduce seed banks of weed species in agricultural environments. Three years of study in the Western Australian Wheatbelt has shown that: (1) predation levels are higher for annual ryegrass than for wild radish and can vary from 0 to 100% within the same field; (2) predation levels tend to be higher on the edges of field rather than in the centre, but only when using artificial seed populations; (3) when using natural weed populations, a threshold in predation level occurs; (4) ants play the dominant role in seed harvesting and were found to consume seeds, rather than disperse them; (5) the presence of particular ant species can possibly be used as a predictor of weed seed predation levels; and (6) crop residue types and tillage practices can affect the level of seed predation.

Bottom-up cascade in a tri-trophic system: different impacts of host-plant regeneration by cutting on performance of a leaf beetle and its natural enemy

H Kagata, M Nakamura, T. Ohgushi
Center for Ecological Research, Kyoto University, Kamitanakami Hirano-cho, Ostu, 520-2113 Japan; kagata@ecology.kyoto-u.ac.jp

The present study examined the effects of artificial cutting of a willow on performance of the willow leaf beetle and predatory ladybird through trophic levels. Laboratory experiments showed that performance (survival rate, developmental time, and adult mass) of the willow leaf beetle, *Plagiodera versicolora* Laicharting, was improved by feeding on leaves of cut willows, comparing to leaves of uncut willows. Performance (developmental time and adult mass) of a predatory ladybird, *Aiolocaria hexaspilota* Hope, was also improved by feeding on the leaf beetle larvae that fed on leaves of cut willows, compared to that fed on leaves of uncut willows. In comparison of improved performance parameters between the leaf beetle and ladybird, regenerated willows more shortened developmental time of the willow leaf beetle than that of ladybird. This indicates that impacts of willow cutting on insect performance differed between second and third trophic levels.

Nitrate and soluble carbohydrates stimulate mosquito production from container habitats of the tree hole mosquito, *Ochlerotatus triseriatus*.

MG Kaufman, ED Walker
Department of Entomology, Michigan State University, E. Lansing, MI 48824; kaufma15@msu.edu

Most habitats of container breeding mosquitoes are dependent on allocthonous input of nutrients. One mechanism of nutrient input into tree hole ecosystems is via stemflow during storm events. Stemflow contains soluble organic and inorganic nutrients and also may serve to flush out potentially inhibitory metabolites or re-suspend particulate nutrients from sediments. We investigated the effects of flushing and soluble nutrient additions on *Ochlerotatus triseriatus* development in microcosms using a factorial experimental design. Both simulated stemflow flushing and nutrients strongly affected mosquito production, however, there was some evidence of interaction between the two factors. In general, the additions of nitrogen (as nitrate) or soluble carbohydrate (as glucose) had positive effects on mosquito production, but flushing had negative effects. Additions of phosphorous (as phosphate) had no effect. Interestingly, the addition of nitrogen enhanced leaf mass loss and contributed to higher soluble carbohydrate levels in the water column, most likely via stimulation of the fungal community associated with leaf detritus. The results are consistent with an indirect effect of nutrient inputs on mosquito larvae that is first channeled through microbial community components.

Ants of the *Formica rufa* group affect nutrient dynamics and forest growth in boreal forests

J Kilpeläinen, L Finér, T Domisch, M Jurgensen, H Mannerkoski, P Niemelä, M Ohashi, L Sundström
University of Joensuu, Faculty of Forestry, P. O. Box 111, 80101 Joensuu, Finland; jouni.kilpelainen@joensuu.fi

Mound-building red wood ants (*Formica rufa* group) are proposed to be a key-species in boreal and subarctic forests of Fennoscandia. The aim of our study is to understand the role of wood ants in the functioning of boreal forest ecosystems. Large-scale disturbances, like clear-cutting, can make wood ants abandon their mounds. Our study areas are located in eastern Finland in medium-rich coniferous forests of four age classes after clear-cutting. Changes in mound number, size and spatial organisation, carbon (C) and nutrients pools will be quantified in each ecosystem. We are assessing annual C and nutrients ant mound inputs (litter, honeydew, invertebrates) and outputs (CO_2, nutrient mineralization). Based on preliminary calculations, the ant-aphid symbiosis can significantly reduce the growth of coniferous trees. The impact of the ant-aphid symbiosis on the growth of conifers is also being measured. Preliminary results indicate that ant mounds are bigger and contain more C and nutrients in older forest stands than in younger stands. The C and nutrient contents of ant mounds are small compared to other pools in forest soils but locally the accumulation and fluxes of C and nutrients in ant mounds can be important to ecosystem processes.

Genetic structuring of western corn rootworm populations in the US based on microsatellite loci analysis

KS Kim and TW Sappington
USDA-ARS, CICGRU, Genetics Lab, ISU, Ames, IA 50011, USA, kkim@iastate.edu

The western corn rootworm (*Diabrotica virgifera* LeConte) (Coleoptera: Chrysomelidae) is a major corn insect pest in the United States. Understanding gene flow and dispersal patterns of this insect is essential to designing efficient strategies of monitoring for resistance to *Bt* toxin in genetically modified corn. Microsatellite markers for population genetics studies of the western corn rootworm have been developed using an enrichment method. As of this writing, 24 microsatellites have been prescreened in automated genetic analysis system with fluorescent-labeled PCR primers. Of these, nine di-nucleotide and two tri-nucleotide repeat microsatellites have been confirmed as polymorphic. These polymorphic microsatellite loci are being surveyed to obtain genetic variation among western corn rootworm populations of 540 individuals sampled from 9 locations across eight U.S. states. The results will be used to infer the magnitude and pattern of genetic differentiation among western corn rootworm populations on a broad geographic scale, as well as genetic structuring of this insect.

The assessment of toxicity of 4-nonylphenols on the *Chironomus flaviplumus* using molecular biomarker

MC Kim, DJ Chun, BC Chung,SS Han
School of Life Sciences & Biotechnology, Korea University, Seoul, 136-701, Korea; ecol20@korea.ac.kr

The assessment of the contamination level consists of comparing the biochemical substances in the macroinvertebrates. Many chemical materials induce an adverse effects on aquatic ecosystems. Alkylphenols selected among the chemical materials in this investigation, because it detected at the study sites. Among the alkylphenols, bisphenol-A and 4-nonylphenols were detected in these samples. Environmental samples were analysed by GC-MS method. Also biochemical marker investigate by the 2-D electrophoresis and MALDI-TOF mass spectrometric analysis. Our studies showed that up-streams as well as downstreams in the study sites have been contaminated by 4-nonylphenols. The distribution of tolerable species to pollution such as Diptera, were in accordance with the higher concentrations of alkylphenols. Fourth-instar *Chironomus flaviplumus* larvae were exposed to the 4-nonylphenols (0, 1, 10, 100 /L) for 24h at 25°C. After acute toxicity test, treated samples showed ascension of vWF activity to the larvae *Chironomus flaviplumus*. The vWF is related to blood coagulation. This result suggesting that vWF is possible for use as a biomarker of toxicant exposure or effect in Chironomidae.

Effects of climatic change on the spruce bark beetle *Ips typographus*, an economically important forest pest

P Krokene, B Økland, E Christiansen
Norwegian Forest Research Institute (Skogforsk), Ås, N-1432, Norway; paal.krokene@skogforsk.no

The spruce bark beetle is the most serious pest of mature spruce trees in Eurasia. At low population densities it breeds in weakened or newly dead trees, but at high densities it becomes a tree killer. The exact factors triggering outbreaks are not fully understood, but climatic variables are important candidates. Populations in SE Norway have been monitored since 1979, and using these data we want to (1) explore the role of climate in outbreaks of the spruce bark beetle in space and time, (2) estimate the distribution of bivoltism under different scenarios of climate change, (3) estimate the risk of forest damage under different scenarios of climate change, and (4) describe forest management practices that will reduce the impact of beetle outbreaks triggered by climate change. Large windfall events appear to be a major instigator and synchronizer of beetle outbreaks in areas subjected to regionalized weather systems. A phenological model sets beetle development as a function of local temperature. This model will be compared to local reports of bivoltism, and finally used for predictions of bivoltism under various scenarios of temperature change.

Dispersal of West Indian sweet potato weevil, *Euscepes postfasciatus* (Fairmaire), in sweet potato field

T Matsuyama, H Kuba, D Haraguchi
Okinawa Prefectural Agricultural Experiment Station, 4-222 Sakiyama-cho, Naha, Okinawa 903-0814, Japan; kubahryk@pref.okinawa.jp

West Indian sweet potato weevil, *Euscepes postfasciatus* (Fairmaire), is one of the most important pests of the sweet potato, *Ipomoea batatas* L., in tropical and subtropical areas including the southwestern islands of Japan. In this study, we made two 5 by 5m square sweet potato fields scaffolding for observation not to disturb the dispersion of this weevil. Forty-eight sweet potato tuber traps were set inside and around each field. We released about 2,000 mated and unmated male weevils into the center of one field. Similarly about 2,000 mated and unmated female weevils were released into the center of another field. These weevils were sterilized before releasing. We marked each weevil with oil-based marker to be able to distinguish mated and unmated, male and female respectively. We checked the traps everyday for 1 week and 15th day. On 15th day, we collected weevils and checked the seminal receptacle of females to confirm the mating. As a result of this experiment, we found that males and mated females dispersed in the field uniformly and moreover went out from the fields, on the other hand, unmated females distributed center of the field contrastively.

Effect of aerial pesticide application on ant foraging activity

TS Kwon, DP Ryu, YS Park, SC Shin
Division of Forest Insect Pests and Diseases, Korea Forest Research Institute, Seoul, 130-712, Republic of Korea; E-mail: insectcom@chol.net

Aerial pesticide application is main control method for pine wilt disease in Korea. Fenitrothion, used for the application, is the chorinesterase inhibitor. This suggests that the aerial pesticide application invoke retardation in activity as well as death of arthropods. This study is aimed to find changes in foraging behavior of ants due to aerial pesticide application. Foraging activity of ants had been observed by using baiting cards across the period of the three aerial pesticide applications in June. The activity was significantly decreased after the pesticide application. Such behavior retardations were different among ant species. As days passed, it recovered gradually and became normal state in 16th day after the application. Feeding behavior of ant species were affected by the presence of other ant species. *Paratrechina flavipes* inhibit *Componotus japonica* in feeding food, and the reverse was true. Interestingly*, Monomorium chinense* was stimulated in feeding by the presence of *Paratrechina flavipes*.

Model application to egg development of aquatic insects – 1. ***Ephemera*** **spp.**

SJ Lee, J H Park
Korean Entomological Institute, School of Life Science & Biotechnology, 5ka, Korea Univ., Anam-dong, Sungbuk-ku, Seoul 136-701, Korea

Because the water system was more stable than terrestrial system in the temperature aspect, temperature related development models would be more useful to estimate the rate of development in aquatic insects than in terrestrial insects. 5 descriptive models on Arthropods, 3 Logan's, Stinner's and empirical model according to the Arrhenius' rule, were examined to evaluate their applicability to aquatic insects. In this study models were applied to egg development of two *Ephemera* spp., because no other factors, except temperature, could be thought to have effects on egg development. Among models, Logan's original model showed best description on the egg development while Stinner's was the worst. As known, Stinner's model did not explain the abrupt decrease of developmental rate after the optimal temperature although this showed good fit to ascending part. Logan's sigmoid model showed two problems. One is the forced sigmoid pattern in ascending developmental rate, which caused large variance. Another problem is the overestimation of maximum developmental rate. The overestimation was also shown in application of empirical model. Though empirical model showed relatively good-fit, this had too many parameters. Logan's modified model did not show good-fit compared with two other Logan's, but had advantage in estimating the base temperature.

Temperature adaptation in Arctic Collembola: thermal reaction norms of egg development rates.

HP Leinaas
Dept. of Biology, Univ. of Oslo, P.O.Box 1066 Blindern, N-0316 Oslo, Norway; h.p.leinaas@bio.uio.no

Thermal reaction norms, expressed as temperature dependent development rates of egg development, have been studied in a number of high arctic collembolan populations. Four related species co-existing in the same study site on Svalbard were compared. In all three species the development rate increased up to 25°C (from 5°C as the lowest temperature). However, the species differed in the slope and shape of their thermal response curves. In the lower temperature range (5-10°C) they were virtually overlapping, but at higher temperatures the increase in rate was much slower in two typical high arctic species than in the two other with a much wider distribution in both temperate and cold areas. Thus, although a warmer climate may have a positive direct effect on all species, the two high arctic ones appear to it relatively less and thus may get an indirect competitive disadvantage. Three species with wide distribution across climatic zones differed fundamentally in intra-specific variation of the thermal reaction norm along climate gradients (latitudinal ranges of ca. 20°), i.e. both increasing and decreasing in populations from increasingly colder environments. This is explained by differential time constraints in the northern populations depending on their phonological strategy and reproduction flexibility.

Effects of temperature on the development of *Aulacaspis murrayae* Takahashi (Hemiptera: Diaspididae)

YA Lin, WJ Wu
No.27, LANE 113, Roosevelt Road, Sec. 4, Taipei 106, Taiwan , R92632001@ntu.edu.tw

The effect of temperature on the development was determined for three stages of an armoured scale insect, *Aulacaspis murrayae* Takahashi (Hemiptera: Diaspididae), a key pest of orange jessamine (*Murraya paniculata* (Linn.) Jack) in Taiwan. The scales were reared on orange jessamine at 4 different temperatures (15, 20, 25, and 30°C). The results showed that an increase in temperature within limits accelerated the rate of development of all stages. The developmental duration of the scales from ovum to adult at 15, 20, 25, and 30°C were 78.2, 60.3, 49.31, 42.81 days. Temperature also influences the reproductive capacity of the scales. Lower temperatures increased egg production of the scales. A linear regression of developmental rate against temperature showed that there was a high correlation between temperature and growth rate for all stages ($r^2 = 0.8926$). Their low developmental threshold temperature (Tb) and thermal summation (K) were: 5.6°C and 174.6 DD in the egg stage; 6.8°C and 128 DD for crawlers, and 2.9°C and 284.3 DD for secondary instars, respectively.

Community dynamics of ground beetles (Coleopetera: Carabidae) in a successional forestry landscape

YC Lin, PD Dolman, R James
Centre Of Ecology, Evolution And Conservation University Of East Anglia, Norwich, Norfolk, NR4 7TJ, UK; yingchilin@hotmail.com

Western European Lowland Heathland is a threatened habitat recognised by the European Community and the UK Biodiversity Action Plan. Much of this valuable habitat, especially for invertebrates, has been replaced by afforestation. Within the UK, distributions of a number of ground beetle species are restricted to Breckland, and the creation of Thetford Forest has contributed to losses of heathland in this area. A two-year survey has shown that clear-felled areas and ride margins within the forest have considerable value for heathland ground beetles. The ground beetle compositions through successional stages, age 0 to 5 years, are studied and also compared to that of mature forest (age 52 to 73 years). The effect of succession on ground beetles was then investigated at species level in relation to their ecology such as habitat preference and dispersal ability. The implications for conservation and forestry management of understanding the ground beetle dynamics in this landscape scale are also considered.

Infestation of *Adalia bipunctata* by a parasitic mite *Coccipolipus hippodamiae* (Acarina: Podapolipidae) in Moscow

YV Lopatina
Moscow State University, Moscow, Russia

The mites of the genus *Coccipolipus* are ectoparasites of coccinellid beetles. The major *C.hippodamiae* host is two-spotted ladybird *A.bipunctata*. The adult beetles were collected in various places of Moscow, Russia. The seasonal dynamics of *C.hippodamiae* abundance was evaluated from May to September 2000 and 2002 by collecting and examining beetles weekly; the mites were counted on 20-50 *A.bipunctata*. A total of about 800 beetles were collected during the study period. Mite infestation of beetles was 14-25% in the beginning of May. The number of mites (larvae, males, females) was 1,7-8,1. In summer (June to August) mite infestation of *A.bipunctata* was higher than 50% (96,3-98,9% in 2000 and 50-90% in 2002), with average abundance of *C.hippodamiae* on one infested beetle about 30. The mites formed large stocks on some beetles. The maximum number of adult females collected from one beetle was 24, whereas the highest number of eggs – 690. There was no *A.bipunctata* sex preference in mite infestation. In September the occurrence and abundance of *C.hippodamiae* were significantly lower. The percentage of infested beetles fluctuated from 4 to 13 in different places in Moscow in 2000, 2002. The average number of mites on one infested *A.bipunctata* was 8,3-13,1. *C.hippodamiae* larvae dominated in summer, females – in September.

Summer raids of *Arocatus melanocephalus* (Heteroptera: Lygaeidae) in houses of Modena city (Italy): is climate change to blame?

L Maistrello, S Vanin, A Reggiani, L Lombroso and E Peoni
Dipartimento di Scienze Agrarie – Università di Modena e Reggio Emilia, Via J.F. Kennedy 17, Reggio Emilia, 42100, Italy; maistrello.lara@unimore.it.

Arocatus melanocephalus is a small lygaeid performing its life cycle on elms (*Ulmus spp.*, Ulmaceae). Its presence has been recorded in many continental European regions. Its occurrence has been ascertained in Northern Italy since the last century; however it never elicited special attention until summer 2000, when it suddenly started to become a problem for the citizens of Modena (Emilia Romagna). Since that time, every summer on several occasions, thousands of adults of *A. melanocephalus* leave the trees to enter the houses, gathering in hundreds all over doors, windows, balconies, and penetrating inside the rooms, causing trouble and anger in the people. Among all the possible reasons for this phenomenon, we suggest that climatic changes observed in Modena during the last 4 years may have affected the behaviour and/or the population dynamics of this bug. In agreement with global warming signals, meteorological recordings for this city show a temperature increase of about + 0.8°C/100 year, and anomalous peaks were observed especially during spring months, likely in coincidence with crucial events in the life cycle of the insect. Studies on the reactions of different stages of *A. melanocephalus* to cold/hot temperatures are currently performed to provide further support to our hypothesis.

Prey suitability of *Myzus lythri* for generalist predators

B Matos, JJ Obrycki
4 Insectary Bldg., Department of Entomology, Iowa State University Ames, IA 50011, United States; bmatos@iastate.edu

Understanding the interactions among the trophic levels that structure the purple loosestrife, *Lythrum salicaria* complex in invaded wetlands will contribute to management options and a better knowledge of invasive species. In 1992, *M. lythri* was observed feeding in abundant numbers on *L. salicaria* in Indiana in the North Central United States. The suitability of *M. lythri* nymphs and adults, for development and survival of *Harmonia axyridis* Pallas, *Coleomegilla maculata* (DeGeer) (Coleoptera: Coccinellidae), and *Chrysoperla carnea* (Stephens) (Neuroptera: Chrysopidae) was quantified by measuring preimaginal development and survival. Individual first instars were assigned to one of two diets: *Acyrthosiphon pisum* (Harris) (Homoptera: Aphididae) or a diet of *M. lythri*. The pea aphids, *A. pisum* serve as the control diet because other studies use these aphids as diets for generalist predators and the predators' development seems optimal. *Coleomegilla maculata* and *C. carnea* development was delayed and lower survival rate with *M. lythri* diet compared to *A. pisum* diet. *Harmonia axyridis* development was delayed with *M. lythri* diet but survival was similar to *H. axyridis* fed *A. pisum*. These studies may provide an insight of what is occurring in the wetland areas where these aphids and predators are present. Trophic interactions such as these may be affecting the density and biomass of purple loosestrife in the wetlands.

Habitat selection by the antlion *Myrmeleon bore* living in a sandy riverbed (Neuroptera: Myrmeleontidae)

T Matsura, Y Yamaga and M Itoh
Department of Biology, Kyoto University of Education, Fushimi-ku, Kyoto 612-8522, Japan; matsura@kyokyo-u.ac.jp

The pit-making antlion larvae *Myrmeleon bore* live in open sand in riverbeds. The spatial distribution pattern of their pits showed an aggregative distribution. We analyzed which environmental factors affect dominantly their spatial distribution out of a biotic factor (prey availability) and abiotic factors (sand temperature and particle size of sand). There was a significant positive correlation between the pit density and the ratio of medium sand to total weight of sand, while there was no significant correlation between the pit density and the temperature of sand or prey availability. Experiments on the oviposition behavior revealed that females of *M. bore* laid more eggs in fine or medium particle size sand than in coarse sand. This suggests that habitat selection by adult females is a major factor that causes the aggregation distribution of the pits, because the larvae rarely relocate their pits.

Shifts in habitat associations of dung beetles: climate change implications

R Menéndez, D Gutiérrez
School of Biology, University of Leeds, Leeds, UK, bgyrmm@leeds.ac.uk

We examined whether dung beetle species shift their habitat associations (vegetation types) with different climatic conditions, using altitudinal and seasonal gradients as analogues of future climate change scenarios. Dung beetle assemblages in Picos de Europa (northern Spain) were monitored by dung-baited pitfall trapping in three vegetation types (woodland, heathland and pasture), three altitudinal zones (520-600 m, 950-963 m and 1230-1275 m) and during two different seasons (summer and autumn) in 1994. Most species shifted their habitat use on the altitudinal and seasonal gradient in response to changes in microclimatic conditions (temperature). They were generally associated with heathland and woodland (shaded habitats) at lower altitudes, but they were increasingly associated with pastures (open habitat) as altitude increased. There was also a greater association with pastures in the coldest season (autumn) and with heathland and woodland in the warmest season (summer). These results suggest that climate change could be a major factor affecting habitat selection in dung beetles. The research presented here supports the feasibility of using microclimatic gradients within a region to study the potential effects of future climate change on both species and communities.

Leaf selection of leaf-mining *Phyllonorycter* **moths in a deciduous oak** *Quercus dentata*

T Nakamura, S Shibata, K Hattori, TA Ishida, H Sato, MT Kimura
Graduate School Of Environmental Earth Science, Hokkaido University, Sapporo, 060-0810, Japan; mtk@ees.hokudai.ac.jp

Phyllonorycter leucocorona and *P. persimilis* are dominant leaf mining moths on a deciduous oak, *Quercus dentata*, in Sapporo, northern Japan. These moths overwinter as pupae and pass two generations in a year: females of the first generation oviposit in June after most ectophagous caterpillars have completed their development, and females of the second generation oviposit in August. Their larvae have two functional stages, the sap-feeding and tissue feeding stages. Here we report leaf selection of these moths. In this study, these two species were treated together, since they could not be discriminated at the sap-feeding stage. The density of their mines was negatively correlated with leaf size, but positively correlated with the degree of leaf damage by ectophagous insects. Survival of sap-feeding larvae was slightly higher in small and damaged leaves than in larger or less-damaged leaves, suggesting a weak preference-performance linkage. On the other hand, the analysis of distribution pattern of mines suggests that adult female moths do not prefer or avoid leaves that have been previously oviposited by congeneric females. In addition, survival of sap-feeding larvae was not affected by the mine density.

The rediscovery of a life cycle form, which has oviparae produced by apterous viviparae, and crossing trials between holocyclic clones in *Aphis gossypii* Glover (Homoptera: Aphididae)

N Yutaka and T Murai
Shimane Agricultural Experiment Station, 2440 Izumo Shimane 693-0035, Japan; ynarai@mx.miracle.ne.jp

The life cycle form of *Aphis gossypii*, that apterous viviparae produced oviparae, has been discovered by Thomas (1968). We found the same form on *Fragaria grandiflore, Chrysanthmum morifolium* and *Lillium* spp etc. 7 different host plants in Japan. We investigated the inheritance of life cycle forms using GP1 clone from *Pyrus serotina*, the same life cycle form, and GHS clone from *Hibiscus syriacus*, that oviparae were produced by only alate viviparae (heteroecious form). We carried out crossing experiments by selfings and reciprocal crossings of GP1 and GHS. All of 27 F_1 clones in selfings of GHS were heteroecious form. 20 F_1 clones in selfings of GP1 were separated into 10 GP1 forms, one heteroecious form, and 9 anholocycles. 78 F_1 clones in crossing of GP1 (female) * GHS (male) were separated into 40 GP1 forms and 38 heteroecious forms. 90 F_1 clones in crossing of GHS (female) * GP1 (male) were separated into 53 GP1 forms, 35 heteroecious forms and 2 anholocycles.

Mortality factors affecting populations of sweetpotato whitefly, *Bemisia tabaci*, in a multi-crop system

L Cañas, SE Naranjo, PC Ellsworth
USDA-ARS, 4135 E. Broadway Rd., Phoenix, AZ, USA 85040; snaranjo@wcrl.ars.usda.gov

The sweetpotato whitefly, *Bemisia tabaci* is a major pest of world agriculture, causing damage by direct feeding, vectoring plant viruses, and excretion of honeydew. *B. tabaci* is a multivoltine insect with no quiescent stage and reproduces by moving from one host to another over the year. Thus, management on any one crop is inexorably tied to other crops and wild hosts surrounding it in space and in time. To better understand the mechanisms governing population development of this insect, whitefly "ecosystems" were established in three geographically and climatically distinct areas in Arizona. These systems consisted of a sequence of six representative hosts including winter broccoli, spring and fall cantaloupes, summer cotton, perennial alfalfa, various annual weeds, and the perennial ornamental, *Lantana*. Source and rates of mortality were quantified, *in situ*, on each host plant by constructing life tables. Factors causing mortality were the same in all hosts; however the contribution of each mortality factor varied among hosts and time of the year. Predation and dislodgement from the plant surface were consistently the largest sources of mortality. An understanding of the year round dynamics of this pest will greatly aid the development of better pest management strategies in all affected crops.

Host-tree decline and pulse eruptive outbreaks of *Creiis lituratus* (Hemiptera: Psyllidae) in *Eucalyptus dunnii* plantations

PJ Angel, JD Nichols and C Stone
Sustainable Forestry Program, School of Environmental Science and Management, Southern Cross University, Lismore, NSW, Australia;
dnichols@scu.edu.au

Localised stressful conditions such as drought or water-logging have been shown to retard the growth of *Eucalyptus dunnii* planted in northeast New South Wales. During a two year field study in *E. dunnii* plantations we observed increasing densities of the leaf damaging psyllid, *Creiis lituratis,* over the autumn, winter and spring months. In most of the study plots the heat-related mortality of approaching summer led to a collapse of the *C. lituratis* population. When the capacity of host trees declined prior to the onset of high temperatures, density-dependent dispersal of the psyllid took place. Areas immediately surrounding hot spots experienced an influx of *C. lituratis* adults, with population development following pulse eruptive dynamics, and resulting in larger areas of severely damaged trees.

The biology of *Lissoderes pusillus* Hespenheide (Coleoptera: Curculionidae: Conoderinae) in *Cecropia* (Cecropiaceae) saplings

J Weng, K Nishida and PE Hanson
Sistema de Estudios de Posgrado en Biología, Escuela de Biología, Universidad de Costa Rica, 2060 San José, Costa Rica; knishida@cariari.ucr.ac.cr

The eggs, larvae, and pupae of *Lissoderes pusillus* Hespenheide occur inside the hollow stems of *Cecropia* saplings, but are usually only present in internodes not occupied by live *Azteca* ants. Eggs are deposited on the inner surface of the internode. Larvae feed on the parenchyma, the same food resource that is utilized by *Azteca* queens. Weevil larvae feed and move about in an upside-down position. Fleshy folds on the dorsum of the body are apparently utilized in locomotion. Larvae are usually restricted to just one internode, but are more likely to move to an adjacent internode in *Cecropia* species possessing a thin parenchyma layer. Pupae hang freely from the inner vertical walls of the internode. Two hymenopteran parasitoids were reared from larvae and prepupae: *Neocatolaccus* sp. (Pteromalidae) and *Heterospilus* sp. (Braconidae). *Menozziola* sp. (Diptera: Phoridae) was observed parasitizing *Azteca* queens. The high mortality of colonizing *Azteca* queens does not appear to be caused by insect parasitoids or by competition with *L. pusillus*.

Thaumastocoris australicus, **the bug turning green Sydney red.**

A Noack, HA Rose.
McMillan Building AO5, University of Sydney. NSW 2006; noacka@agric.usyd.edu.au

Over the past six years a thaumastocorid bug, *Thaumastocoris australicus*, has had a devastating impact on some *Eucalyptus* species in the Sydney metropolitan area. The symptom of this infestation is now so widespread it is commonly called "winter bronzing". Initially this winter bronzing was found on two eucalypt species, *Eucalyptus scoparia* and *E. nicholii*, both very common street trees in Sydney. Infested trees display a reddening of leaves. Severely infested trees can die but usually are removed. Over the past two seasons another nine eucalypts have been verified as infested. Given the magnitude of the problem with respect to the bug's numbers and expanding host range, combined with the logistics of control, a study of the bug is being undertaken. A standard stratified technique was used to sample thaumastocorids at each aspect of three *E. nicholii* trees over 18 months and a comprehensive range of data has been recorded. These data include: sex ratios of adults; numbers and instars of nymphs; numbers and location of eggs; presence of parasitoids. Laboratory work has been conducted to elucidate aspects of the bug's life cycle.

Evolution of the mate recognition key stimuli (ultraviolet wing color) in the cabbage butterfly, *Pieris rapae crucivora*

Y Obara
Behavioral Biology, Department of Agriculture, Tokyo University of Agriculture & Technology, Fuchu, Tokyo 183, Japan; E-mail:obara@cc.tuat.ac.jp

The female of the Japanese subspecies of cabbage butterfly, Pieris rapae crucivora, has been shown to have the ultraviolet (UV) color on the wings which is an essential component of the key stimuli for the mate recognition by the conspecific male. There occurs, however, no UV color in the female wings of British subspecies, P. r. rapae. This raises some interesting subjects to be tackled. One is where in the Eurasian Continent between the two countries the female wings with UV color evolved. The results of UV photographs taken through UV filter transparent only to UV light (300-400 nm) revealed that the female specimen from all the regions of the Continent but East China had no UV color, suggesting that female UV wing color should have evolved in East China. The other is whether there occurs behavioral isolation between the two subspecies due to the difference in the key stimuli. The results of the behavioral experiments showed that the males preferred each their own subspecies of females. The British subspecies of males, however, were strongly attracted by the short-day form of Japanese females with intermediately strong UV color. The behavioral isolation is, therefore, partial.

The effect of male killing on spatial and temporal distribution of the African monarch butterfly (*Danaus chrysippus*) population in Kenya.

M Otieno
Department of Zoology, Kenyatta University, P.O. Box 43844 Nairobi – Kenya; markotieno@yahoo.com

Danaus chrysippus (L.) (Lepidoptera: Danaidae) butterfly is the commonest, most polymorphic of all butterflies found in the old world tropics. The danaid butterflies are the most unique of all tropical species since they are known to use chemicals for protection against predators, thereby becoming prime models in mimicry complexes. A maternally inherited male killing bacterium (*Spiroplasma)* that infects the butterfly and kills their male during the early developmental stages and result in a female biased brood has been found in Kenya. Ordinary butterfly nets were used to collect the butterflies for analysis. The results show a steady decline in the number of males in the wild. The five sites sampled in Kenya show low hatch rates (53.13 - 86.95%). Seasonal results show that females dominate (71%) with *dorripus* form (67.9%) being the most common followed by *chrysippus* form (22.6%). Female butterfly population seem to outweigh their male counterparts although eggs are laid singly which suggests that the ecological conditions favouring male killers are quite widespread. From the results, the male population face significant depression. More research needs to be done on the spatial - temporal distribution and dynamics of male – killing *Spiroplasma* bacterium to model male *D. chrysippus* population trends.

Tyrophagus putriscentiae (Schrank) (Acaridae: Astigmata): a predator of *Lasioderma serricorne* (F.) (Coleoptera : Anobiidae) reported for the first time in tobacco stores.

SC Papadopoulou
Technological Educational Institute of Thessaloniki, School of Agricultural Technology, Laboratory of Entomology, P. O. Box 14561 GR-54101; e-mail: papsm@cp.teithe.gr

Studying the biological complex of *Lasioderma serriccorne* inside tobacco stores, during the years 2002 and 2003, the presence of the cosmopolitan mite species *Tyrophagus putriscentiae* preying on live *L. serriccorne* larvae was noted. During the above two-year period, samples of dried tobacco leaves infested by *L. serriccorne* were taken and the rate of parasitism by the mite was measured. The rate of *L. serriccorne parasitized* by *T. putriscentiae* depended on time and tobacco store, was about 20%. *T. putriscentiae* is reported for the first time as a predator of *L. serricorne* in tobacco stores in Greece.

Tephritoidea species infesting Myrtaceae fruits in the state of São Paulo, Brazil

A Raga, RA Machado, MF Souza Filho, ME Sato, RC Siloto
Instituto Biológico, P.O. Box 70, 13001-970, Campinas, SP, Brazil; adalton@biologico.sp.gov.br

A field survey was conducted from August 1997 to January 2003 to identify the Tephritoidea diversity from 15 Myrtaceae species (including guavas) collected in the State of São Paulo, Brazil. A total of 38,386 fruits (203,93 kg) were collected from unsprayed trees. From 188 samples of fruits 25,162 puparia and 15,439 adults of Tephritoidea were recovered. *Anastrepha* spp. and *Ceratitis capitata* adults were obtained from 78,7% and 16.5% of the samples, respectively. About 95.8% of all adults collected were Tephritidae and 4.2% were Lonchaeidae. Only 1.7% of Tephritidae adults corresponded to *C. capitata*. From 14,540 specimens of *Anastrepha* we obtained 6,642 *Anastrepha* females identified as: *A. fraterculus* (87.7%), *A. bistrigata* (5.7%), *A. obliqua* (3.7%), *A. sororcula* (2.4%), *A. zenildae* (0.2%), *A. striata* (0.2%) and *A. turpiniae* (0.1%). All seven *Anastrepha* species were recovered from guavas. Mean infestation indices were 0.66 puparia of Tephritoidea/fruit and 123.4 puparia/kg of fruits. The samples infested by Tephritoidea was higher than 88%.

Spatial distribution and dispersal of *Heteronyx crinitus* and *H. dimidiata* in Tasmania.

HLH Redgrove
Co-operative Research Centre for Sustainable Producton Forestry, Private Bag 12, Hobart, Tasmania, 7001, Australia; hilton.redgrove@ffp.csiro.au

High populations of *Heteronyx dimidiata and H. crinitus* can cause serious defoliation to young *Eucalyptus nitens* in Tasmania. An understanding of the distribution and dispersal in the soil of these species is important for determining critical thresholds and population dynamics. This study investigated the homogeneity of their distribution around the host's root-zone. Destructive sampling, which involves removal of entire tree as a monolith can link residual population to a host. Soil populations were investigated by destructive sampling 120 random trees over 12 rows. *H. dimidiata and H. crinitus* populations coexisted, but were present in different densities. Site characteristics, including tree size, leaf totals, general condition and winow proximity were found to be of low importance. A species ratio of 1:8.4 (*H. crinitus*: *H. dimidiata*) was found. It was concluded that *Heteronyx spp*. in an over-wintering state displayed a heterogeneous spatial distribution which was uncorrelated to *E. nitens* host tree physical characteristics. . Further work will examine temporal and inter-coup variation aspects by sampling with novel pitfall traps.

Acoustics and ecology – a study of the biology and acoustics of bush crickets in their natural habitat.

P Ash, M Hall, D Robinson
Dept. of Biological Sciences, Open University, Milton Keynes, MK7 6AA, UK; d.j.robinson@open.ac.uk

The bush cricket *Leptophyes punctatissima* is a flightless tettigoniid that communicates using ultrasound. The acoustic behaviour of this species has been studied in the laboratory in the past. Experiments conducted in the field are providing information about distribution, migration, mate choice and acoustic behaviour, under natural conditions. Studies of the development of the immature stages suggest that there is a succession of food plants and that the choice of sites for egg-laying may be influenced by the food plant required by the first instars. Differences in preferences for food plants are known to exist between different populations and the implications of this have been studied in populations from different parts of the UK. Preference for food plants has been demonstrated to change during development from 1st instar stage to adult. Early instars show preference for species in the family Lamiaceae, in particular wood sage, *Teucrium canadense*. We suggest that plants in the Lamiaceae contain phytosterols essential precursor molecules for synthesis of cell membranes and steroid hormones. We discuss the type of environment favourable to this species of bush cricket, both from an acoustic and a developmental perspective.

Habitat loss decreases predator: prey ratios in a pine-bark beetle system

KL Ryall and L Fahrig
Department of Biology, Carleton University, Ottawa, Ontario, Canada, K1S 5B6 kryall@connect.carleton.ca

Using a pine-bark beetle ecosystem as a model, we tested the hypothesis that the predator:prey ratio should decrease with increasing habitat loss at the landscape scale. We selected ten red pine (*Pinus resinosa*) sites, representing extremes of available habitat within a 2-km radius surrounding each stand (low: 14.9% vs. high: 55.1% conifer forest cover). The bark beetle, *Ips pini*, its predators and parasitoids were sampled using baited multiple funnel traps and naturally-infested trap logs. Effects of habitat loss were considerable; ratios of predators to prey (mean +/- SE) were significantly reduced in isolated stands (1.63 +/- 0.41) as compared to those with large amounts of surrounding conifer habitat (0.38 +/- 0.09). The decline in ratio occurred both because there was: 1) a lower abundance of predators (ca. 0.5-0.8 X), but also 2) a significantly higher number of prey (ca. 2.2 X) in isolated stands. Loss of habitat, therefore, differentially affected the two trophic levels, supporting predictions of theoretical models. Next, we investigate possible mechanisms causing higher prey populations in isolated sites: is this due to local predator-prey dynamics over successive generations or differential immigration, emigration, reproduction or mortality among the scolytid and its predators because of loss of habitat?

Fungal endophytes decrease aphid performance in grasses: effects on virus transmission?

P Lehtonen, K Saikkonen, M Helander
University Of Turku, Section Of Ecology, Department Of Biology, 20014 Turku, Finland; patule@utu.fi

Systemic grass fungal endophytes may form a mutualistic relationship with their host plants. Endophytes live within the host tissues, receiving protection, nutrients, and transmission to the next plant generation via host seeds. The plant may benefit from endophyte infection through increased biomass production and improved herbivore resistance. Grass endophytes are able to produce toxic alkaloids, thereby negatively affecting several herbivore species. We examined how endophyte infection and nutrient availability affects the performance of bird-cherry aphid (*Rhopalosiphum padi*) in meadow fescue (*Lolium pratense*). Endophyte infection reduced aphid performance and the negative effects of endophyte infection were conditional on the soil nutrients; aphid performance decreased considerably on fertilized plants. This presumably indicates improved ability for investment in nitrogen-based alkaloid mycotoxins. The direct antiherbivore properties of endophytes can be exploited for instance in biocontrol. Barley yellow dwarf viruses (BYDVs) are aphid-transmitted viruses, which have worldwide distributions and infect species from the Poaceae. *R. padi* is an important vector species of BYDV. We study the interactions between BYDV, endophyte infection and aphids, and conduct experiments in field to find out whether endophyte infection inhibits virus transmission. In preliminary field experiments we have detected differences in virus incidences between endophyte-infected and uninfected *L. pratense*, indicating lower virus frequencies in endophyte-infected plants.

Melon: a new host of *Sesamia nonagrioides* **(Lefebre)**

L Sannino, B Espinosa
Istituto Sperimentale per il Tabacco, Via P. Vitiello 66, 84018 Scafati (SA), Italy; e-mail: luigi.sannino@tin.it

Sesamia nonagrioides (Lefebvre) (Lepidoptera Noctuidae) has been found for the first time on melon in a greenhouse in the Caserta province (South Italy) at the end of June 2003. Damage was caused by larval instars feeding on fruits and partly on leaves. Damage was observed on 70-80% of fruits. Eggs were laid on the leaves, from which newly hatched larvae moved to fruits, mostly boring at the bottom side. Moulting always took place in the fruits, where the head capsule of all instars were found. Larvae firstly eat tiny galleries, which are gradually enlarged up to 6-8 cm diameter. Even if erosions did not reach the flesh, fruits were seriously damaged because of invading larvae of Mediterranean fruit fly, *Ceratitis capitata* Wiedemann (Diptera), along with several saprophagi, as Coleoptera Nitidulidae (*Carpophilus* spp.), Diptera Phoridae (g. sp.) and Syrphidae Milesiinae (g. sp.). On growth completion, the fully fed larva crawled to the ground to pupate. Heavier losses occur when fruits are attacked in the last cycle phases, as they easily decay for pathogenic microorganisms (*Trichothecium roseum*, *Erwinia* spp.) growing on lesions produced by larvae. To kill adults before oviposition, pesticide applications, determined upon adult monitoring, are usually necessary.

Effects of life-history characteristics and resource predictability on population genetic structure of *Ogyris* (Lycaenidae) butterflies.

DJ Schmidt, JM Hughes
Griffith University, Molecular Ecology Laboratory, Nathan, QLD, 4111, Australia; d.schmidt@griffith.edu.au

Persistence of a butterfly metapopulation requires patches of host plants that are available for colonisation by dispersing individuals. The spatial and temporal predictability of patches is expected to influence the movement of individuals in the patch network. For example, a species utilising small, unpredictable patches may exhibit a relatively high level of dispersal in order to maintain the metapopulation. This study compares population genetic structure of the mtDNA COI gene in three *Ogyris* taxa (*O. amaryllis amaryllis*, *O. a. meridionalis*, *O. zosine*) from eastern Australia. The taxa differ in several life history characteristics that are hypothesised to influence patch predictability. The species with the most stable and predictable resource patches (*O. a. amaryllis*) displayed the strongest genetic structuring at both low and high clade levels. Species with less predictable resource patches (*O. a. meridionalis* and *O. zosine*) displayed less structure across clade levels. These results are consistent with the theory that spatial and temporal predictability of resources is an important influence on animal dispersal and population turnover.

Tri-trophic level interactions between the New Zealand flower thrips (*Thrips obscuratus*) and botrytis bunch rot (*Botrytis cinerea*) in grapes

K Schmidt, SD Wratten, DAJ Teulon, M Jaspers
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand, schmidtk@lincoln.ac.nz

Botrytis Bunch Rot in grapes is caused by the fungus *Botrytis cinerea* and can lead to significant economic losses in vineyards world wide. The disease pathways of this fungus are numerous and complex, of which the spread by insects is the least investigated. The New Zealand Flower Thrips (NZFT), *Thrips obscuratus*, a thrips species endemic to New Zealand, is widespread in vineyards at flowering and thrips eggs, larvae, and adults can be abundant at that time and later, some can also be found in fruit bunches. Therefore, it seems likely that a large part of the life-cycle of NZFT may take place on the vines, inter-row plants and weeds that grow in, and in areas surrounding the vineyards. The first step to investigate the interactions between the fungus and the insect is to determine the population dynamics of the thrips in vineyards. At two field sites in the New Zealand South Island regions of Nelson and Canterbury, population monitoring of NZFT from spring to autumn was carried out. White water traps at three different heights were placed randomly in the vineyard and changed weekly. Additionally, 7.5m high suction traps (based on the Johnson-Taylor trap) were placed in those regions to monitor local flight activity. Results of the thrips population dynamics from those traps in grapes are given here.

Phenoloxidase-like activities and the function of virus-like particles in ovaries of the parthenogenetic parasitoid *Venturia canescens*

O Schmidt, D Li, M Beck, W Kinuthia, J Bellati, HLS Roberts
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia; otto.schmidt@adelaide.edu.au,

The ichneumonid endoparasitoid *Venturia canescens* successfully develops inside the hemocoel of another insect by using maternal protein secretions, including nucleic acid-free virus-like particles (VLPs), to manipulate host physiology. These VLPs consist of four major proteins, which are produced mainly in the calyx tissue and transferred into the host insect together with the egg. One of the protein-coding genes (*vlp1*), with similarities to phospholipid-hydroperoxide glutathione peroxidases (PHGPx), exists in allelic forms producing two protein variants with different protein properties. We summarise observations indicating that oocytes and eggs are the source of reactive electrons, which potentially damage the lining and membranes of calyx tissues. We discuss the possible role of VLP1 in counteracting the damaging effects of oxidised phospholipids on membranes surrounding VLPs in the calyx lumen.

Lack of synchrony between apple leafcurling midge (*Dasineura mali*) and its parasitoid, *Platygaster demades*, limits biological control

PW Shaw, DR Wallis
HortResearch, PO Box 220, Motueka, New Zealand; pshaw@hortresearch.co.nz

Apple leafcurling midge (ALCM, *Dasineura mali,* Kieffer) is found in all pipfruit growing regions of New Zealand. In central New Zealand there are five generations per year of which the second is the largest and most damaging to trees. The egg parasitoid, *Platygaster demades* (Walker) which was introduced to New Zealand in 1925 to control the pear leafcurling midge is the most important natural enemy of ALCM. However, despite high levels of parasitism, ALCM populations can still reach damaging proportions. Monitoring of ALCM and *P. demades* populations over three seasons on several Nelson orchards revealed differences in the synchrony of host and parasitoid generations. The parasitoid was largely absent when the second generation of *D. mali* began, allowing for a significant population build up. Percentage parasitism in later generations was high but population levels of *D. mali* were also high. Emergence data indicated that first emergence of *D. mali* adults from the first generation was 6-11 days earlier than for *P.demades*, thus allowing for most of the second generation midge eggs to escape parasitism. The influence of host and parasitoid phenology and parasitism levels on population control of ALCM is discussed.

Life history traits of the bamboo gall maker and its inquiline in the bamboo stand

E Shibata, M Ito
Lab For Prot, Grad Sch Bioagr Sci, Nagoya Univ, Chikusa, Nagoya 464-8601, Japan; shibatae@agr.nagoya-u.ac.jp

The developmental stages of the gall maker, *Aiolomorphus rhopaloides* Walker (Hymenoptera: Eurytomidae), and its inquiline, *Diomorus aiolomorphi* Kamijo (Hymenoptera: Torymidae), in bamboo galls were determined by examining soft-X ray photography in the stand of the bamboo *Phyllostachys heterocycla* Matsumura (Monocotyledoneae: Gramineae). The gall makers overwintered as pupae and its inquilines as larvae. Adults of the gall maker emerged from the galls from mid-April to early May, coinciding with the bamboo bud elongation period. This synchronization suggests that eggs laid in the new shoots have a nutritional advantage for resulting larvae, and that a slight advance or delay in emergence may reduce suitable oviposition sites, causing population fluctuations. The inquiline emerged from late April to early June during the bamboo shoot elongation period and females could lay eggs in elongated shoots providing relatively higher nutrition for larvae.

Adaptive significance of oviposition of diapause eggs in summer in the rice leaf bug, *Trigonotylus caelestialium*

Y Shintani
Laboratory of Applied Entomology, Department of Horticulture, Minami-Kyushu University Minami-Takanabe 11609, Miyazaki 884-0003, Japan; shintani@nankyudai.ac.jp

The rice leaf bug, *Trigonotylus caelestialium*, is one of the major insect pests of rice in northeastern Japan, because it intrudes into paddy fields and causes damage of pecky rice by sucking young grains. This species produces five or more generations a year in Hokuriku District and overwinters in the egg stage in diapause state. This egg diapause is maternally induced by short days at moderate temperatures in autumn. However, it has been reported that incidence of diapause eggs increases temporally in summer as well. In the present study, adaptive significance of oviposition of diapause eggs in summer in *T. caelestialium* was examined by field researches and laboratory experiments. Seasonal prevalence of diapause eggs was different in summer among research sites with different flora in an experimental field and it was shown that oviposition of diapause eggs follows deterioration of food conditions. In mid-summer, nymphal performance was worse because of food scarcity and thus oviposition of nondiapause eggs in summer seemed less adaptive. Therefore, oviposition of diapause eggs in summer is an adaptation for avoiding food scarcity and this indicates that *T. caelestialium* has a life cycle strategy with bet-hedging to survive the summer environments.

The influence of transmission modes, host wasp & host tree preference on the population structure of *Amylostereum* symbionts of siricid woodwasps.

B Slippers, R Vasiliauskas, MJ Wingfield, J Stenlid
Department of Forest Mycology and Pathology, Swedish University of Agricultural Sciences, Uppsala, Sweden; bernard.slippers@mykopat.slu.se

Siricid woodwasps (Hymenoptera) whose larvae develop in softwoods have an obligate symbiosis with species of the fungus *Amylostereum* (Basidiomycotina). While numerous Siricid species are known, only *A. areolatum*, *A. chailletii* and *A. laevigatum* are known to have such specific symbioses. The association is species specific for the wasp, but not for the fungus. Two wasp species carrying the same fungal species often prefer different host trees to oviposit in. For example, *S. juvencus* and *S. noctilio* overlap in regional occurrence and both carry *A. areolatum*, but the former species preferentially breed in *Picea*, while the latter prefers *Pinus*. Here we study we the consequences of wasp association and tree host on population structures of *Amylostereum* spp. We also compare populations from different geographic areas in order to characterize patterns of spread of both symbiotic partners. Transmission of the fungus between generations is thought to be vertical (i.e. from mother to daughter). The shared fungal species between different wasp species, and oviposition of wasps in the vicinity of previous Siricid and *Amylostereum* infections, however, indicates a possibility for horizontal transfer as well. Using population and phylogenetic data of the fungus we aim to evaluate the influence of different modes of transmission.

Impacts of perchlorate and hexavalent chromium at the bottom of the food web

MA Sorensen, JT Trumble
Entomology, University of California, Riverside CA 92521, USA mary.sorensen@email.ucr.edu

Perchlorate and hexavalent chromium (Cr VI) are significant anthropogenic pollutants in many areas of the world. We investigated the individual and joint effects of these pollutants on the bottom of the food web in representative ecosystems. The primary test organisms were *Megaselia scalaris*, a terrestrial detritovore, and *Culex quinqufaciatus*, a common vector of encephalitis. For *M. scalaris*, Cr VI slowed development and acted as a toxicant. However, perchlorate increased the rate of growth and was relatively non-toxic. In combination, the joint effects canceled, and development was not significantly different from untreated controls. Thus, removal of either pollutant will have substantial effects on the fitness and survival of these insects. We also tested the hypothesis that perchlorate, Cr VI, or the combination of pollutants, would interact with control strategies for mosquito larvae based on the bacteria *Bacillus thuringiensis var israelensis* (Bti). Significantly more Bti (57%) was required for control when perchlorate was removed from the system. The implications of this research for both ecosystem health and mosquito control are substantial.

The population dynamics of genetically modified mosquito populations in laboratory microcosms

SL Stowell, C Locke, SM Sait, P Eggleston, JM Crampton
Biosciences Centre, University of Liverpool, Merseyside L69 7ZB, UK; (terlzgen@liv.ac.uk)

Over recent years, rapid progress has been made in the stable germline transformation of mosquitoes. The ultimate aim of this technology is the mass release of transgenic mosquitoes into the field but there is a paramount pre-requisite to determine the potential risks and environmental consequences associated with such a release. Fundamental to any risk assessment is the need for a full understanding of the life history characteristics of the transgenic individuals and populations in relation to wild-type mosquitoes. Any effect of genetic modification on the reproductive capability or competitive ability of the transgenic mosquito will necessarily have an impact on the dynamics of the population as a whole and, ultimately, it's ability to invade and become established in natural populations. The approach which we have adopted is to explore the population ecology of transformed mosquitoes in laboratory microcosms. We have established continuous "free-flow" cultures of *Aedes aegypti* mosquitoes, stably transformed with the EGFP gene. We are able to monitor and analyse the patterns in abundance of all developmental stages of transformed and non-transformed mosquitoes over multiple generations. Furthermore, the population dynamics are underpinned by experiments that explore the impact of competition for resources on measures of fitness such as survivorship, developmental rates and fecundity.

Dispersal of rice leaf bug, *Trigonotylus caelestialium,* in Italian ryegrass fields

A Takahashi, Y Shintani, H Higuchi, K Yamamura
Inada 1-2-1, Joetsu, Niigata, 943-0193, Japan; gaoqiao@affrc.go.jp

The rice leaf bug, *Trigonotylus caelestialium* (Kirkaldy), is known as a pest which attacks developing rice grains and causes pecky rice. To trace the movement of the adult bugs, mark and recapture experiments were carried out in Italian ryegrass fields. For labeling the adults, rubidium was used as an internal physiological marker. Field collected adults were labeled and released to field plots where Italian ryegrass was cut at different date. Sampling censuses with a sweep net were conducted within the released plot at 1 and 2 days after release. The population parameters were estimated using Yamamura's method (Yamamura, 2003), on the assumption that the probability of capturing the bugs was constant during two consecutive sampling censuses. The estimated rates of colonization were 0.44 - 1.0 for female and 0.33 - 0.71 for male, respectively. The results showed that females are less likely to disperse than males.

Intensity of density effects in larval performance and oviposition pattern in drosophilid flies

KH Takahashi, MT Kimura
Graduate School Of Envitonmental Earth Science, Hokkaido University, Kita 10 Nishi 5, Sapporo 060-0810, JAPAN, kazu@ees.hokudai.ac.jp

Spatial aggregation of eggs has been suggested to promote coexistence of competing species on patchy, ephemeral resources. In former studies, however, aggregation was assessed by species composition and abundance of emerging adults from patches instead of the egg distribution. This might produce a bias in the assessment of aggregation if interspecific relationship, for example, superiority in competition, differs among species or changes density-dependently. Additionally, if the effect of density on performance or survival differs among species, oviposition pattern may also differ among them; for example, species that receives strong negative effect at high density may distribute eggs uniformly. Here I examined 1) the effect of density on performance and survival in five drosophilid species, 2) interspecific relationship (e.g., competitive or mutualistic relationship) among them, and 3) patterns of egg distributions in them. It appeared that the effect of density varied among species. In addition, the outcome of competition differed with density, suggesting the inappropriateness of the assessment of egg distribution by emerging number of adults. Species showing high performance even at high density tended to exhibit highly aggregated egg distribution. The connection between the intensity of density effect and oviposition pattern would affect coexistence of them.

Causes of pest outbreaks

W Tshernyshev
Dept of Entomology, Faculty of Biology, Moscow State University, 119992, Russia, tshern@yandex.ru

Contrary to a well-known opinion, biodiversity in arable fields may be higher than in natural adjacent biotopes and its level has no relation to pest outbreaks in crops. The outbreaks arise due to: 1) the monoculture crop itself is a strong source of olfactory and visual attractive stimuli for herbivores but not always for predators and parasites colonising the field later when there is sufficient amount of their victims there; 2) many crop pests are hortobionts and can be invulnerable because many hortobiont predators are able to penetrate into the field only after "canopy forming" by the plants. Herpetobiont predators climb plants relatively seldom; 3) the most of entomophagous species prefer the edge of the fields, hence the central zone is more favourable for pests; 4) almost all natural enemies use field grassy margins as shelters for overwintering and in other unfavourable situations. These narrow strips of land is often insufficient to supply all territory of the field with entomophagous arthropods; 5) some herbivores increase their populations fast (*i.e.*, aphids) and their natural enemies are often not able to overtake them.

Shoot sprouting of three willow species in response to damage by a stem-boring insect affects insect herbivores at different intensities

S Utsumi, T Ohgushi
Hiranocho, Kamitanakami, Otsu, Shiga, 520-2113, Japan; shun@ecology.kyoto-u.ac.jp

We investigated the indirect effects of the stem-boring insect *Endoclyta excrescens* on two insect herbivores on three willow species, *Salix gilgiana, S. eriocarpa*, and *S. serissaefolia.* When the branches were damaged by the stem-boring insect, the willows were stimulated to vigorously produce lateral shoots. This enhanced lateral shoot growth was also found after physical damage by artificial boring. Newly-emerged lateral shoots were longer and upper leaves had a higher water and nitrogen content. Larvae and adults of the leaf beetle *Plagiodera versicolora* were significantly more abundant on lateral shoots than on current-year shoots. Similarly the density of the aphid *Chaitophorus saliniger* was significantly higher on lateral shoots than on current-year shoots. Although densities of the two insect species on current-year shoots did not differ among willow species, we found significant differences in densities on lateral shoots among willow species. The stem-boring insect positively affected the aphids and the leaf beetles by producing new food resources as a result of the resprouting responses of the three willow species. However the intensity of the positive effects caused by the stem-boring insect was different among the three willow species because of different regrowth responses to boring damage.

Arthropods living in the subnivean space in the Dolomites (north-eastern Italy)

S Vanin, M Turchetto
Department of Biology, University of Padova, via U. Bassi 58/b, I-35121 Padova, Italy; stefano.vanin@unipd.it

In the temperate regions, during the winter, snow cover forms an insulating blanket between two very different environments: the y, very cold and windy atmospheric air environment and the moist, relatively warm and stable-air microenvironment under the snow. In the subnivean space (3-5 cm between snow and soil) the high humidity, constant oxygen input and temperatures near 0°C allow some invertebrates to be active. During two consecutive winter seasons, we collected arthropods active under the snow cover using modified pitfall traps in a valley of the Dolomites (NE Alps). Arachnida (12%), Collembola (80%), and Insecta (18%) were found. The most abundant insects were Coleoptera (39%) and Diptera (43%). Some species of Collembola and Diptera, found active under the snow, are known to be troglophilous: specimens of *Chionea* have been reported during the summer from natural and artificial cavities, whereas the collembolan species *Tomocerus minor* and *Arrhopalites caecus* had so far often been collected from caves. The presence of troglophilous species shows that the subnivean space becomes an expansion of underground microhabitats, as they are both characterized by constant microclimatic conditions.

Biological assessment of non-wadeable Midwestern (USA) rivers using macroinvertebrates

KJ Wessell, RW Merritt, KW Cummins, JGO Wilhelm, JD Allan.
Department of Entomology, Michigan State University, East Lansing, MI 48824 USA

There are relatively few state or federal programs designed to monitor and evaluate non-wadeable rivers. Many of the more traditional population and community level metrics used in wadeable stream assessment may not be appropriate for assessing non-wadeable systems. We analyzed macroinvertebrate samples from non-wadeable river reaches subjected to a wide array of anthropogenic influences to determine which potential metrics provided the most unique information and accounted for the largest amount of among-reach variability. The final protocol allows for two types of assessments: One that targets large woody debris habitats only, and one that relies on samples from all habitats present in the study reach. Both assessment types evaluate sites based on scores from 7 individual metrics incorporated into a summary index. When properly implemented and combined with the habitat assessment procedures, the macroinvertebrate protocol will allow for the objective evaluation of non-wadeable rivers in the midwestern United States and may provide a framework for evaluating non-wadeable river systems in other regions.

Modelling population dynamics of light brown apple moth *Epiphyas postvittana* (Walk.) (Lepidoptera: Tortriciade) in Australia: how many generations are there?

RS Walgama, MP Zalucki
School of Life Sciences, University of Queensland, St. Lucia, QLD 4072, Australia. Division of Entomology, Tea Research Institute, Talawakelle, Sri Lanka. sampathwalgama@hotmail.com

The light brown apple moth (LBAM) is a serious pest of fruit crops and ornamentals. It is native to southeast Australia including Tasmania and has been introduced to New Caledonia, British Isles, Hawaii, Western Australia and New Zealand. The pest is highly polyphagous, causes significant economic damage to its principal host apple and has been classified as a noxious pest in USA and Canada leading to restrictions on imports of Australian primary produce. The moth is cold adapted and believed to undergo three generations a year including a summer, autumn-winter and spring generations in Victoria, in the Australian Capital Territory, in Tasmania and in New Zealand. Knowledge of the biology and ecology of this species is relatively comprehensive and the published data have been re-analyzed and used in the construction of a population dynamics model. The model is built using DYMEX^{TM}, a process based modular modelling package for constructing stage structured population models. The model is designed to be driven by the climate data. The model predictions indicate the three generation phenology with climate data from locations like Victoria and Hobart (Tasmania) but 4 generations in locations like Mildura and Victoria. These predictions lead us to re-assess the estimated number of generations previously reported for LBAM.

Can volunteers be used to estimate the abundance & diversity of butterflies using the Pollard walk? An Australian example.

N Collier, DA Mackay
School of Biological Sciences, Flinders University, G.P.O Box 2100 Adelaide 5001; neil.collier@flinders.edu.au

In some circumstances volunteers can be used to collect various ecological data. We have been investigating the usefulness of volunteers in collecting data on the abundance and diversity of the urban butterfly fauna in Adelaide, South Australia. The program is modelled on other programs such as the British butterfly monitoring scheme. Volunteers received training to record the diversity and abundance of butterflies using a 'Pollard walk' protocol. Kits containing information on butterfly identification, data sheets, and instructions for conducting surveys were provided to each volunteer. We analysed the effects of factors such as weather conditions, observer experience, and whether or not observations were made on an individual or group basis. Our preliminary results indicate that volunteers are useful in detecting and identifying butterflies of certain groups *e.g.* Nymphalidae, Papilionidae, but less efficient in detecting and identifying other groups of butterflies, *e.g.* Hesperiidae and Lycaenidae. This may be due, in part, to the similar colouration and cryptic behaviour of butterflies from these families. Unfortunately, the latter two groups contain several taxa of conservation concern and therefore this censusing technique may have some shortcomings in identifying conservation priorities for butterflies

Estimation of leafhopper biodiversity (Auchenorrhyncha: Cicadellidae)

S Kamitani
Entomological Laboratory, Faculty of Agriculture, Kyushu University, Hakozaki, Fukuoka, 812-8581, Japan; kamitani@agr.kyushu-u.ac.jp

Leafhoppers are an important component of terrestrial food web, because they occur in high density and species richness in most terrestrial ecosystems. To assess true species richness of leafhoppers is no easy task, because extraordinarily intensive field surveys are needed. When leafhopper diversity is surveyed by an intensive but short-term field survey, it is required to explain that it is true diversity. In this study, the author tried to indicate the most suitable estimator to estimate true species richness for leafhoppers using statistical sampling data. Although most of the estimators such as Chao1 were not consistent with the true species richness, an incidence-based coverage estimator of species richness was the most appropriate method to estimate the true species richness. The estimator, ICE, estimates the total species number of leafhopper in the sensus field, but it does not show each component species of fauna. To estimate component species, possibility of an occurrence for each species is simulated using floral data and GIS meteorological data without using the aforementioned estimator, because all of leafhoppers are phytophagous insects and their occurrence strongly depends on the existence of their host plants and meteorological elements.

Antipodes antipasto: mice make a meal of subantarctic insects

JWM Marris
"Ecology and Entomology Group, PO Box 84, Lincoln University, Canterbury, New Zealand; marris@lincoln.ac.nz"

The introduction of mammalian predators to New Zealand has had a major detrimental impact on the native fauna. Predation by introduced mammals has caused the extinction of many species and reduced the numbers of numerous others. Most research, however, has focused on the impacts of larger predator species (cats, mustelids and rats) on the avifauna. Invertebrate survey work on the subantarctic Antipodes Islands, 730 km southeast of New Zealand, shows the negative impact of the introduced house mouse (*Mus musculus* Linnaeus) on the invertebrate fauna. Comparisons between mouse-infested Antipodes Island, where mice were introduced about 100 years ago, and neighbouring, mouse-free Bollons Island indicate that mice have had a significant impact on the faunal composition and abundance of Antipodes Island invertebrates. Two species, *Loxomerus* n. sp. (Coleoptera: Carabidae) and an undescribed weta (Orthoptera: Rhaphidophoridae), may be extinct on Antipodes Island, probably due to mouse predation. Evidence also strongly indicates that mouse predation has markedly reduced the abundance of most of the larger beetle species (length > 4 mm). Long-term impacts of mouse predation and prospects for mouse eradication are discussed.

Comparison of the weevil settlements (Coleoptera: Curculionoidea) of four reservoirs in central Serbia

S Pešić
Faculty of Science; P.O.Box 60; 34000 Kragujevac; Serbia and Montenegro; snpesic@kg.ac.yu

The weevils investigations in Kragujevac and surroundings were initiated in 1987. Parallel study of four Reservoirs (Gruža, Grošnica, Šumarice and Bubanj) started in 2001. All representative habitats, from the lakes shoals to 50-100m from the water were covered: swampy meadows, moist meadows, valley meadows, neglected lands, ruderal vegetation, boundaries and tilled grounds, as well as forests. The sampling techniques included sweeping and shaking of plants, rinsing of aquatic plants, beating of the tree branches and bushes, mowing of the ground floor vegetation, hand collecting and separation of insects from the soil with the aid of Tulgren-Berlesse apparatus. Comparatively presented results are:

Reservoir	Findings	Species	Males	Females	Specimens

The focus was on aquatic weevils. During this study most of this kind of the weevils (like *Bagous bagdatensis* Pic) is registered for the first time in Serbia.

The focus was on aquatic weevils. During this study most of this kind of the weevils (like *Bagous bagdatensis* Pic) is registered for the first time in Serbia.

Similarity of the soil weevil fauna (Coleoptera: Curculionoidea) in the west, central and east Serbia

S Pešić
Faculty of Science; P.O.Box 60; 34000 Kragujevac; Serbia and Montenegro snpesic@kg.ac.yu

According to the authoress weevil materials collected from the soil since 1980s, on different localities in Serbia (West: Suvobor, Čemerno, Mučanj, Ivanjica; Central: Gledićke planine, Gruža, Rudnik, Bukulja, Žeželj, Grošničko jezero, Jastrebac, Goč; East: Beljanica, Kučajske planine, Resavska klisura) Central Serbia is a real bridge between West and East Serbia. There are 12 species. Six of them are common in the West (*Ruteria hypocrita, Acalles camelus, A. commutatus, A. echinatus, Acallocrates colonnelli* Bahr, 2003 and *Aparopion costatum*), and five in East Serbia (*Echinodera valida, E. behnei, Acalles papei, Aparopion costatum* and *Ubychia holdhausi*). Just one Cryptorhynchinae species, *Acalles ganglbaueri* (on Goč mt.), and quite common in the oak forests short-nosed *Brachysomus hirtus* are registered only in Central Serbia. *Aparopion costatum* is the only one soil weevil species common for all. *Acalles micros* has up to now been collected only in the East Serbia (on Beljanica mt.). The similarity expressed through the Sørenson index is: West-Central 0.667, Central-East 0.556 and only 0.167 for West-East.

How does cultivation in the vineyard affect beneficial invertebrates?

D Sharley, A Hoffmann, L Thomson, A MacGregor
"P.O. Box 905 Mildura, Vic, 3502, Australia. david.sharley@dpi.vic.gov.au"

Cultivation of the soil has been a common management practice in Australian vineyards for many decades. This is especially true for the irrigated vineyards in the Sunraysia region of north-west Victoria. Growers tend to cultivate for a variety of reasons including, frost protection, decreased soil compaction and increased drainage. However, cultivation also tends to disturb the soil, thus disrupting soil invertebrates such as earthworms and carabid beetles. Invertebrates are known to react sensitively to viticultural management practices and are considered important for their bioindicative value. An investigation into the impact of cultivation on soil and canopy invertebrates in vineyards in Sunraysia is in progress as part of my PhD. The experimental design of this study consists of five randomised plots within one vineyard. Each plot contains cultivated and non-cultivated areas. Within each plot, samples are collected along a transect using pitfall and yellow stick traps. Samples are being sorted to order, where analysis will determine which orders are significantly affected by cultivation. These orders will then be sorted to species level. In this experiment potential indicators of cultivation impacts will be identified and tested further in a regional study set to begin later this year.

Coleoptera in agrolandscape of Kuban-Azov lowland.

A Sujazov
Department of Entomology, Faculty of Biology, Moscow State University, Moscow, 119992, Russia; Attagenus@mail.ru

Coleoptera have been studied in agricultural fields at different distances from their edges and in adjoining biotopes (in forestbelts, field grassy margins) for 5 years. About 1000 species of 69 families were found in this landscape seriously affected by man activity. Maximal numbers of Coleoptera were registered in field grass margins and in edges of the fields. In the central zone of fields, number of species is considerably reduced. The following families had the maximal number of species: Curculionidae (123), Staphylinidae (107), Chrysomelidae (104), Carabidae (71), Cerambycidae (42), Scarabaeidae (37), Tenebrionidae (36), Buprestidae (32), Elateridae (31). Some species collected in lowland fields were typical for the mountain meadows and woods, i.e. some representatives of Staphylinidae, Scaphidiidae, Trogositidae, Cucujidae, Erotylidae and Curculionidae. These beetles were founded on the plain only in spring.

Omaliopsis (Coleoptera: Staphylinidae) – old or new south-north connections?

MK Thayer
Field Mus. Nat. Hist., 1400 S Lake Shore Drive, Chicago IL 60605, USA; mthayer@fieldmuseum.org

At least 16 lineages of the vast family Staphylinidae have endemic species disjunct among three or more austral areas, usually Australia/New Zealand/southern South America. The only lineage analyzed to date appears to have a New Zealand clade as sister to the rest of its species, which show multiple connections between South America and Australia. The genus *Omaliopsis* currently includes six African or Madagascan and two Chilean species; it was originally characterized as one of several "old Gondwanan lineages" of Omaliinae. I have discovered that *Omaliopsis* includes 40 more species (mostly undescribed) adding to its distribution northeastern India, Australia, the northern Andes, New Guinea, and non-Gondwanan areas Taiwan, southern China, Borneo, and Mexico (to southwestern USA). The sparse fossil record shows that Staphylinidae, perhaps even Omaliinae in particular, were present and widespread on Pangaea. Phylogenetic relationships within a widespread and potentially ancient clade such as *Omaliopsis* could be expected to reflect, at least partly, Pangaean or Gondwanan-Laurasian fragmentation. Reconstruction of relationships within *Omaliopsis*, with its northern and southern elements, will allow testing the origins of the distribution. In particular, the phylogenetic position of the southern Asian species differs in the predictions made by Pangaean and Gondwanan breakup models.

Modelling population dynamics of light brown apple moth *Epiphyas postvittana* (Walk.) (Lepidoptera: Tortriciade) in Australia: how many generations are there?

RS Walgama, MP Zalucki
School of Life Sciences, University of Queensland, St. Lucia, QLD 4072, Australia. Division of Entomology, Tea Research Institute, Talawakelle, Sri Lanka. sampathwalgama@hotmail.com

The light brown apple moth (LBAM) is a serious pest of fruit crops and ornamentals. It is native to southeast Australia including Tasmania and has been introduced to New Caledonia, British Isles, Hawaii, Western Australia and New Zealand. The pest is highly polyphagous, causes significant economic damage to its principal host apple and has been classified as a noxious pest in USA and Canada leading to restrictions on imports of Australian primary produce. The moth is cold adapted and believed to undergo three generations a year including a summer, autumn-winter and spring generations in Victoria, in the Australian Capital Territory, in Tasmania and in New Zealand. Knowledge of the biology and ecology of this species is relatively comprehensive and the published data have been re-analyzed and used in the construction of a population dynamics model. The model is built using DYMEX^{TM}, a process based modular modelling package for constructing stage structured population models. The model is designed to be driven by the climate data. The model predictions indicate the three generation phenology with climate data from locations like Victoria and Hobart (Tasmania) but 4 generations in locations like Mildura and Victoria. These predictions lead us to re-assess the estimated number of generations previously reported for LBAM.

Fires, forest mosaics & boreal beetle diversity

C Bergeron, J Spence, J Volney
442 Earth Sciences Building, University of Alberta, Edmonton, AB, T6G 2E3 Canada; cb1@ualberta.ca

Forest composition, age structure, density, and growth rate vary in space, providing a range of different habitats for boreal wildlife. Carabid beetle (Coleoptera: Carabidae) communities are sensitive to habitat variation and, therefore, we studied concomitant spatial variation between forest habitat and carabid beetle communities. A systematic grid of 200 plots (640 m apart) was established on the EMEND study site (7 km by 13 km of boreal mixedwood in northwestern Alberta). Forest characteristics and beetle assemblages collected by pitfall trapping were compared in each of these 200 plots. Distinct late successional tree and beetle species assemblages occurred mainly on north facing aspects of the landscape where fires have been uncommon during the last 150 years.

Bugs beneath the surface: biodiversity, degradation & the functional roles of soil macroinvertebrates in maintaining ecosystem health in Australia's tropical savannas

T Dawes-Gromadzki
"Tropical Savannas Management CRC and CSIRO Tropical Ecosystems Research Centre, PMB 44 Winnellie, NT 0822, Australia; Tracy.Dawes-Gromadzki@csiro.au "

Soil macroinvertebrates such as termites and ants play a pivotal role in sustaining production and biodiversity in Australia's tropical savannas. Through their foraging and nesting activities they recycle nutrients and carbon and produce soil pores that facilitate water infiltration. The challenge ahead is to quantitatively understand the relationships and process that drive this. What roles do different species and functional groups play in various landscape processes? What are the effects of disturbances (eg. cattle grazing) on these relationships, and the consequences for landscape health? Increased degradation is often associated with declines in macroinvertebrate diversity and activity. Termites appear to be one of the most resilient groups, capable of maintaining activity in degrading landscapes. This study examines the effects of long-term stock exclusion on termite abundance, diversity and function in Queensland, and the use of termites as a tool to kick-start the rehabilitation process in degraded savanna sites in the Northern Territory. This paper presents (i) an overview of the importance of soil macroinvertebrates to soil functioning, and (ii) experimental results that suggest variation in macroinvertebrate community structure and soil water relations with changing land condition, and the role of termites in soil rehabilitation.

Canopy beetles of the western Amazon Basin: β-diversity in time and space

TL Erwin, V Aschero
"Entomology, MRC 187, Smithsonian Institution, Washington, DC 20560 USA; erwin.terry@nmnh.si.edu"

Beetles sampled as part of a monitoring program of Oil Company activities in the western Amazon Basin were subsequently reinvestigated to test for β-diversity between two western Amazon rainforest sites located on the equator at 21 kilometers distance from each other. Coleopteran families selected for this study were Artematopodidae, Attalabidae, Buprestidae, Cantheridae, Carabidae, Ceratocanthidae, Chrysomelidae, Cleridae, Curculionidae, Elateridae, Erotylidae, Mordellidae, and Tenebrionidae. A total of 14,622 adults representing 1915 morphospecies were processed from 1200 samples (10,944 m^2 trap surface area). Assessments using EstimateS$^{\copyright}$ were made to determine whether the sampling regime was adequate to obtain a complete representation of species in the two plots. For those families adequately sampled, a test of Complementarity for the two plots resulted in values ranging from .48 to .69, the species-rich families having the higher values. These results suggest a markedly high degree of species turnover across small distances in generally similar forest composition in the western Amazon Basin, which in turn suggests that a conservation strategy of making a few large conservation areas may not preserve a large share of existing biodiversity. This further suggests that a new conservation paradigm is necessary if we are to protect much of Earth’s precious natural heritage.

The identification and ecological role of dipteran larvae in tertiary fossil lake ecosystems

S Wedmann, G Richter
Institute of Zoology and Anthropology, Section Morphology and Systematic, University of Goettingen, Berliner Str. 28, D-37073 Goettingen, Germany; swedman@gwdg.de

The sediments of fossil lakes often yield numerous remains of terrestrial insects. In contrast to this, in many fossil sites autochthonous, water-living forms are only rarely found. This is the case for the former Maar lakes of Messel, Eckfeld and Enspel (all Germany). Thus, analysis of the insect fauna may yield interesting clues to the terrestrial environment of the former lake but is not able to yield information on the ecosystem of the lake itself. Our analysis of fossil faeces from planctivorous fish of the fossil site Messel has for the first time revealed that larvae of phantom midges (Chaoboridae) and biting midges (Culicidae) existed in the former lake. The identification of the larval midges was possible on the base of isolated mouthparts, i.e. mandibles and filter tufts. Due to the quantity of these remains it can be concluded that the aquatic midges formed large populations in the former lake. Therefore, the larvae and to a lesser degree also the pupae of these midges were very important factors of the food web and are crucial elements for the understanding of the function of the former lake ecosystem.

From metapopulation patterns to processes at the individual level: lessons from long-term butterfly studies

M Baguette, N Schtickzelle
Biodiversity Research Centre, Catholic University Louvain (UCL), Croix du Sud 4 B-1348 Louvain-la-Neuve, Belgium ; baguette@ecol.ucl.ac.be

Metapopulation biology provides a sound theoretical framework for the understanding of population persistence in fragmented landscapes. Long-term comparative studies of metapopulations of several butterfly species in contrasted landscapes generate some results that might be relevant for the future of research in the field: (1) dispersal rates decrease according to the fragmentation process, which leads to dispersal rates adapted to each metapopulation in its particular habitat network and (2) local population growth rates are related to the rate of efficient dispersal. Two related processes acting at the individual level may generate such patterns: a decrease of the dispersal propensity due to higher dispersal mortality according to fragmentation, which subsequently modifies the trade-off between dispersal and fecundity. The first process linking lower dispersal propensity with higher cost of dispersal is documented by solid empirical evidences, whereas the change in the trade-off between dispersal and fecundity is currently inferred from interspecific comparisons only. According to both processes, selection against dispersal in fragmented landscapes would lead to changes in individual reproductive performances, which could affect the evolutionary future of the population. From a conservation perspective, individuals from (meta)populations and species sacrificing dispersal at the expense of reproductive performances are most vulnerable to habitat loss and fragmentation, because of their higher sensitivity to stochastic events.

Indirect interactions and quantitative food webs

HCJ Godfray, F van Veen, RJ Moris
NERC Centre for Population Biology, Imperial College, Silwood Park, Ascot, Berks, SL5 7PY, UK; c.godfray@imperial.ac.uk

Quantitative food webs are a means by which the multitrophic structure of natural communities can be described, and hypotheses about indirect interactions formulated. We will describe the construction of quantitative food webs representing communities of plants, herbivorous insects, parasitoids (and hyperparasitoids), in particular communities based around aphids and leaf miners. We will show how the webs can be used to predict possible examples of apparent competition, and how these hypotheses can be tested using experimental manipulations in the field.

Trait-mediated indirect interactions between herbivorous mammals and insects: claiming for an integrate view of the terrestrial communities

JM Gómez, A González Megías
Dpto Biología Animal y Ecología, Universidad de Granada, E-18071 Granada, Spain; jmgreyes@ugr.es

My goal in this presentation is to assess the importance that the trait-mediated indirect interactions (TMII) play in the interaction between herbivorous mammals and insects, by reviewing the existing literature on both the diverse effects of mammals on plants and on competition between phytophagous insects and mammals, and by showing my own studies on mammal-insect-crucifer interactions. The main idea is that TMIIs are crucial for insects since in most cases 1) ungulates outcompete insects, and 2) the main short-term effect of ungulates is not a change in plant density but a modification of chemical, physiological, morphological and architectural traits of plants (induced resistance). I will also extend the consideration of TMIIs to those phytophagous insects like nectar- or pollen-feeders that are mutualists of plants, specifically when both ungulates and insects select plants according to the same traits. In addition to the potential ecological consequences of TMIIs, I will argue that ungulates and insects can sometimes act as conflicting selective pressures on plants, since an evolutionary consequence of TMIIs has been little considered. All of these ideas suggest the necessity of considering together both phytophagous vertebrates and invertebrates in order to draw a more accurate picture of the dynamics of terrestrial communities.

Climate change and recovery of endangered species

C Parmesan
Integrative Biology, 1 University Station C0930, University of Texas at Austin, Austin, Texas, 78712 USA; parmesan@mail.utexas.edu

In a quantitative analysis of 99 wild species, Parmesan and Yohe (2003) estimated that the magnitude of range shifts with 20th c. climate warming was 6.1 km/decade poleward. Because endangered species typically live in rare habitats, either historically or as a result of habitat destruction, shifts of this magnitude in climate space will have profound implications for the abilities of endangered species to persist in traditional preserve systems. Under climate change, management and recovery of endangered species will necessitate a fundamentally different approach from traditional recovery plans. These processes (climate change impacts and management options) will be discussed in light of an endangered sub-species of butterfly, the Quino Checkerspot (Euphydryas editha quino), which occurs in southern California, USA.

Dynamics of insect-plant association in a human-disturbed butterfly metapopulation

M Singer, CD Thomas, DA Boughton
The University of Texas at Austin, Integrative Biology, 1 University Station C0930 Austin, Texas 78712-0253, USA.

A relatively homogeneous patch network for Edith's checkerspot butterfly (Euphydryas editha) was converted by humans to a network with two patch types: forest clearings and unlogged patches (rocky outcrops). In the clearings a novel host species, Collinsia torreyi, was colonized. Initially, clearings supported higher population growth than outcrops and acted ecologically as a set of sources. Metapopulation-level effects that resulted from this role included effects of isolation from clearings on both insect density and host preference in outcrops. Evolution of host preference in outcrop patches was driven by gene flow against the direction of natural selection in those patches. Ecological stability of the overall system was augmented by a negative association between the habitat quality of clearings and the quality of adjacent outcrops. High quality clearings lay adjacent to low quality outcrops and vice versa. For about 20 years the system comprised a reversible source-sink with alternative stable states. Clearings could act either as sources or as sinks. With succession the reversibility of the source-sink system has evaporated and the patch type that comprised strong population sources in the 1980's, the clearings, now consists of a set of permanent sinks. The insects have all returned to their traditional host species. Nonetheless, a strong evolutionary legacy of the events of the past 20 years can still be detected in the system.

Assessing predation rate of biological control agents using video techniques

SD Wratten, C Merfield
National Centre for Advanced Bio-Protection Technologies, PO Box 84, Lincoln University, Canterbury, New Zealand; wrattens@lincoln.ac.nz

In biological control research, key questions include: Which are the most important predators or parasitoids in a particular agro-ecosystem? What host/prey species do they attack? For particular or parasitoid species, a further question is: What is the attack rate or prey/host consumption rate? Answering the first two questions above can involve assessing natural enemy density, followed by dissection and/or immunological or molecular analyses of diet. The third question is particularly difficult to answer in the field. Real-time observation of the natural enemies in the field is possible but is very time consuming. The use of "prey facsimiles such as laboratory-produced blow fly eggs or Drosophila pupae can give "predation rate" but, alone, does not identify the predator species. Using prey facsimiles or real prey (in combination with infra-red illumination for nocturnal predators) along with time-lapse video recording can address this key question more easily. Analogue video recording using tapes has many drawbacks including tape and VCR wear and time-consuming searching for relevant parts of the recording. Digital video can overcome this problem. The potential of this method is illustrated with examples from nocturnal polyphagous predators on the soil surface and from parasitoid f

Competitive coexistence in patchy environments: the interplay between spatial variation and density-dependent dispersal

P Amarasekare
Department of Ecology and Evolution, University of Chicago, 1101 East 57th Street, Chicago IL 60637, USA; amarasek@uchicago.edu

It is well known that dispersal from localities favorable to a species' growth and reproduction (sources) can prevent competitive exclusion in unfavorable localities (sinks). What is perhaps less well known is that too much emigration can undermine the viability of sources and cause regional competitive exclusion. I investigate two biological mechanisms that reduce the cost of dispersal to source communities. The first involves increasing spatial variation in the strength of competition such that sources can withstand high rates of emigration; the second involves reducing emigration from sources via density-dependent dispersal. I compare how different forms of spatial variation and modes of dispersal influence source viability, and hence source-sink coexistence, under dominance and preemptive competition. A key finding is that while spatial variation substantially reduces dispersal costs under both types of competition, density-dependent dispersal does so only under dominance competition. Thus, the diversity reducing effects of high dispersal rates persist under preemptive competition even when dispersal is density-dependent, but can be significantly mitigated under dominance competition if density-dependent dispersal occurs in response to crowding rather than Allee effects. These results lead to testable predictions about source-sink coexistence under different regimes of competition, spatial variation and dispersal.

Diversity-stability relationships in host-parasitoid communities: an empirical exploration

P Amarasekare
Department of Ecology and Evolution, University of Chicago, 1101 East 57th Street, Chicago IL 60637, USA; amarasek@uchicago.edu

The relationship between diversity and stability is crucial in understanding the dynamics of multi-trophic interactions. There are two hypotheses about the causal link between diversity and stability. The first is that fluctuations in resource abundance allow consumer coexistence, thus increasing diversity at the consumer trophic level (resource variability hypothesis). The second is that interactions between coexisting consumer species reduce consumer efficiency and damp consumer-resource fluctuations, thus increasing stability (consumer efficiency hypothesis). The two hypotheses lead to three predictions: (i) Fluctuations should be greater (resource variability) or smaller (consumer efficiency) in resource populations with coexisting consumer species, compared to those invaded only by the consumer species superior at resource exploitation, (ii) Average resource abundance should be greater (resource variability) or smaller (consumer efficiency) in resource populations with greater fluctuations, and (iii) Removal of the inferior resource exploiter should increase or unaffect resource population fluctuations (resource variability), or increase them always (consumer efficiency). I tested these predictions with data from a host-multiparasitoid community. The results contradict the expectations of the resource variability hypothesis, suggesting that host population fluctuations are unlikely to be driving parasitoid coexistence. They are consistent with the consumer efficiency hypothesis, that interactions between coexisting parasitoid species damp host fluctuations.

Estimation of developmental zero and thermal constant for alfalfa root weevil ((Sitona discoideus Gyll.(Col.: Curculionidae)) egg

A Arbab
Department of Agriculture, Takestan Islamic Azad University, POBox:34185-315, Takestan- Iran; abasarbab@hotmail.com

The alfalfa root weevil, Sitona discoideus Gyll, is one of the important pests of lucerne. This insect have wide distribution in Iran, and cause loss of yield and longevity of lucerne fields. The knowledge of developmental zero and thermal constant is a method that will be effective for estimation of time of activity and increasing accuracy of control methods. The eggs were reared in five constant temperatures (15,20,23,26, 28 &30°c) and 100% R.H., and developmental rates were calculated. With using of five models, Linear, Logan, Logan6/Lactin1, Lactin2 and Biere2, evaluated relationship between constant temperatures and developmental rates. The linear model had the most efficiency. This model estimated developmental zero and thermal constant.

Spatial distribution of immature stages of alfalfa seed weevil, Tychius aureolus(Col.: Curculionidae), and alfalfa seed wasp, Brochophagus roddi, (Hym.: Eurytomidae) in alfalfa seed fields

A Arbab
Department of Agriculture, Takestan Islamic Azad University, POBox:34185-315, Takestan- Iran; abasarbab@hotmail.com

Alfalfa seed pests, such as alfalfa seed wasp, Brochophagus roddi (Hym.Eurytomidae) and alfalfa seed weevil, Tychius aureolus (Col.Curculionidae), cause high damage in alfalfa seed production, but do not development any sampling program for population estimate and management of them. In during two years (2001& 2002), the spatial distribution of immature stages of these insects was analyzed using the crowding indices (ID ,Cx ,X*, Id & 1/k) , Taylor's power law and Iwao's regression technique. All indices indicated an aggregated distribution of two insects in lucerne seed fields. Compared with Iwao's regression, Taylor's power law provided a better description between variance and mean density. The coefficient of Taylor's power law for alfalfa seed wasp and alfalfa seed weevil were (a= 0.5, b= 1.02 ± 0.06, r2 = 0.95) and (a= 0.275, b= 1.06± 0.05 r2= 0.82) resp. and these for Iwao's regression were (a= 0.8, ß= 2.95± 0.06 r2= 0.5) and (a= 0.9, ß= 1.07± 0.14 r2= 0.29) resp.

Biodiversity, an emergent property of plant-mediated indirect interactions?

J K Bailey
Department of Biological Sciences & the Merriam-Powell Center for Environmental Research, Northern Arizona University, Flagstaff, AZ 86011 USA; JKB22@dana.ucc.nau.edu

Although, indirect interactions among species, particularly herbivores, have been considered unimportant, most terrestrial ecosystems lose 15-20% of above-ground net primary productivity (ANPP) to herbivores. There are at least 4 major plant-mediated pathways through which herbivores can indirectly impact biodiversity of dependent community members. Individually, specific herbivores can alter plant architecture, plant secondary chemistry, plant species composition, and/or build structures all of which can affect microclimate, host-plant quality, and host-plant spatial distribution and abundance. In natural systems species rarely exist in isolation, but are part of a greater tangled web of direct and indirect effects of many species as well as biotic and abiotic ecological factors. Because of this tangled web of interactions, synergistic community responses (i.e., responses that are attributable to a combination of factors rather than any single factor alone) are probably common, though rarely studied. In an aspen and cottonwood system I show that arthropod species diversity is driven by the synergistic impact of plant mediated indirect interactions among common herbivores, including a gall-forming sawfly, elk, and beavers. Specifically I argue that the individual and combined effects of common, dominant and keystone herbivores create a gradient of habitats or conditions that increase the probability of unique indirect interactions, increase the heterogeneity of potential niches for other species, and increase, the possibility of synergistic outcomes, all of which can positively affect biodiversity.

Integrating mark-recapture, weather, and remote sensed data to predict movement

JS Bancroft
17053 N. Shafter Av., Bakersfield, CA 93263, USA; jsbancroft@pw.ars.usda.gov

The most difficult part of understanding population dynamics is acquiring movement data that can be analyzed in a sound theoretical context. The movement of animals among resources has been studied using many empirical techniques and analytic theory. I will use arthropod systems to show technical challenges and analytic methods that may be applied to your system. I show how multiple approaches may provide a synthesis for understanding movement in a given system, and I finish by couching the results in simulation studies that predict population dynamics.

Metapopulation dynamics of host-parasitoid interactions: the role of space and stochasticity

MB Bonsall, MP Hassell
Department of Biological Sciences, Imperial College London, Silwood Park Campus, Ascot, Berkshire. SL5 7PY U.K.

The pairwise interaction between parasitoids and their hosts has shaped our understanding of fundamental and applied concepts in ecology and in particular in population dynamics. Recently, work to extend these concepts to more spatially-explicit interactions has revealed how patterns of persistence in host-parasitoid systems may be influenced by both ecological and stochastic factors. In this talk, we will focus on how the patterns of host-parasitoid interactions are altered in spatially-explicit environments using both quantitative methods and experiments. In particular, we will focus on the use of a time series approach to understanding how space can affect persistence and how stochasticity can affect the dynamics of specific host-parasitoid interactions. We will briefly discuss the sorts of methods we have used to develop our understanding of these host-parasitoid systems.

Coexistence and niche segregation in cockroach guilds in cultivated fields

S Boyer, C Rivault
stephane.boyer@univ-rennes1.fr

Cockroach guilds were surveyed to investigate the coexistence and niche segregation of different species. Habitat selection of each species was described in relation to environmental factors. Guilds of seven species present in sugar-cane fields on La Réunion Island were studied for one annual cycle in fields with different ecological parameters. Structure variations of cockroach communities were analysed at the field scale, at the sample unit scale and according to variations related to the cycle of sugar-cane growth. A Canonical Correspondence Analysis was used to elucidate relationships between species diversity, population abundance and environmental characteristics. Our results allowed us to characterize the ecological niches of these cockroach species and to explain the specific patterns of their establishment and population outburst in sugar-cane fields. Three pairs of species were evidenced, each pair occupying a particular type of habitat. The seventh species occupied another type of habitat. Although both species of a pair shared the same type of habitat, the population peaks of each species of a pair presented a temporal shift. This suggests that niche separation is based both on ecological factors and interspecific competition. Factors favouring cockroach outbursts, and factors enhancing the coexistence of species are discussed.

Persistence time of apparent competition in a host-parasitoid microcosm is increased by metapopulation structure

JC Bull, NJ Pickup, MB Bonsall, MP Hassell
Department of Biological Sciences, Imperial College London, Silwood Park Campus, Ascot, U.K.; j.c.bull@imperial.ac.uk

In order to quantify the role of spatial scale on the population dynamics of ecological assemblages, we use well-replicated, laboratory microcosm designed experiments. We have developed an experimental system containing an apparent competition interaction between two bruchid beetle hosts, Callosobruchus maculatus and C. chinensis, mediated by the shared parasitoid Anisopteromalus calandrae. The effects of metapopulation structures, of varying sizes, on the persistence of this apparent competition interaction are presented. The three species interaction persists longer in the spatially explicit environments where dispersal between patches is limited when compared with freely dispersing populations. We also show that the relative strengths of the ecological mechanisms of density dependence and parasitism that underlie this increase in persistence time alter as a result of the scale over which the interaction is observed changes.

Abundance, seasonality and biological aspects of Trypoxylon (Trypargilum) opacum (Hymenoptera; Sphecidae) at Parque Municipal Das Araucárias, Guarapuava (Pr), Brazil.

MLT Buschini, LL Wolff
Depto de Biologia, UNICENTRO, Rua Presidente Zacarias 875, 85010-990, Guarapuava (PR), Brasil; isatunes@yahoo.com.br

Sphecidae wasps are mostly solitary and predators of a broad spectrum of insects and spiders. Their nests can be found in the ground, in hollow stems and pre-existing burrows, or made of mud and affixed to different types of substrates. The genus Trypoxylon is cosmopolitan however poorly represented in Australia and in the Pacific Islands. In this genus the greatest diversity is found especially in south and central America. The Trypoxylon biology has been studied in Brazil, but there are few information concerned to Trypoxylon (Trypargilum) opacum. Therefore, the purpose of this research was investigated the abundance, seasonality and some biological aspects of this species. It was collected 320 nests of T. opacum by trap-nests at Parque Municipal das Araucárias in Guarapuava (PR) Brazil, at 25o23´36´´S- 51o 27´19´´W. Nesting most frequently occurred during the hot season. Completed nests consisted of a linear series of brood cells ranging from 1 to 8, separated by mud partitions, usually followed by an empty vestibular cell and mud final-closure plug. Brood cells were provisioned usually with spiders of the family Araneidae. The number of females was always higher than males and they were randomly distributed. Natural enemies included Chrysididae, Ichneumonidae, Sarcophagidae, Bombyliidae and ants.

Physiologically structured host-parasitoid interactions: consolidating the physiological basis of increasingly complex models

J Casas, D Giron
Institut de Recherches sur la Biologie de l'Insecte – IRBI UMR CNRS 6035 – Université de Tours, 37200 Tours, France; casas@univ-tours.fr

Physiologically structured host-parasitoid population dynamics models and behavioral models of host handling decisions – host feeding or oviposition - make different assumptions about nutrient acquisition and allocation to survival and fecundity in parasitoid females, leading to diverging predictions. While all these models are getting increasingly realistic, they now dangerously outgrow the experimental basis on which they were built. In this talk, we describe a model of lifetime dynamics of nutrients in a synovigenic, host feeding parasitoid. We followed a cohort of females over their entire life and recorded each oviposition and host-feeding events. Using micro-colorimetric methods, we then quantified the amounts of lipids, glycogen, sugars and proteins in emerging females, in eggs and at death. We also quantified the daily maintenance needs and the gains from host feeding for these four classes of nutrients. A daily nutrient budget, based on more than 20 experimentally measured parameters, combined with further experiments, enabled us to identify the elusive 'metabolic reserves' in this highly dimensional space, and to quantify host-feeding gains in terms of survival and fecundity. We end the talk with a list of approximations which we consider useful to pursue in modelling physiologically structured host-parasitoid interactions and others which we consider negligible.

Plant-plant interactions affect the behavior of herbivorous and predatory mites in a tritrophic context

Y Choh, J Takabayashi
Center for Ecological Research, Kyoto University, Otsuka 509-3, Hirano, Kamitanakami, Otsu, 520-2113, Japan; choh@ecology.kyoto-u.ac.jp

In response to herbivory, plants emit a specific blend of volatile compounds called herbivore-induced plant volatiles (HIPV). One of the ecological functions of HIPV is to attract the carnivorous natural enemies of herbivores. HIPV are also known to mediate plant-plant interactions. We studied these plant-plant interactions in a system consisting of lima bean plants (Phaseolus lunatus), herbivorous mites (Tetranychus urticae), and predatory mites (Phytoseiulus persimilis). Upon reception of HIPV released by T. urticae-infested plants, intact plants start emitting a blend of volatiles similar to HIPV. The release of volatiles by the receiver plants can be explained by a process involving adsorption of HIPV onto the plant's surface followed by its re-emission. Furthermore, upon herbivory, the HIPV-receiver plants emitted higher amounts of HIPV and attracted more predatory mites than unexposed plants. These data suggest that the reception of HIPV by lima bean plants can prime an indirect defense against herbivory. We also discuss the effect of plant-plant interactions on the behavior of herbivorous and predatory mites, and present data on their behavioral responses to exposed plants.

Interactions between habitat connectivity and population exchange of adult aquatic insects

K Collier, P Smith, U Shankar, Leathwick, J
NIWA, PO Box 11-115, HAMILTON, NEW ZEALAND, k.collier@niwa.co.nz

New Zealand's landscape has become highly fragmented over the last century with the clearance of large tracts of forest and conversion of land to agriculture. Understanding the permeability of river networks and landscapes to movement by aquatic organisms is important for planning the location of restoration activities aimed at enhancing aquatic biodiversity. To help understand relationships between landscape connectivity and population exchange of caddisfly and mayfly species, we investigated linkages between genetic distance and measures of terrestrial habitat quality and environmental distance (based on a range of climatic variables). Land cover data were divided into forested areas and non-forested areas, and connectivity metrics were calculated among pairs of sites. Several metrics showed relationships with genetic distance based on allozyme frequency for a hydropsychid caddisfly, with genetically similar populations generally occurring at sites with higher levels of connectedness than populations with "medium" and "high" genetic distance. Analyses of genetic distance among populations of a leptophlebiid mayfly species based on DNA markers suggested greater genetic distance among pairs of sites that were environmentally more distinct and where the intervening landscape was more patchy. We discuss the utility of this approach for interpreting connectivity/dispersal relationships over long (evolutionary) and short (contemporary) timescales.

Evolution of indirect plant mediated interactions in a community centered on Eurosta solidaginis (Diptera: Tephritidae)

TP Craig
Department of Biology, 1110 Kirby Drive, University of Minnesota Duluth, Duluth MN, 55812, U.S.A.; tcraig@d.umn.edu

Indirect effects occur when the impacts of one species on another are influenced by one or more intermediate species. Modification of host plant traits by herbivores initiates indirect interactions between organisms that utilize the same host plant. We studied the evolution of indirect interactions mediated by plant traits in a community centered on galls induced by Eurosta solidaginis on goldenrod, Solidago altissima. Eurosta larval survival and the composition of the natural enemy community is influenced in a complex manner by gall morphology. Gall morphology shows strong geographic variation as the result of differing selection pressures. In part of Eurosta's range gall size is under stabilizing selection: small galls are attacked by the parasitoid Eurytoma gigantea, and birds attack large galls. In other parts of the range birds are absent and selection by parasitoids has led to the evolution of large galls. Large galls have in turn led to the reduced rates of Eurytoma parasitism and evolution of longer Eurytoma gigantea ovipositors. Altered gall size, and reduced Eurytoma parasitism has complex effects on other inquilines and parasitoids that attack Eurosta. Common garden experiments have shown that gall size is influenced by the interaction of plant genotype, insect genotype and the environment.

Spider effects on planthopper mortality, dispersal and spatial population dynamics

JT Cronin, KJ Haynes, F Dillemuth
Department of Biological Sciences, Louisiana State University, Baton Rouge, LA 70803, USA; jcronin@lsu.edu

Non-lethal effects of predators on prey populations scarcely have been considered in spatial ecological studies. Here, we report on the effects of spider predators on the mortality, dispersal and spatial population dynamics of the prairie planthopper, Prokelisia crocea. Based on survey data, the density of spiders declined significantly as host-plant patch size increased. Spider density also was negatively correlated with planthopper density per patch. Finally, planthopper extinction risk increased significantly with an increase in spider density. To evaluate whether spider effects on planthopper spatial dynamics were mediated by predation and/or spider-induced dispersal, we performed an experiment in which host-plant patches were either caged or left open and received different spider densities. For caged patches, planthopper recaptures declined only slightly with increasing spider density, suggesting that mortality effects of spiders on planthoppers were weak. In contrast, planthopper recaptures in open patches declined by 85% between the lowest and highest spider treatments. This decline was attributed to spider-induced emigration. We conclude that spiders have a greater impact on planthopper densities through induced emigration than consumption. The non-lethal effects of spiders may play a very important role in determining critical patch size, source-sink properties of patches, and the spatial distribution of planthoppers.

Plant-mediated competition in herbivorous insects: mechanisms underlying competitive superiority and consequences for population dynamics

RF Denno, I Kaplan
Department of Entomology, 4112 Plant Sciences Building, University of Maryland, College Park, MD, 20742 USA; rd12@umail.umd.edu

Feeding-induced plant resistance is a well-documented phenomenon for both sap-feeding and leaf chewing insects. Feeding-induced resistance via altered plant nutrition or allelochemistry provides a mechanistic basis for many cases of interspecific competition. An overwhelming number of cases of competition are asymmetric whereby one species is the superior competitor. Mechanisms underlying competitive superiority are diverse and complex. We review competitive interactions between phytophagous insects and determine the frequency of cases that are plant mediated. We also assess competitive superiority across several feeding guilds of insect herbivores and determine the specific plant-mediated mechanisms promoting such asymmetry. Drawing from our own studies we show that competitive superiority is linked to manipulation of plant nitrogen coupled with the ability to tolerate deteriorating plant quality via compensatory feeding. Moreover, competitive superiority is linked with reduced dispersal and the ability to tolerate diminished plant nitrogen. By contrast, colonizing species are poor competitors and meet nitrogen demands by dispersing to high-quality patches. Thus, plants as they interface with the life-history strategies of insect herbivores mediate competitive outcomes and dictate landscape-level differences in population dynamics. By integrating our work with published studies we determine the prevalence of plant-mediated competition and the constraints competitive superiority places on population dynamics.

Sex ratio in Melittobia parasitoid wasps: an exception to Hamilton's local mate competition theory

LD Deyrup, RW Matthews
Dept. of Entomology, University of Georgia, Athens, GA 30602; lsdeyrup@hotmail.com

Melittobia is a eulophid wasp explicitly identified by Hamilton as appearing to satisfy his ideal extreme inbreeding biofacies. Few quantitative data have been available to support this position, despite this genus being perhaps the most common parasite of a wide variety of solitary bees and wasps. In addition, the few studies published have not taken into account two important life history aspects: a mother plus up to 30 daughters combine their reproductive output on a shared host, and daughters develop in two morphological forms (morphs), long-winged dispersers and short-winged stay-at-home breeders. In a comparative study of five species of Melittobia, we placed groups of 1-5 colonizing long-winged females on both natural and factitious hosts, then tabulated offspring sex and form. Results did not support predictions for sex ratio adjustment with varying foundress number. Instead, sex ratio remained constant, with close to 98% females in the disperser morph. However, the sex ratio of the short-winged morph was much less strongly female biased, and increased as the number of females per host increased. Findings will be discussed in the context of current sex ratio models.

Predator avoidance and the ecology of multitrophic interactions

M Dicke
Laboratory of Entomology, Wageningen University, P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands; Marcel.Dicke@wur.nl

Terrestrial ecologists have long investigated how predators locate their prey and the role of chemical information. This has resulted in extensive knowledge of the effects of chemical cues from arthropod prey and their food on the searching behaviour of predatory arthropods. In contrast, aquatic ecologists have historically concentrated on how prey use chemical cues from their predators to avoid being found and consumed by their predators. In the past few years ecological entomologists that are interested in terrestrial predator-prey interactions have started to pay attention to the effects of predator cues on prey behaviour and physiology. The data show that terrestrial arthropod prey also use chemical cues from their predators to avoid becoming a meal. Recent studies in our group have addressed the origin and specificity of the predator cues as well as the responses of arthropod prey to predator cues in relation to other environmental cues. The data show that we have long neglected the role of prey behaviour in the behavioural ecology of multitrophic interactions. In this paper I will address recent data as well as the major questions that lie ahead.

Are eastern North American monarch butterflies a homogenous group in terms of their migratory strategy?

C Dockx
University of Leiden. Institute of Biology. P.O.Box 9516. 2300 RA Leiden. The Netherlands; cristinadockx@yahoo.com

It was previously believed that the eastern North American monarch migrates only to discrete wintering colonies in Mexico. However, this monarch butterfly also migrates to Cuba. These two monarch migratory populations are not only different in their destinations, but in their strategies as well. Mexican migrants arrive at their over-wintering colonies in the Neovolcanic Belt at the end of October to early November. During their over-wintering, the butterflies amass on trees and are reproductively dormant, surviving on lipid reserves. In March, the butterflies mate and fly northwards. In contrast, Dockx's research suggests that Cuban migrant monarchs are not only different in their migratory destination, but in their migratory and reproductive behavior, mating strategy, and certain morphological traits. The Cuban migrants arrive in November to Cuba, but they do not over-winter, and most of them are not reproductively dormant. The majority of these Cuban migrants are reproductively active (90%). This implies that Cuban migrant monarchs could hybridize with the resident Cuban populations producing offspring in Cuba. This work reveals that the North American monarch butterfly migration phenomenon is more complex than originally thought, and that this influx of monarchs into the neotropics likely has a significant impact on the genetic diversity of monarchs in Cuba.

Genetic structure among dune lake populations in species with different dispersal mechanisms

A Duffy, PB Mather
School of Natural Resource Sciences, Queensland University of Technology, GPO Box 2434, Brisbane, QLD, 4001, Australia; a.duffy@qut.edu.au

The perched dune lakes of Fraser Island, Australia represent naturally isolated habitats as they have never been connected to each other or to other freshwater systems. Inhabitants of these lakes must have had the ability to disperse in order to have colonised the lakes in the first place but the scale of ongoing dispersal is likely to be different for species with different dispersal mechanisms. This study assessed the population genetic structuring of two species, the dragonfly Orthetrum boumiera and the freshwater shrimp Caridina indistincta, using the mtDNA COI gene in 50 individuals per lake from five lakes separated by no more than 3.5km. The dragonfly O.boumiera, showed little population genetic structuring among lakes at this scale suggesting that aerial dispersal of the adults is maintaining gene flow among seemingly isolated populations. Conversely, populations of the freshwater shrimp C.indistincta showed a pattern of in-situ genetic radiation from the founding haplotype suggesting that inter-lake gene flow in this species is rare. This study suggests that even at very small spatial (<3.5km) and temporal (<500,000 years) scales, isolated populations may be evolving independently.

Using a top-predator to assess the effects of habitat degradation on invertebrate diversity

H Esselink, P Beusink, GJ van Duinen, M Geertsma, JT Kuper, M Nijssen
"Department of Animal Ecology / Bargerveen Foundation, University of Nijmegen, PO Box 9010, 6500 GL Nijmegen, The Netherlands; esselink@sci.kun.nl
"

In Western Europe breeding numbers of the Red-backed Shrike, an avian predator on large invertebrates and small vertebrates, decreased dramatically in the last century. We hypothesize that decreasing invertebrate availability led to lower prey availability and subsequently to declining Red-backed Shrike numbers. Availability of invertebrate species strongly differs in time due to phenology (seasonal effects), activity (weather and diurnal patterns) and peak abundance (between-year variation). Only a broad spectrum of potential prey species can maintain a continuously sufficient food supply. Our hypothesis was supported by a comparitive study between degraded (encroached) dunes, due to atmospheric deposition, in The Netherlands and an intact dune area, with low atmospheric deposition, in Denmark. In the dutch dunes only a few pairs remained, while in the danish dunes a vital population was present. Results showed that chick growth and fledging success was much lower in the Netherlands. Some groups of insect species were missing in the Dutch diet. Moreover, a shift to smaller prey species was found. We conclude that the effects of habitat degradation on invertebrate diversity is reflected in the reproductive success of the Red-backed Shrike. So a negative change in population status indicates lowered invertebrate diversity due to environmental stress factors.

Impact of the introduction of Digitonthophagus gazella (Coleoptera: Scarabaeidae) on the native fauna of coprophagous Scarabaeidae in Brazil

CAH Flechtmann
Department of Plant Protection, FEIS/UNESP, Av. Brasil 56, 15385-000 - Ilha Solteira/SP – Brazil;

Dung pads are a food source to many insects, mainly Coleoptera, Diptera and Isoptera, including several nematodes and flies associated with cattle, especially the horn fly, Haematobia irritans, one of the main pests of Brazilian cattle. Coprophagous Scarabaeidae (CS) while burrowing pads improve nutrient cycling, soil structure and forage growth for cattle, besides acting as efficient biological control agents of flies and nematodes of veterinary importance. Digitonthophagus gazella (DG) is an exotic CS to Brazil, and it was first registered at the UNESP Farm in Selvíria (Mato Grosso do Sul state) in 1993. Since 1989 CS are being weekly collected in a light trap in order to evaluate the impact of DG on the native fauna of CS. The diversity of species dropped sharply after DG invaded the area, which increased slightly three years later. For the majority of paracoprid species there was a reduction in the population density after DG was detected, while for some endocoprid species it increased. Some paracoprid species, considered common before DG colonized the area, are either not trapped anymore or in only small numbers. Ten years after DG invaded the Farm, it is still not clear if a new equilibrium was reached.

Testing the growth/differentiation balance hypothesis on willow

C Glynn, DA Herms, C Orians, R Hanson, S Larsson.
The Forestry Research Institute of Sweden, Uppsala Science Park, SE 751 83 Uppsala Sweden; carolyn.glynn@skogforsk.se

The Growth/Differentiation Balance Hypothesis (GDBH) has been used as an experimental framework for examining environmental effects on secondary metabolism production. Yet, it has not been put to adequate test. We rigorously tested GDBH on two willow species, Salix eriocephala (rich in condensed tannins), and S. sericea (contains tannins as well as phenolic glycosides). In order to reveal potential temporal variation in response to environmental factors, we made four sequential harvests of cloned willow plants. We measured growth, rate of photosynthesis, and levels of carbon-based secondary metabolites on willows grown at a gradient of five soil-fertility levels (from no fertilizer to very high levels). There was remarkable correspondence between the two willow species in their physiological responses. Growth increased with increasing nutrient availability, as predicted by GDBH. Photosynthetic rate, as predicted, was less sensitive to nutrient availability than was growth. The predicted parabolic response of constitutive secondary metabolites across the soil fertility gradient received partial, but not complete, support. Perhaps our most important result was that the secondary metabolic responses were dynamic over time. The effects of nutrient availability on these willows seem to be dependent on the rate and degree to which plants acclimated to changes in resource availability.Density dependent processes in interactions between the parasitoid Microctonus hyperodae Loan and its host Listronotus bonariensis

Trait-mediated indirect interactions between herbivorous mammals and insects: claiming for an integrate view of the terrestrial communities

JM Gómez, A González Megías
Dpto Biología Animal y Ecología, Universidad de Granada, E-18071 Granada, Spain; jmgreyes@ugr.es

Herbivorous mammals are ubiquitous and important plant consumers in most terrestrial communities. Mammalian herbivores, in addition to decrease plant density, can affect their resource in a variety of ways. In fact, due to the very plastic nature of plants, they can affect plants by modifying their life history, overall architecture, leaf morphology, the production of chemical compounds, and also by altering their spatial distribution (habitat selection). In an evolutionary time, mammalian herbivores can even act as selective pressure provoking long-term changes in phenotypic traits in plants. By sharing the resources with insects, these two very disparate organisms are often entangled in competitive interactions. My goal in this presentation is to assess the importance that the trait-mediated indirect interactions (TMII) play in the interaction between these two kind of herbivores, by reviewing the existing literature on both the diverse effects of mammals on plants and on competition between phytophagous insects and mammals, and by showing my own studies on mammal-insect-crucifer interactions. The main idea is that TMIIs are crucial for insects since in most cases 1) ungulates outcompete insects, and 2) the main short-term effect of ungulates is not a change in plant density but a modification of chemical, physiological, morphological and architectural traits of plants (induced resistance). I will also extend the consideration of TMIIs to those phytophagous insects like nectar-feeders or pollen-feeders that are mutualists of plants, specifically when both ungulates and insects select plants according to the same traits. In addition to the potential ecological consequences of TMIIs, I will argue that ungulates and insects can sometimes act as conflicting selective pressures on plants, since an evolutionary consequence of TMIIs has been little considered. All of these ideas suggest the necessity of considering together both phytophagous vertebrates and invertebrates in order to draw a more accurate picture of the dynamics of terrestrial communities.

Islands in a sea of sand and stone: genetic evidence on the role of flooding in the dispersal of mound spring wolf spiders in the deserts of South Australia

TB Gotch, M Adams, N Murphy, AD Austin
Centre for Evolutionary Biology and Biodiversity, School of Earth and Environmental Sciences, The University of Adelaide, SA, 5005 Australia; travis.gotch@adelaide.edu.au

Scattered around the margins of the Great Artesian Basin are numerous springs and seepages (referred to as mound springs in South Australia) forming a discontinuous arc of wetlands containing a diverse and specialised fauna. This fauna includes a number of endemic crustaceans and molluscs but is dominated by lycosid spiders. Of these Venatrix fontis is the dominant species in springs along the western edge of the Great Artesian Basin. This species is totally water adapted and cannot live away from free water. The vectors of dispersal available to these spiders are extremely limited, thus the springs can be considered analogous to islands. Exactly how these species move about has not been directly observed, however we present genetic evidence that shows that dispersal between springs is taking place and the importance of periodic flooding in the movement of these spiders from spring to spring. Allozyme electrophoresis and SSCP analysis of the ND1 region of the mitochondrial DNA show significant substructuring of spring group spider populations. Principle Components Analysis of Nei's genetic distance shows clustering of spring populations by to drainage catchment. Mantel tests support this and show that genetic distance correlates to distance along drainage channels rather than linear distances.

Parasitoid mark-release-recapture techniques: development of marking and trapping techniques for small parasitoids

JR Hagler, L Williams
USDA-ARS, 4135 E. Broadway Road, Phoenix, Arizona, USA; jhagler@wcrl.ars.usda.gov

Small parasitoids of Bemisia argentifolii were marked with the purified protein, rabbit immunoglobulin G (IgG). When marked parasitoids were assayed using an anti-rabbit IgG ELISA, virtually all of the marked Eretmocerus sp. contained enough protein to be distinguished from unmarked parasitoids. A field mark-release-recapture study was conducted to examine the dispersal characteristics of Eretmocerus emiratus. Parasitoids were released on three separate dates into the center of a cotton field bordered by cantaloupe and okra. A total of 1388, 637, and 397 marked and unmarked wasps were captured in suction traps over the three trials, respectively. The majority of parasitoids were captured between 0600 and 0800 h. Our traps consistently contained more males which suggests gender-specific differences in the dispersal behavior of E. emiratus. The distribution of the marked parasitoids revealed two distinct patterns. First, almost all of the marked parasitoids recaptured in the cotton plot were in suction traps adjacent to the release site. Second, marked parasitoids were recaptured more frequently in distant traps located in the cantaloupe plot than in distant traps located in the cotton and okra plots, suggesting that the parasitoids were moving toward the cantaloupe plots.

Primary succession of Collembola near a receding glacier in Norway

S Hågvar
Department of Ecology and Natural Resource Management, Box 5003, Agricultural University of Norway, 1432 Ås, Norway; sigmund.hagvar@ina.nlh.no

The Hardangerjøkulen glacier in central south Norway has been shrinking during the last 250 years. The Collembola fauna was studied in 25 plots along a gradient from newly exposed soil to 8000 years old soil. All soil samples were taken in Salix herbacea vegetation (at 0-3 cm depth) to standardize the habitat. Both the total density of Collembola and the number of species increased with increasing age of the soil. Collembola were very efficient colonizers. Among a total of 34 species, 14 were present in 30-45 year old soil, and 26 after 70 years. One species, Agrenia bidenticulata, occurred only at the very border of the glacier. The youngest soil was dominated by large, surface-active species (especially Isotoma olivacea), while smaller, deep-living species usually waited until an organic layer had been developed. After 50-70 years, I. olivacea was still abundant, but its dominance was shared by Folsomia brevicauda and F. quadrioculata. The structure of the Collembola community was astonishing similar in 70-250 year old soil compared to 8000 year old soil, with Tetracanthella brachyura as dominant species, followed by the two Folsomia species, I. olivacea, and Friesea truncata. Oribatid mites were much slower colonizers.

Effect of habitat loss and invasion by scotch broom (Cytisis scoparius) on rare butterflies of Garry oak meadows

Wayne Hallstrom, J Roland
Department of Biological Sciences, CW 405, Biological Sciences Centre, University of Alberta, Edmonton, Alberta, Canada, T6G 2E9;
wayne.hallstrom@ualberta.ca

Within Garry oak (Quercus garryana) ecosystems in British Columbia there are a number of species that are rare and endangered, including several species of insects. Habitat loss and degradation are undoubtedly factors in the endangerment of many of these species, as only five percent of the original Canadian distribution of Garry Oak ecosystems remains in an undeveloped state. This project examines metapopulations of rare butterfly species to determine 1) the effect of loss and fragmentation of habitat on butterfly populations, and 2) the effect of degradation of habitat quality of Garry oak meadows due to the invasive weed, Scotch Broom. Identification of which characteristics of meadows (nectar resources, larval host plant abundance, meadow size / spatial location, and abundance of Scotch Broom) have the strongest effect on viability of populations of several different species of butterfly is the goal of this project. Two networks of meadows (~100 meadows each) were surveyed in Duncan and on Saltspring Island. GLM regression and ordination methods were used to define habitat quality. For example, there were significant positive relationships between butterfly populations and increasing meadow size, density of oak trees, and presence of certain flower species. These data were used to adjust for 'effective habitat area' and to parameterize a predictive metapopulation model.

Evolution of dispersal in butterfly metapopulations

I Hanski
Metapopulation Research Group, Department of Biological and Environmental Sciences, PO Box 65, FI-00014 University of Helsinki, Finland; ilkka.hanski@helsinki.fi

Recent studies of butterfly metapopulations have demonstrated evolutionary life-history changes in response to habitat change and climate change. An important component of selection relates to the spatial dynamics of the species, establishment of new local populations and persistence of old ones. In the Glanville fritillary butterfly (Melitaea cinxia), females in newly-established populations in a large metapopulation are significantly more dispersive than females in old populations. Furthermore, mobility increases with decreasing connectivity (increasing isolation) among females from new populations, whereas the opposite trend occurs among females in old populations. The observed patterns in female mobility were predicted by an evolutionary metapopulation model. We demonstrate with the model parameterised for the Glanville fritillary that increasing landscape heterogeneity increases variance in mobility among individuals in a metapopulation, supporting the general notion that complex landscape structure may maintain life-history variation.

Climate change and the phenology of European aphids

R Harrington, P Verrier, C Denholm, S Welham, S Clark, M Hullé, D Maurice, M Rounsevell, N Cocu,
EXAMINE consortium, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK; Richard.harrington@bbsrc.ac.uk

Aphids, because of their short generation time and low developmental threshold temperatures, are an insect group destined to respond particularly strongly to environmental changes. Standardised, daily data on the abundance of flying aphids have been brought together from countries throughout Europe and spanning up to 40 years, through the EU Thematic Network `EXAMINE'. Relationships between aphid phenology and environmental data have been quantified using the residual maximum likelihood (REML) methodology. These relationships have been used with climate change scenario data to suggest likely changes in aphid phenology over the next 50 years. Strong relationships between aphid phenology and environmental variables have been found for many species, but they are notably weaker in species living all year on trees, suggesting differences according to guild in the factors influencing phenology. In general, the date of first record of species in suction traps is expected to advance, the rate of advance varying with location and species, but averaging 8 days over the next 50 years.

Microbial impacts on plant-herbivore interactions

SE Hartley, SN Johnson
Dept. of Biology and Environmental Science, University of Sussex, Falmer, Brighton. UK; S.Hartley@sussex.ac.uk

The role of indirect interactions in structuring communities is becoming increasingly recognised. Plant-mediated interactions between insects are now well established, but colonisation by fungi may also affect insect herbivores by modifying the suitability of a shared host plant. For example, mycorrhizal fungi have been shown to affect the palatability of plants to insect herbivores, whilst plant pathogens may alter both the nutrient and secondary compound content of plant tissue, with consequences for the behaviour and performance of insects. This presentation will review the most recent work in this area, before considering a specific example, namely the plant-mediated interactions between a fungal pathogen, Marssonina betulae (Dueteromycotina: Melanconiales) and an aphid Euceraphis betulae (Homoptera: Drepanosiphinae) on silver birch (Betula pendula). Aphids preferred to feed on birch leaves inoculated with the fungus and their population growth was positively correlated with levels of infection. Inoculated leaves contained higher levels of free amino acids which may explain the positive interaction between the fungus and the aphid. We conclude by highlighting priorities for future research in this topical aspect of multi-trophic interactions.

Going with the flow: plant vascular systems mediate indirect interactions between plants, insect herbivores and hemi-parasites

SE Hartley
Dept. of Biology and Environmental Science, University of Sussex, Falmer, Brighton. UK

Indirect interactions between organisms exploiting a shared host-plant are recognised as an important phenomenon in community ecology. Traditionally, research into these indirect effects has focused on interactions between different types of insect herbivores, but I will consider the interactions between sap-sucking insects and other organisms that exploit the plant vascular system, specifically hemi-parasitic plants. Parasitic plants have major impacts on plant community structure, but their effects on insect herbivores sharing the same host plant remain little studied and poorly understood. I examine interactions between a host, (grasses Poa annua and Poa pratensis), a phloem-feeding aphid (Sitobion avenae, Sternorrhyncha: Aphidae), a xylem-feeding plant-hopper (Neophilaenus lineatus, Auchenorrhynca: Cercopidae) and a hemi-parasite which obtains nutrients from the xylem by attaching to the host's roots (Rhinathus minor, Scrophulariacae). Both positive and negative interactions occur between the components of this system, mediated by alterations to the host vascular system and resource removal. Aphids improved the performance of the parasite because they led to an increase in root biomass and hence more opportunities for the parasite to connect to the host. In contrast, the parasite had a negative effect on the performance of both insects. This work demonstrates that plants mediate interactions between taxonomically diverse organisms.

Interpatch movement and edge effects in heterogeneous landscapes: the role of behavioral responses to matrix composition

KJ Haynes, JT Cronin
Dept. of Zoology, 212 Pearson Hall, Miami University, Oxford, OH 45056 USA; hayneskyle@hotmail.com

To date, there has been little empirical exploration of the mechanistic basis of matrix effects on either interpatch movement or the generation of edge effects in animal density. In an earlier study (Haynes and Cronin 2003), we found that the planthopper Prokelisia crocea exhibits higher rates of movement among host-plant patches embedded within a non-host grass (brome) than a mudflat matrix. Additionally, census data indicated that the planthopper exhibits edge effects (i.e., aggregates near the patch perimeter) in mudflat-bordered patches, but not in patches bordered by non-host grasses. Here, we investigate the underlying mechanisms of these matrix effects using individual movement trials. Whereas movement through mudflat was highly linear, movement was much more tortuous through brome. Within patches, brome edges were 3 times more permeable to emigration than mudflat edges. We suggest that the effect of matrix composition on the planthopper's interpatch movement rate is driven largely by differences in movement tortuosity within the matrix. Tortuous movement through brome likely increases the planthopper's rate of encounter with spatially aggregated host-plant patches. Furthermore, the effect of the matrix on planthopper edge effects can be attributed to the differences in edge permeability between matrix types.

Interactions between complementary sex determination and Wolbachia in Braconid parasitoids

GE Heimpel, L Weiser, MF Antolin
Dept. of Entomology, University of Minnesota, 1980 Folwell Ave., St. Paul, MN 55108, USA.; heimp001@umn.edu

We discovered Wolbachia endosymbionts in field and long-standing laboratory populations of the parasitoid Habrobracon hebetor. Since this species is known to exhibit complementary sex determination (CSD), we tested the hypothesis that Wolbachia enables CSD by comparing diploid male production in Wolbachia-infected and experimentally-cured lines of H. hebetor. Diploid males were produced in both lines, suggesting that the Wolbachia does not enable CSD. Instead, standard curing/mating studies showed that the Wolbachia causes cytoplasmic incompatibility (CI) in H. hebetor. We developed mathematical models to investigate the effect of CSD on fixation of CI Wolbachia under various assumptions regarding CSD. The simulations showed that CSD has very little effect on the generations to fixation if diploid males die (as in H. hebetor), but that the time to fixation is increased if diploid males survive. Other parameters explored in this model included whether or not surviving diploid males are accepted as mates, whether eggs 'fertilized' by diploid sperm die or develop as haploid males, and whether uninfected eggs that are fertilized by Wolbachia-infected haploid sperm die or develop as haploid males. We also investigated the effect of mating structure (which is itself affected by CSD) on fixation dynamics of CI Wolbachia. We used this model to generate predictions regarding the distribution of C.I. Wolbachia among parasitoids with various sex-determining systems and mating structures. We evaluated these predictions with a survey of Wolbachia across parasitoids with known sex determination and mating structure. For this analysis, we used both known cases of known presence or absence of Wolbachia from the literature, and our own data on Wolbachia presence or absence from selected species.

To what extent do aphids act as extrafloral nectaries?

DH Hembry, T Ohgushi
Center for Ecological Research, Kyoto University, 509-3 Otsuka, Kamitanakami Hirano-cho, Otsu, Shiga 520-2113 Japan; hembry@ecology.kyoto-u.ac.jp

Recent research has revealed that plants bearing extrafloral nectaries can respond to herbivory by increasing the output of extrafloral nectar or growing new extrafloral nectaries, often only on the part of the plant affected by herbivory. It is also known that phloem-feeding homopterans can be beneficial to their host plants if herbivory pressure is high and the homopterans are tended by ants that remove other herbivores. However, it remains unknown whether plants can manipulate the homopterans' honeydew output in response to damage by other herbivores so as to become more attractive to ants. In other words, can some plants use the aphids' honeydew output as an inducible defense in the same way as other plants use extrafloral nectaries? Here, we present laboratory results addressing this question using the Japanese willow Salix gilgiana and its ant-tended aphids (Homoptera: Aphididae).

Diseased interactions: how “hidden players” like pathogens mediate interactions between plants and herbivorous insects

M Hilker, M Rostás
Freie Universität Berlin, Institute of Biology, Haderslebener Str. 9, D-12163 Berlin, Germany; hilker@zedat.fu-berlin.de

Microorganisms are well-known to affect interactions between plants and herbivorous insects. Infection of plants by phytopathogens may have beneficial, detrimental, or no effects on herbivores. Vice versa, herbivory may positively, negatively, or not affect the plant´s susceptibility to plant pathogens. A plethora of studies is available analysing the effects of tripartite interactions between plants, herbivores, and phytopathogens (1). However, little is known on the mechanisms. A study will be presented which shows that fungal infection of Chinese cabbage induces an increase of peroxidase activity which may be considered to cause negative effects on the mustard leaf beetle Phaedon cochleariae. Other fungus-induced changes of the cabbage´s primary and secondary metabolism obviously did not affect the leaf beetle (2). Furthermore, while numerous studies analysed interactions between plants, phytopathogens and herbivores, a fourth player has been neglected so far: the entomopathogens. Here we provide evidence that phytopathogenic infection of a plant enhances the susceptibility of herbivore larvae to an entomopathogen (3).Impacts of climate change on species’ range margins

Can mite-fungal mutualisms affect the population dynamics of bark beetles?

RW Hofstetter, KD Klepzig, JC Moser, MP Ayres
Dartmouth College, Hanover, NH 03755, USA; rwh@dartmouth.edu

Phoretic mites and fungi are common associates on the exoskeleton of beetles. A bluestain fungus, Ophiostoma minus, commonly carried by Tarsonemus mites, is hypothesized to out-compete fungi associated with the southern pine beetle, Dendroctonus frontalis. Here, we test whether antagonistic interactions between beetle-mycangial fungi and O. minus affect broad patterns in beetle population growth. We hypothesize that mutualistic interactions between phoretic mites and O. minus influence bluestain abundance within beetle infestations, and determine whether the mite-fungal mutualism is part of an endogenous feedback loop. Field surveys suggest that beetle populations declined sharply when mite and O. minus abundances are high. Experiments support evidence of a strong interaction chain: from mites to O. minus to beetles. However, O. minus and mite abundances appear to function independent of beetle abundance and may be driven, in part, by exogenous variables such as climate. Our results suggest that mite-fungal interactions can influence broad scale patterns in beetle populations.

Elevated CO2 and insect herbivores

L Hughes
Dept. of Biological Sciences, Macquarie University, North Ryde, NSW, 2109, Australia; lhughes@rna.bio.mq.edu.au

Plants grown at elevated CO2 have reduced nitrogen concentrations, increased C:N ratios, and often, increased concentrations of carbon-based defensive compounds. The impact of this reduction in resource quality for the performance of herbivorous insects has been the subject of over 60 experimental studies. Variation in responses, both between and within insect species, has been found, but some generalities have emerged. The ability of particular species or feeding guilds to exhibit compensatory feeding in response to poorer food quality appears to be the key factor influencing their performance. Leaf chewers feeding on whole plants appear better able to compensate for poorer quality than do leaf miners. Phloem feeders show variable responses with some species appearing to be advantaged under elevated CO2. Investigation of the impacts of elevated CO2 on herbivorous insects is increasingly being conducted under more realistic environmental conditions and in conjunction with other factors such as temperature, nutrients and light. Large questions remain, however, as to the relative importance of changes in climate, CO2-mediated changes in plant quality and impacts of natural enemies for herbivore populations in the future.

Population regulation and key factors responsible for population fluctuations of sunn- pest (Eurygaster integriceps Put.) in Varamin cereal fields

Sh.Iranipour, A.Kharrazi Pakdel, Gh.Radjabi
Departement of Plant Protection, Faculty of Agriculture, University of Tabriz, Tabriz, 51666-14888 Iran. E-mail: shiranipour@tabrizu.ac.ir

Sunn-pest is the most serious insect pest of wheat and barley in most areas of Iran. Life table studies were carried out in Varamin (a county in the vicinity of Tehran) during 1998-2000. Because of a considerable distance (about 30 km) between fields and resting sites (nearby mountains), sampling was done separately in two places. Key factor analysis was carried out both for whole stages and submortalities. Adults, which usually spend a period of ca 9 months in diapause, suffered an overcompensatory density-dependent mortality. This was the first key factor contributing around 73% of the total variance of mortality. Other important mortality factors were egg parasitism by Trissolcus vassilievi Mayr, adult parasitism by tachinids, and adult loss of fecundity due to environmental constraints. Among them T.vassilievi had an important effect on fluctuations of the adult numbers, even though it had a minor contribution on overall variance of K. The adult mortality resulted by scramble competition along with the parasitoids, regulated population of the pest at a level around 81.7 adults/m2.

Indirect effect of a lace bug and disturbance on a chrysomelid beetle via host willow quality

M Ishihara, M Matsuoka, M Sakamoto, C Ujiie, K Hesaka
Dept. Environ. Sci., Osaka Women's Univ., Daisen-cho 2-1, Sakai, Osaka 590-0035, Japan; mishiha@center.osaka-wu.ac.jp

In the riverside willow forest of the Kinokawa river (Wakayama, Japan), the population size of a willow leaf beetle, Plagiodera versicolora, decreased drastically in summer and recovered in autumn. This seasonal population dynamics synchronized with the leaf phenology of host willows. At this site, first leaf flush occurred in early spring and these leaves were maintained until summer in which second leaf flush occurred. This second flush was a compensative response for damages by floods, which occurred in summer or early autumn, and enhanced leaf quality due to the increase in young leaves. Because leaf age is generally related with leaf quality for herbivores, the intrinsic rate of natural increase of P. versicolora might decrease in summer and increase in autumn. In addition, a lace bug, Metasalis populi, increased drastically in mid summer and decreased in autumn. This severe leaf damages by feedings of M. populi in summer might accelerate the decrease in host leaf quality for P. versicolora. In fact, P. versicolora adults fed on leaves damaged by M. populi could not lay eggs. This evidence suggested that indirect effects of M. populi and disturbance on the seasonal population dynamics of P .versicolora via host willow quality.

Arthropod community of a temperate non-tidal sandy beach: multitrophic interactions between washed-up seaweeds and insects in the supralittoral zone

MF Jedrzejczak
Dept. of Marine Ecology, Institute of Oceanology, Polish Academy of Sciences, Powstancow Warszawy 55, 81-712 Sopot, Poland; humbak@praeter.pl

Sandy beaches are usually inhabited by numerous insect species with varying degrees of dependence on and adaptation to marine environments. At Hel Great Beach (northern Poland, Baltic Sea) a total number of 16465 of macrofaunal arthropods belonging to 30 species or genera was collected using the litterbags, and 32082 individuals from 61 species or genera by the use of the Barber's traps during three-year study (1999/2001). Coleoptera were the most numerous group, making up 67% of the total of identified arthropod specimens. The macrofaunal composition varied considerably not only from one sampling approach and locality to another but more from season to season. Ephemeral resource units, such as wrack-bed communities, were generally characterised by a successional change of species with different groups associated with different qualitative stages of decomposition and ageing of the stranded seaweeds. The major arthropod groups could be subdivided into "early", "mid" and "late" in relation to their appearance in the wrack. The successional colonisation of wracks was thus strongly influenced by the species' physiological and trophic needs and their appearance or disappearance in the wracks was due to the progressive microclimatic changes of the deposits in relation to their varying position on the beach.

Spatial variation in outbreak densities of Yponomeuta evonymellus in Finland

M Käär, T Vuorisalo, K Ruohomäki
Section of Ecology, Department of Biology, University of Turku, FIN-20014 Turku, Finland; miia.kaar@utu.fi

A challenging task for ecologists has been explaining the spatial and temporal variation in densities of natural populations. The small ermine moth, Yponomeuta evonymellus (Lepidoptera, Yponomeutidae), is a specialist insect herbivore feeding on bird cherry. We have found records of large-scale fluctuations in Y. evonymellus densities in Finland since 19th century. During the peak years, bird cherry trees become totally defoliated. However, outbreaks are observed in only certain populations and within populations, there is considerable variation in larval densities even within adjacent trees. We examined the factors contributing to spatial variation in population densities of Y. evonymellus during increase and peak phases of population cycle. We evaluated the potential role of host plant distribution and quality, habitat type (open/forest), parasitism and oviposition behaviour in determining the spatial structure of Y. evonymellus populations during high density years. Our results indicate strong effects of small scale variation in factors related to habitat quality. This aspect is highly relevant when considering e.g. the effects of forest fragmentation on forest pest populations.

Bark and ambrosia beetle (Scolytidae)-fungal interactions on broadleaf trees in Japan

H Kajimura, H Masuya
Laboratory Of Forest Protection, Graduate School Of Bioagricultural Sciences, Nagoya University, Nagoya 464-8601, Japan; kajimura@agr.nagoya-u.ac.jp

The European elm bark beetle, Scolytus multistriatus, and its fungal associates, Ophiostoma ulmi, have been well studied, as economic pest causing Dutch elm disease. However, less is known about interactions between other broadleaf-tree infesting bark beetles and fungi. Recently, mortality of Pittosporum tobira trees has occurred in Japan. Beetle species involved in the mortality is Scolytogenes birosimensis. We have initiated studies to examine aspects of the biology of this insect, and present recent data on fungi associated with S. birosimensis. We also review results of our past and current studies on some species of scolytid ambrosia beetles, Xylosandrus spp. and Scolytoplatypus spp., and discuss symbiotic systems and the effects of fungi on the beetles.

When are grass endophytes plant-defending mutualists?

S Kari
MTT Agrifood Research Finland, Plant Production Research, Plant Protection, FIN-31600 Jokioinen, Finland; karisaik@utu.fi

Endophytic fungi are considered to be mutualists because (1) the fungus subsists entirely on resources extracted from the host, and in grasses also asexual dispersion by growing into the host's seeds, (2) while the host receives benefits through increased resistance to herbivores, pathogens and drought and flooding stress, and enhanced competitive abilities. Using meta-analyses, I reveal that the reasons for the strong mutualistic stamp of endophytes are largely historical and system-based. Although ecological, evolutionary, mycological and agronomical studies involving fungal endophytes in grasses have proliferated within past decades, most of the conceptual framework for endophyte-plant symbiosis has been based upon endophyte-plant-herbivore studies of two, economically important, artificially selected and introduced agricultural grass cultivars (tall fescue and perennial rye grass). Our studies (as well as few others) with native grass- and tree-endophyte systems reveal, however, that (1) endophyte-plant interactions are much more complex than described in past literature, (2) they represent a diverse continuum from antagonistic to mutualistic interactions, and finally (3) because benefits from endophytic fungi do not come without associated costs, the defensive mutualism may be conditional on available resources, particularly nutrients in soil.

Metapopulation dynamics of interactions between cannibalistic predator and its prey

P Kindlmann
Fac. Biol. Sci., Univ. S. Bohemia & Inst. Landscape Ecol. AS CR, Branisovska 31, 370 05 Ceske Budejovice, Czech Republic; pavel@entu.cas.cz

Here I propose a model involving three features, typical for many insect predator-prey interactions: (i) Insect pests are characterized by periodic outbreaks, during which predators are not able to regulate their numbers efficiently. (ii) Dynamics of many insect species is characterised by periods of local existence in a patch (e.g., larval period in butterflies, aphid colonies) periodically interrupted by periods of migration, during which prey and predator individuals redistribute themselves between patches. (iii) Cannibalism is common among insect predators and is often dramatically reducing their numbers. Nevertheless, it is usually ignored in models of predator-prey interactions. Here I assume that the predator considers any individual it meets (either prey or weaker conspecific) to be an edible item. The model based on these assumptions consists of a continuous-time within-season component describing population dynamics within one-patch, and of a discrete-time between-seasons metapopulation component involving between-patch migration. I use the model to predict the efficiency of such predator in controlling its prey and to study stability of this system.

Symbiotic secrets: reciprocity and antagonism in bark beetle-fungal interactions

KD Klepzig, JB Mahfouz, RW Hofstetter, MP Ayres
USDA Forest Service, Pineville, LA 71360, USA; kklepzig@fs.fed.us

Reciprocal effects are commonly found between bark beetles and their fungal associates, and a diverse array of interactions, from antagonism to mutualism, is found within the group. Bark beetles vary in life history, but all feed in nutritionally poor substrates, especially phloem and cambial tissues of living or recently killed trees. Associations with fungi are apparently universal within this group. However, little is known of the contributions of fungi to bark beetle success, and even less is known about how these fungi interact with one another. We review the current state of knowledge on bark beetle fungal interactions and present recent data on the involvement of water potential, melanin and cellulases in these complex symbioses.

Overwintering strategy and mating behavior of Orius species

T Kobayashi, M Osakabe, S Yano, A Takafuji
Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan, kobatake@kais.kyoto-u.ac.jp

Both males and females overwinter in many insect species. In Orius species, however, only female adults overwinter successfully while male adults cannot. Mendia scotti has been reported the female-biased survivorship during overwintering period. M. scotti males give nutrition to females through copulation, resulted in a low survival rate of the male. We supposed that Orius females also obtained nutrition from males through copulation, but before overwintering. To confirm this hypothesis, two experiments were conducted on Japanese Orius species. First, overwintering survival of females that had copulated in autumn was compared with that of unmated females. Second, copulation duration was compared between Orius individuals reared under autumn?like condition (OAC) and under summer?like condition (OSC) in a laboratory. If males of Orius species nutritionally contribute females' overwintering survivorship, the survival rate of mated females will be higher than that of unmated females, and the copulation duration in autumn might be extended rather than that in summer. In results of the experiments, the survival rate was higher in mated females than unmated females. Copulation duration was longer in OAC pairs than OSC pairs. These suggest males' nutritional contribution to females' overwintering survivorship in Orius species in autumn.

The influence of human land use on a diverse insect community – dung beetles in a relic tropical rain forest and surrounding farmland in Kenya

V Mahiva, FT Krell, S Krell-Westerwalbesloh
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, U.K.

Kakamega Forest in western Kenya is the easternmost remnant of the Guinean-Congolian rainforest. Embedded in a highly populated agricultural region, the area has been exposed to various types of anthropogenic degradation (logging, farming, wiping out the large mammals, etc.). As expected from general ecological preferences, dung beetle assemblages show a lower abundance in forests than in grasslands. The less disturbed forest has the fewest dung beetles, but a higher species number and diversity compared to a secondary forest. Grassland in an area where farmers collect 80% of the dung of their cattle for building and manure purposes has a much poorer dung beetle fauna than grazed grassland on a small farm where dung is not removed by men and is thus always available for beetles. The roller guild, generally very common in the Afrotropics, was almost completely absent all year round. Seasonal patterns were less pronounced in the less disturbed forest than in the more open habitats. Human land use influences dung beetle assemblages significantly, but in various directions.

Beetle-associated fungi and methyl jasmonate elicit tree defences and interfere with host selection and colonization in the Eurasian spruce bark beetle Ips typographus

P Krokene, E Christiansen
Norwegian Forest Research Institute (Skogforsk), ÅS, N-1432, Norway; paal.krokene@skogforsk.no

Pioneer bark beetles select their host through a combination of visual and chemical stimuli that mediate landing, inspection and tunnelling. In an acceptable host beetle development proceeds with mating, gallery construction, oviposition, and brood development. Phytopathogenic fungi vectored by the beetles elicit defence responses that may interfere with both host selection and beetle development. Chemical elicitors such as methyl jasmonate appear to have similar effects, inducing activation of phenol-rich cells in the bark and formation of traumatic resin duct in the sapwood. Induced trees seem to be less attractive to colonizing bark beetles and are more resistant to later mass-attacks. Induced host responses may inhibit beetle tunnelling by altering the chemical state of the phloem, and affect beetle survival directly through production of allelochemicals. These responses open up new possibilities for tree protection and management of tree-killing bark beetles.

Conservation strategy of Cicindela chinensis flammifera in Korea

O Kwon, H Bang
Weed Management Division, Department of Agricultural Biology, National Institute of Agricultural Science and Technology, 249 Seodun-dong, Kwonseon-gu, Suwon, Gyeonggi-do 441-707, Republic of Korea; ecoento@hanafos.com

The distributions of tiger beetles in Korea have been rapidly decreased due to the urbanization of the countryside in past 30 years. Family Cicindelidae in Korea is consisted of 2 genus 16 species. Among them, 2 species are protected by law. However, many other tiger beetle species are facing a danger of extinction in result of the changes in their natural habitats. Ecology of Cicindela chinensis flammifera is studied for past 5 years in order to protect from possible species extinction. A conservation program including artificial mass rearing technique is developed, enabling a life cycle completion time from 2 years to about 7 months. Artificial ovipositing chamber and a rearing kit are developed. Up to 80 eggs can be collected from a single female, and 70% of them can successfully become adults. Best habitat condition including soil conditions, temperature ranges and space requirements has been experimented to implement the conservation program. A life cycle model is developed for the artificial mass rearing of other tiger beetle species.

The effects of climatic conditions on seasonal population fluctuation of date palm scale [Parlatoria blanchardi Targ (Hom: Cicadellidae)]

M Latifian, M Zaerae
Ahwaz, 10th kilometer of Ahwaz-Khramshahr road, Date palm and tropical fruits research institute, P.O.Box: 61355/16, Iran; m_latifian@hotmail.com

Palatoria blanchardi Targ is a pest in date palm orchards of Iran. This investigation has been carried out from 1996 to 2000. The population was monitored monthly by leaf sampling. Sample unit was 3 leaves that taken in 3 strata in the palm canopy of ten trees. Climatic data (Temperature, Humidity and Rainfall) were obtained from Abadan meteorology station. Correlation analysis and sigmoid models were used to studying the climatic effects. The correlation of temperature (r=-0.58) and relative humidity (r=0.53) were Significant. The order of relative influences of climatic factors on seasonal population fluctuation was temperature> relative humidity> rainfall. The highest population fluctuation occurred in temperature between 16c and 24c and relative humidity between 42 and 63 percent. Date palm scale activities started at March and increased with temperature and humidity slowly. Seasonal monitoring showed three overlapping periods in field. First, second and third periods of activities started at March, April and December respectively. The longest period was the first period and the smallest was third. Scale nymphs were more susceptible to temperature and humidity than other developmental stages and their mortality increased at high temperature and low humidity. So, these stages get to aestivation at first periods of seasonal population fluctuation.

The use of water pan trap to estimate beetle abundance and vertical distribution in mosaic habitat in Kanazawa, Japan

AS Leksono, N Nakagoshi, K Nakamura, S Koji
Graduate School for International Development and Cooperation, Hiroshima University, 1-5-Kagamiyama, Higashi Hiroshima City, Japan 739-8529; leksono72@yahoo.com

A continuous canopy sampling by using water pan trap was performed to observe beetle abundance, richness, color efficiency and vertical distribution in mosaic habitat in Kanazawa, Japan. A total of 845 individuals of which distributed in 47 families were collected from May to December 2000. Scolytidae was the most abundant (17.48 %), followed by Chrysomelidae (9.83 %) and then Cantharidae (9.14 %). Traps in bottom layer captured relatively high number of families and individuals, but the effect of vertical arrangement of traps did not differ significantly. Among the functional groups, herbivores and scavengers were shown to have a higher proportion in this layer. Some families were considered as layer specialists, but no clear stratum restriction was observed. Yellow trap demonstrated higher capture efficiency in beetle abundance than in blue trap. Effects of color were significant for herbivores ($P<0.01$) and predators ($P<0.05$), both were more abundant in yellow trap. Some families such as Attelabidae and Chrysomelidae showed a clear preference to yellow traps, but only Attelabidae was restricted to yellow traps.

Herbivore-induced responses in plant morphology and their impact on the third trophic level

I Lesna, MW Sabelis, CGM Conijn
Section Population Biology, Institute for Biodiversity and Ecosystem Dynamics, Universtiy of Amsterdam, Kruislaan 320, 1098 Sm Amsterdam, The Netherlands; lesna@science.uva.nl

To free themselves of ectoparasites in nasty places, animals are known to display specific behaviour that promotes exposure of the parasites to their enemies. Plants tend to be regarded as more static organisms, but we report for the first time that they exhibit in essence quite similar behaviour. Tulip bulbs modify their internal structure in response to attack by a herbivorous arthropod (the rust mite Aceria tulipae). This herbivore is so tiny that it can move in between the scales of the bulbs. The resulting changes in distance between bulb scales are microscopic, yet sufficient to allow predatory arthropods (i.e. the phytoseiid mite Neoseiulus cucumeris) – three times larger in diameter than the herbivore – to enter the interior space of the bulb. The consequence of this plant behaviour is dramatic: with predators the inside of the bulb is cleared from herbivores, but without the bulb is eaten from within and dries out. The crucial changes in bulb morphology enabling predator access are controlled by ethylene, a plant hormone released upon herbivore attack. This was demonstrated in experiments on predator-prey dynamics in which the effect of ethylene was either promoted or blocked (using 1-methyl-cyclopropene).

Coexistence of competitors in a fragmented landscape: an experimental approach using a tropical insect and its parasitoids

OT Lewis
Department of Zoology, University of Oxford, South Parks Road, Oxford OX1 3PS, UK; owen.lewis@zoo.ox.ac.uk

In the fugitive model for the coexistence of competitors, the superior competitor is a weaker disperser, and the inferior competitor is able to persist by using isolated or newly created patches. I studied a patchily distributed plant, a monophagous insect herbivore, and two specialised insect parasitoids that share this herbivore as their sole hosts in a tropical forest in Belize, Central America. I describe a combination of observational work (mapping the patch network and the spatial distribution of herbivores and parasitoids) and experiments (manipulating the degree of habitat fragmentation by destroying patches in different locations) to test the fugitive model as an explanation for the coexistence of these competing parasitoids, and to investigate how their abundance and incidence are affected by fragmentation. Spatial patterns of parasitism were consistent with the fugitive model. Furthermore, as predicted by the model of Nee & May (1994) and others, the superior competitor was disproportionately affected by habitat fragmentation.

Spatial dynamics of forest insect outbreaks

AM Liebhold, DM Johnson, ON Bjørnstad
Northeastern Research Station, USDA Forest Service, 180 Canfield St., Morgantown, WV 26505 USA; aliebhold@fs.fed.us

Outbreaks of phytophagous forest insects are often spectacular, causing defoliation of millions of hectares of forests. A common characteristic in these outbreaks is the phenomenon of spatial synchrony among populations separated by as much as 1,000 km. By comparing patterns of synchrony among insect species exhibiting varying degrees of dispersal capabilities we are able to draw inferences about the relative role of dispersal vs. weather (the "Moran effect") as causes of spatial synchrony. Results suggest that weather is a more dominant cause of synchrony but the mechanisms by which weather function are often difficult to identify. There is also considerable evidence that the synchronizing effect of weather may be indirectly imposed via trophic interactions (e.g., predators or host populations). The 'new frontier' in the study of time-space data is the search for complex spatial dynamics (e.g., population waves). Application of novel statistical methods to historical larch budmoth data reveal has revealed the existence of outbreak waves in populations emanating from specific foci. These recurrent waves are associated with geographical trends in connectivity; simulations using a spatially explicit host parasitoid model suggest that these waves are the result of nonlinear reaction-diffusion processes interacting with variable habitat connectivity.

The response of Hemipteran assemblages to the restoration of Heather Moorland

N Littlewood, R Pakeman, S Woodin, P Dennis
Macaulay Institute, Craigiebuckler, Aberdeen, AB15 8QH, UK. and School of Biological Sciences (Plant & Soil Science), University of Aberdeen, Aberdeen, AB24 2TZ, UK; n.littlewood@macaulay.ac.uk

Moors dominated by Calluna vulgaris (heather) and other dwarf shrubs host distinct and geographically specialised invertebrate assemblages. The habitat is diminishing in the UK, largely due to high grazing levels. The resultant loss of dwarf shrubs produces a degraded, grass-dominated, plant community. Increasingly restoration management is being used to re-establish dwarf shrubs to such sites. We report the first study of the extent to which moorland vegetation restoration aids the reassembly of associated insect assemblages. Hemiptera were sampled by suction apparatus in grass dominated (degraded), restored and long established dwarf shrub (target) areas at each of eight restoration locations. Vegetation composition and soil characteristics were measured at each sampling point. Hemipteran assemblages differed between degraded and target sites. Species richness was significantly higher at the degraded sites whilst target sites hosted more specialised species. Samples from restored sites were, in all cases, more similar to their corresponding target than to samples from degraded sites. Plant community composition was the most significant predictor of hemipteran assemblages. Of measured soil characteristics, pH was the most significant predictor. This project demonstrates that restoration of dwarf shrub cover on degraded sites does aid the re-establishment of hemipteran assemblages typical of long established heather moors.

Can we predict insect community responses to climate change? Examples from grassland ecosystems

GJ Masters, VK Brown, IP Clarke
CABI Bioscience, Bakeham Lane, Egham, Surrey, TW20 9TY, UK; g.masters@cabi.org

It is increasingly apparent that individual species and, indeed, genotypes within species can respond differently to environmental change. However, to assist prediction there is a need to attempt generalisations, particularly with respect to population and community responses. Through investigation of the responses of insect herbivore communities on limestone grassland to the field manipulation of local climate, certain groups of species/traits appear to respond in a consistent fashion. The insect communities have been suction sampled regularly since 1993 on limestone grassland manipulated to reflect two climate change scenarios, warmer winters with either wetter or drier summers. There is a consistent gross response to summer drought while responses to winter warming are more species specific. Responses of the insect community dynamics and composition over the last twelve years have been tested against a simple trait based model of predicted general responses to climate change.

Responses of microarthropods to climate change on Marion Island: experimental evidence

MA McGeoch, EA Hugo, PC leRoux, SL Chown
Spatial, Physiological and Conservation Ecology Group, Department of Conservation Ecology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa; mcgeoch@sun.ac.za

Our understanding of the direct, indirect and interactive effects of climate change parameters on invertebrates remains fragmentary. This is particularly true in the southern hemisphere. On Marion Island (Prince Edward Islands, sub-Antarctic), a significant reduction in mean annual rainfall and increase in temperature over the past half-century is evident. On this island we examined the effect of experimentally-induced drying, warming and shading on Collembola and Acari associated with a keystone plant species, Azorella selago (Apiaceae). Microarthropods were sampled from the centre of A. selago plants with an O'Conner split corer, and extracted from cores using a MacFadyen higher gradient extractor. In general, significantly more individuals were found in control compared to treatment plants, with no difference in species richness between treatments. Individual species responded differently to the treatments. These results suggest that microarthropod abundance on Marion Island will generally decline with ongoing climate change in the region, springtails will respond more strongly than mites, and at least one introduced springtail species will be favoured by these changes. Although no significant differences in species richness were recorded in this localized, short-term experiment, ongoing declines in species abundance across the island would inevitably result in species losses from the system.

Spatial population structure of Timarcha lugens: the importance of spatial autocorrelation

A González Megías, JM Gómez, F Sánchez Piñero
Dpto. Biología Animal y Ecología. Facultad de Ciencias, Universidad de Granada. 18071, Granada.

Species inhabit patchy habitat can persist as metapopulation, define as a group of patchy populations connect by immigration. We studied the distribution of an endemic high mountain beetle living in a patchy environment, Timarcha lugens (Coleoptera, Chrysomelidae), in Sierra Nevada National Park (Southeast of Spain). For this purpose we study during five year 20 patches of the host plant. In addition, we analysed the importance of different variables to identify the factor to regulate this process, and the important of spatial autocorrelation. We used conventional analysis and non-conventional (Moran' I autocorrelation analysis and partial Mantel test to correct by the spatial autocorrelation) to determine the factor affecting beetle distribution. We found spatial autocorrelation in most explanatory and dependent variables and different results between conventional and non-conventional analyses. The main factors explaining T. lugens distribution were the position of the patches in relation to the river, isolation and plant density. Our result also shown that the distribution of T. lugens could be better explains by a mechanism of source-sink dynamic. In conclusion, spatial autocorrelation was important in this study, the use of specific spatial analyses being necessary to identify the real factors that contribute to regulate T. lugens populations.

Climate change and community-level turnover in British butterflies

R Menéndez, A Gonzalez-Megias, CD Thomas, R Fox
School of Biology, University of Leeds, Leeds, UK; bgyrmm@leeds.ac.uk

Butterfly richness patterns in Britain are well described by climatic variables and as a result the current changes in climate have led to many species extending their geographic ranges. Climate change is also thought to be leading to systematic changes in species richness and the structure of communities. This has not, however, assessed for British butterflies or for any other species assemblage. Here we investigate changes in the structure of butterfly assemblages (generalist vs. specialist) between two periods 1970-82 and 1995-99. We examined changes in species numbers and species turnover at three spatial resolutions across the whole Britain (50, 20 and 10 km grid cells). Though total species number has increased across Britain between the two study periods, the number of sedentary specialist butterflies has decline in some areas. Therefore, butterfly assemblages have became dominated for more mobile generalist species at least in some areas of the country. We discuss the results in relation to current climate warming and their implications for the future of global biodiversity.

Fitness consequences of predator-specific anti-predator behaviour in spider mites: Should I stay or should I go?

M Montserrat, M Egas, S Magalhães, A M de Roos, M Sabelis, A Janssen
University of Amsterdam, IBED, Section Population Biology, Kruislaan 320, 1098 SM Amsterdam, The Netherlands; montserr@science.uva.nl

Prey are expected to adopt predator-specific strategies when antipredator behaviour is effective against one predator but not against another. In this work, we quantify the fitness consequences of antipredator behaviour of the spider mite Tetranychus urticae, in order to predict and test its antipredator behaviour when exposed to different predation risks. The analysis of antipredator behaviour requires the quantification of costs and benefits of these two conflicting actions in terms of a common currency. Since spider mites have locally unstable populations, yet persist in a network of local populations connected by dispersal (i.e. a metapopulation structure), an adequate measure for fitness is the number of dispersing offspring per female produced during a local predator-prey interaction. Using a simple predator-prey we predicted the number of dispersing offspring produced by a female when faced to different predators. This model predicted prey should adopt predator-specific strategies to escape extinction. Experiments in which prey could display both strategies confirmed these predictions. Consequences for population dynamics are discussed.

Experimental evidence for apparent competition in a tropical forest food web

RJ Morris, OT Lewis, HCJ Godfray
NERC Centre for Population Biology, Imperial College London, Silwood Park Campus, Ascot, Berkshire, SL5 7PY, UK; r.j.morris@imperial.ac.uk

Tropical insect communities are some of the most diverse on earth, but the processes that structure them and determine their diversity are largely unknown. Apparent competition is one of the major candidate processes. We experimentally removed two species of herbivore from a community of leaf-mining insects in a tropical forest in Belize. We predicted that other species which share natural enemies with the removed species would experience lower parasitism and have higher population densities in treatment compared with control sites. In both cases we found significantly lower parasitism, and in one case significantly higher abundance a year after the manipulation. This is the first demonstration of long-term apparent competition in any terrestrial arthropod community and suggests that apparent competition may be an important structuring force in tropical insect communities. Our results also have implications for the impact of human activities on tropical forest biodiversity.

Insects in a warmer world: ecophysiology of reproduction and overwintering of the southern green stink bug Nezara viridula in a recently colonized area in Japan

DL Musolin, H Numata
Biological Research Institute, St. Petersburg State Univ., St. Petersburg, 194908, Russia; musolin@dm1037.spb.edu

From 1960s to 2000 N. viridula expanded its range northwards in Japan and reached Osaka (34.7 N; 135.5NE) following climate warming recorded in the region. The timing of diapause induction and its effect on life-history traits were studied under quasi-natural conditions in Osaka. Adult diapause induced in September–October ensured high winter survival. The timing of diapause induction strongly affected overwintering success and post-diapause performance: Females that emerged and entered diapause in October survived longer and produced more eggs than females that attained adulthood in September. Females from the early series reproduced until November, although progeny from the eggs laid in late September died during winter. Pre-winter reproduction of adults that emerged in mid-September or later was a result of the imperfect timing of diapause induction. It is an ineffective allocation of resources and considered the ecological cost of range expansion. To establish in the region, N. viridula will probably evolve a lengthening of the critical photoperiod of the diapause induction. This will allow to enter diapause earlier and, thus, avoid maladaptive late-autumn reproduction, but, perhaps, increase the duration and cost of diapause. The response of the species to climate warming will be compared with those reported in other species.

The role of dispersal in the population dynamics of locally unstable populations of prey and predators, using spider mites and predatory mites as a model system

G Nachman
Department of Population Biology, Institute of Biology, University of Copenhagen, Universitetsparken 15, Dk 2100 Copenhagen Ø, Denmark;
gnachman@bi.ku.dk

The population dynamics of the two-spotted spider mite (Tetranychus urticae) and its natural enemy, the phytoseiid predator Phytoseiulus persimilis, is highly unstable, leading to frequent extinctions of either species at the scale of individual plants. In spite of this, coexistence at a larger spatial scale may still be possible provided that local extinctions and colonizations occur asynchronously. To understand the role of local versus regional dynamics in maintaining population persistence, a series of small-scale greenhouse experiments were conducted and a generic model was developed to simulate within- and between plant dynamics. The model incorporates the functional, aggregative and numerical responses of the predators to the local density of prey, the negative feed-back between the prey's growth rate and the state of the host plant, and condition-dependent dispersal of mites among plants. The model shows good agreement with the experimental data and provides a good analytical tool to investigate strategies for biological control of fugitive pest species by means of specialist predators.

Parasitoids on Acronicta rumicis in South Korea

SH Nam
Dept. of Biology, Daejeon Univ., 96-3 Yongun-dong, Dong-gu, Daejeon 300-716 Korea; themoth@empal.com

The endoparasitoids of Acronicta rumicis were studied from May 2000 to October 2002 at Yong-Un dong area of Daejeon city in S. Korea. The number of species and parasitic rates were recorded. The number of endoparasitoids was 8 Species in 2 Orders 3 Families : Glyptapanteles liparidis and Microplitis sp. belonging to Order Hymenoptera, Family Braconidae. Diadegma sp. and Mesochorus semirufus belonging to Order Hymenoptera, Family Ichneumonidae. Compsilura concinnata, Euexorista sp., and Exorista sp. belonging to Order Diptera, Family Tachinidae. Among them, G. liparidis and C. concinnata are well known endoparasitoids of Lymantria dispar. Of the 322 field-collected larvae of A. rumicis, 74 showed parasitoids (22.98% parasitism). The collected field record showed relatively high parasitism in May (39.50±34.04%) and in October (50.05±2.70%). In addition, Parasitism by Hymenopteran and Dipteran parasitoids was about 85.61±7.30% and 12.22±4.42% respectively.

A computer program for estimation of fertility life table parameters using jackknife and bootstrap techniques

VH Naveh, H Allahyari, M Saei
Dept. of Plant Protection, College of Agriculture, University of Tehran, Iran; vnaveh@ut.ac.ir

Fertility tables are powerful tools for understanding of the population dynamics of a species. Intrinsic rate of natural increase (rm) is the most important estimator derived from fertility life table analysis and describes the maximal rate of increase that is possible for the species under the given physical and biotic environment. To compare fertility life table parameters of different groups, it is necessary to have information on the uncertainty degree associated with its estimates. The rm program has been provided for entomologists who want to have precise estimations of the five main fertility life table parameters; R0, rm, T, DT, , and precision associated with them using both bootstrap and jackknife techniques. This program is the first specific program that allows calculations using bootstrap technique. The Bootstrap replicates and Jackknife pseudovalues are stored into an Excel file for ease of comparing of different groups using statistical tests. The rm program is prepared by using visual basic programming language and can be run under all windows operating systems.

About bisexual population dynamics

LV Nedorezov, YuV Ut'yupin
International Centre of Insect Physiology and Ecology, P. O. Box 30772 - 00100, G. P. O, Nairobi, Kenya; leo@icipe.org

Let be the moments of appearance of new generations and let's assume that on the time intervals there are the monotonous decreasing of individuals:

About periodic impacts onto isolated population dynamics

LV Nedorezov, AM Sadykov
International Centre of Insect Physiology and Ecology, P. O. Box 30772 - 00100, G. P. O, Nairobi, Kenya; leo@icipe.org

In model of insect population dynamics it's assumed there exist moments which correspond to "moments of harvesting":

Indirect interaction webs of insect herbivores: consequences of plant-mediated indirect effects

T Ohgushi
Center For Ecological Research, Kyoto University, Kamitanakami, Otsu, Shiga 520-2113, Japan; Ohgushi@Ecology.Kyoto-U.Ac.Jp

Since effects of herbivorous insects on matured plants are almost nonlethal but subsequently induce changes in various plant traits, herbivore-induced indirect interactions are ubiquitous in plant-insect systems. Nevertheless, the subject has not been considered as important as direct effects. I will illustrate how herbivorous insects are connected each other through plant-mediated indirect effects on the willow, Salix miyabeana. For example, the enhanced shoot growth as a compensatory response to spittlebug oviposition links spittlebugs and leafrolling caterpillars. The leaf shelters connect leafrolling caterpillars with aphids and ants, and the increased tending by ants links aphids and leaf beetles. Ant-mediated indirect interaction between aphids and leaf beetles is maintained by provision of leaf shelters. Hence, these plant-mediated indirect effects generate the interaction linkage of insect herbivores on the willow. The interaction linkage can be depicted using indirect interaction webs that include nontrophic indirect links. The indirect interaction web revealed more than three times as much as direct and indirect interactions involved in the willow-insect system. Consequently, the structure of indirect interaction webs on plants may be greatly different from that of the traditional plant-based food webs, and will provide a more realistic understanding of interaction networks in insect communities.

Role of aphid bacterial symbionts in resistance to parasitism

KM Oliver, NA Moran, MS Hunter
University of Arizona, Dept. of Entomology, 410 Forbes Building, Tucson, Arizona, U.S.A. 85721-0036; kmoliver@u.arizona.edu

Molecular diagnostic tools have recently shown that bacterial symbionts of arthropods are extremely common, yet the effects of these symbionts on their hosts are largely unknown. In addition to the well-characterized obligate primary symbiont, Buchnera aphidicola, which supplies nutrients lacking in the plant sap diet, the pea aphid, Acyrthosiphon pisum, harbours diverse facultative or 'secondary' symbionts (SS). Pea aphids may harbour combinations of at least five vertically transmitted SS, including three independent lineages in the ?-proteobacteria designated as the R-, T- and U –types, a Rickettsia, and a Spiroplasma. Two of the three types of symbionts tested (R- and T-type) confer resistance to the braconid parasitoid, Aphidius ervi, by causing mortality of developing wasp larvae. The consequences of infection with both resistance conferring symbionts (R and T-types) on the aphid host and developing parasitoid will be discussed. These findings will be related to the distribution of SS in natural aphid populations. This interaction between a symbiotic bacterium and a host natural enemy provides a mechanism for the spread and persistence of these bacteria, and may be an important component of the widespread variation in susceptibility of pea aphid clones to parasitoid attack.

Genetic diversity and oviposition host preference of Bemisia tabaci (Gennadius) (Homoptera; Aleyrodidae) associated with four crops in Ghana

BA Omondi, D Obeng-Ofori, RAK Kyerematen, EY Danquah
African Regional Postgraduate Programme in Insect Science (ARPPIS) University of Ghana, P. O. Box LG 82, Legon, Accra; omondiaman@yahoo.com

The grave importance of Bemisia tabaci as a crop pest worldwide is mainly due to its wide host range, heterogeneous damage and intraspecific variation. Over 20 biotypes have been reported with varying host preference and vectorial capacity. In West Africa, two biotypes of this pest have been described by molecular and ecological studies. However, greater understanding of host-pest population interaction is necessary for its sustainable control. This study investigated the host acceptance of cassava and okra biotypes of B. tabaci using landing, oviposition and development preference on eight crops. The cassava biotype significantly preferred cassava for landing and oviposition ($p<0.001$), but did not oviposit on okra. The okra biotype significantly preferred okra ($p<0.026$), oviposited and developed on all other hosts except cassava ($p =0.001$), while the cassava biotype did not develop on okra, cabbage, and pepper. Mortality was highest in the first-instar nymph stage while development time was longer on marginal hosts than the preferred hosts ($p<0.05$). Thus, the observed host spectrum of each biotype is wider than earlier reported by host transfer experiments and molecular genetic surveys. Cowpea, garden egg and tomato are additional shared hosts whose role as reservoir hosts and biotype interbreeding grounds should be investigated further.

Significance of microhabitat on metapopulation structure in spider mites

M Osakabe, K Goka, S Toda, T Shintaku, H Amano
Graduate School of Agriculture, Kyoto University, Kyoto 606-8502, Japan; mhosaka@kais.kyoto-u.ac.jp

Restricted migration and habitat fragmentation promote genetic differentiation between populations. Spider mites exhibit two major dispersal behaviours, crawling and aerial drift. Tetranychus urticae infests many herbaceous and woody plant families, being considered that they disperse between adjacent plants mostly by crawling. Panonychus citri is another polyphagous species, yet most of its hosts are woody plants. Therefore, P. citri faces more risks by dispersion between host plants than T. urticae. If so, population structures of P. citri and T. urticae may be maintained in different ways due to different dispersal system. We analysed gene flow of P. citri in Japanese citrus groves from a broad geographic level to the patch level using molecular markers (esterase, a microsatellite and COI) and acaricide resistance genes. At the broad geographic level, gene diversity decreased with decreases in area size and distance between populations. Within a locality, on the other hand, genetic divergence of mites between citrus trees within groves was higher than that between the groves. From these results, we concluded that P. citri frequently migrates between groves within localities but not across wider areas, and within a locality they migrate between groves by aerial drift rather than moving to adjacent trees.

Parasitoid impact on aphid populations in UK cereal crops and attempts at manipulation

W Powell
Plant & Invertebrate Ecology Division, Rothamsted Research, Harpenden, Hertfordshire LU6 3QQ, U.K.; wilf.powell@bbsrc.ac.uk

Parasitoids are a key component of the natural enemy guild that frequently prevents cereal aphids from reaching damage thresholds in the U.K. To be effective, they must be present in cereal crops early enough in the season to coincide with aphid colonisation. This early spatio-temporal synchrony between aphids and parasitoids in the crop can be disrupted by climatic factors and by crop husbandry procedures. Field data will be presented to demonstrate the effects on aphid population dynamics of disruption of parasitoid activity during the early stages of crop invasion. The results of attempts to increase parasitoid impact by manipulation of field margin habitats and the use of aphid pheromones to manipulate parasitoid spatio-temporal distribution will be described. Changes in the sex ratio of adult parasitoids in the crop, from female biased early in the season to male biased late in the season reflect dispersal patterns between crop and semi-natural habitats in response to host availability. Preliminary data indicate that the deployment of aphid pheromones can positively influence the spatial distribution of adult parasitoids, encouraging early movement into the crop from field boundaries.

Historical perspective on multitrophic interactions

PW Price
Department of Biological Sciences, Northern Arizona University, Flagstaff, Arizona 86011-5640, USA; Peter.Price@Nau.Edu

Community views of nature have prevailed since well before Darwin's time, which have emphasized interacting species at multitrophic levels. Sophistication in understanding has increased from blatant and direct effects, such as predation and competition, to the many more subtle, but critical, indirect effects emphasized in multitropic-level-interactions ecology today. Enabled by advances in phytochemical analysis, the field advanced into the roles of constitutive plant chemicals, and plant odors and exudates in the ecology of higher trophic levels based on plants. Indeed, body odors (BOs) of all kinds have proven to be significant, whether from plants or insects, or waste products, or damaged cells, such that the ecology of BO is a burgeoning field. However, the science of multitrophic level interactions has remained largely idiosyncratic, while the potential for synthesis and empirically-based theory has been underexploited. Some examples of areas of future synthesis worth exploring on multitrophic interactions include: 1. the geographic mosaic of coevolution; 2. spatial variation in interactions; 3. long-term studies; 4. trait-mediated indirect effects; 5. the genetic basis of complex interactions; and 5. macroevolutionary perspectives employing phylogenetic comparisons among related species of plants, insect herbivores or natural enemies.

You are what you eat? Investigating the link between plant nutrient status and the performance of insect herbivores

J Pritchard
School of Biosciences, University of Birmingham, Birmingham, B15 2TT, UK; J.Pritchard@bham.ac.uk

Predicting the consequences of global climate change may involve direct effects on insects but is likely to contain a strong component of altered diet. Therefore the effect of climate change on herbivorous insects cannot be determined without understanding the effect on the plant. Components of climate change including water and nutrient availability impact on plant quality, in particular the phloem. Aphids are herbivores that feed almost exclusively in the phloem. We are interested in the way in which phloem composition affects their growth and reproduction. Our strategy has been to modify sieve composition environmentally by altering water (drought) and nutrient input to the plant. By exploiting molecular genetics in the model plant Arabidopsis we are also able to modify sieve element composition using knockout mutations. Phloem sap is extracted using stylectyomy. Aphid performance (Rm) and behaviour (EPG, honeydew clocks) can then be measured and correlated with changes in diet. This work reveals that simple relationships between sieve element composition (diet) and aphid performance are modified by complex behavioural and metabolic manipulation of dietary flux by the aphid itself. These data inform models attempting to predict the effect of climate change and suggest that current prediction models may lack necessary complexity.

Restructuring of an exotic fungus-fly mutualism after establishment

S Rao, D Baumann
3017 ALS, Corvallis, OR 97331, USA; sujaya@oregonstate.edu

Botanophila flies and the endophytic fungus Epichloë spp. that infect Pooidae grasses have a mutualistic interaction. During oviposition flies transfer spermatia between Epichloë mating types for cross fertilization. Flies lay eggs on fungal stromata and larvae feed on the fungus. Studies on Epichloë spp. infecting wild grasses indicate that, in the absence of the fly, perithecial development following fertilization is reduced considerably. We were interested in examining the fungus-fly relationship after E. typhina was inadvertently introduced into Oregon in the United States. We observed that perithecia were common in D. glomerata but there was variation in the presence of the fly. At 12 sites we observed 6 to 98 % infestation of stromata (n = 50 per site) with fly larvae. At the 13th site, no fly eggs or larvae were detected on stromata but near uniform orange perithecia were found. An exclusion study conducted in a cultivated D. glomerata field also indicated that fertilization occurred without the fly. These results suggest that Botanophila could play a role in E. typhina fertilization in Oregon but it is not the sole factor involved. Hence, while Botanophila benefits from its association with E. typhina, the benefit to the fungus is questionable.

Host defense and parasitoid reproductive strategies limit niche breadth in a host-parasitoid system

AD Rice, GR Allen
CRC SPF, Private Bag 12, Hobart Tasmania 7001; Anthony.Rice@ffp.csiro.au

Defensive behaviour of larval Chrysophtharta agricola and host-stage preferences of two tachinid flies that parasitise it (Paropsivora australis and Tachinidae sp.) were examined. Data collected was used in conjunction with the results from other studies we conducted to establish the extent that host defence, host developmental biology and parasitoid reproductive strategies are impacting on the niche breadth of the two tachinids. Our data shows that Tachinidae sp. takes a relatively long time to oviposit and prefers early instar hosts which have less vigorous defensive behaviour than the final fourth instar, which thrashes its abdomen with sufficient vigour to dislodge the fly and interrupt oviposition. P. australis however, prefers to oviposit on fourth instars but as it can deposit an egg very quickly it effectively avoids being dislodged during oviposition. We discuss these results in relation to developmental interactions between host and parasitoids, and suggest that intraspecific host choice of these two tachinid flies is a result of interactions between both the biology and defensive behaviour of the host, and the reproductive strategies of the parasitoids.

Compositional changes of functional feeding groups in mountainous streams in a temperate region

TH Ro, JH Park, DJ Chun
Korea Environment Institute, Eunpyong-gu, Seoul 122-706, Korea; thro@kei.re.kr

The ecosystem attributes of mountainous stream were analyzed using functional feeding group (FFG) ratios in three lotic systems in Korea. As the elevation went down from 800m to 400m, aquatic insect community structures were also changed and reflected the different ecological characteristics of each stream section. Although total biomass of communities in 3 streams were distinctively different, the longitudinal changing patterns of FFG ratios demonstrated tendencies that might be generalized. The ratio filtering collectors to gathering collectors was less than 0.5, and its values at higher elevations (alt. 800m & 600m) were very lower than those at lower elevation (alt. 400m). The ratio indicated the substrate stability was higher at both upstream and downstream sites comparing with the ratio at mid-stream. The ratios indicating the trophic type were much lower than 0.75. These values decreased along with elevation changing from 800m to 400m. The proportion of predators at each elevation also decreased from upstream to downstream. The ratios shredders to total collectors indicated that normal shredder association linked to functioning riparian system occurred at mid-stream. This study provided essential information in building the hypothetical river continuum model and generalizing FFG functions for the mountainous streams.

Two genetically distinct lines co-exist in populations of the endoparasitoid Venturia canescens

HSL Roberts, A Reineke, O True, J Belatti, O Schmidt
Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia; otto.schmidt@adelaide.edu.au

In a laboratory colony of the solitary endoparasitoid Venturia canescens (Hymenoptera: Ichneumonidae) two genetically distinct lines (named RP and RM) appear to coexist sympatrically. The two lines differ in a cluster of phenotypic characters, including ovarian morphology, parasitism behaviour and reproductive success. Controlled oviposition experiments showed that RM females produce fewer offspring under single egg parasitism but more under con-specific superparasitism, compared to RP wasps. Investigations of interlarval combat under in vitro conditions showed that the higher reproductive success of the RM line under conspecific superparasitism is due to a physiological difference between the newly hatched larvae of the two lines which results in an advantage to the RM larva independent of the order or time interval between ovipositions. Examination of field-derived wasps has found that wasps displaying the two phenotypic clusters occur in natural populations. A model, using an iterative approach with experimental data to predict the stable composition in a mixed population of wasps displaying RM and RP, suggests that the two lines will coexist sympatrically when overall rates of superparasitism are greater than 5 to 10%.

Possible involvement of microorganisms in the production of Tetranychus urticae-induced lima bean leaf volatiles

W Sasaki, R Ogasa, K Matsuda, R Ozawa, J Takabayashi
Graduate School of Agriculture, Kinki University, 3327-204 Nakamachi, Nara 631-8505, Japan,

Lima bean leaves infested by spider mites emit volatiles that attract carnivorous natural enemies of spider mites. The predator-attracting volatiles consist of (Z)-3-hexenyl acetate, terpenes and methyl salicilate (MeSA), and their qualitative and/or quantitative composition has been shown to affect the atractiveness. The author has found that acidic as well as basic PR-protein coding genes were expressed in lima bean leaves in response to the infestation by the spider mites Tetranychus urticae. Since the acidic PR genes are generally induced by microbial attacks, we inferred that microorganisms that were pertinent to the spider mites might play a role in the volatile production in the infested leaves. Thus the microbial population in the mites was reduced as much as possible by rearing them under the aseptic condition, and their capability of eliciting the volatile production was investigated. The amounts of some of the volatiles from the lima bean leaves infested by the "aseptic" mites was markedly reduced compared with that in the leaves infested by the normal mites, suggesting a contribution of the microorganisms to the volatile production.

Statistical analysis of movement data in a heterogeneous landscape and behaviour at patch edges

N Schtickzelle, M Baguette
Biodiversity Research Centre, Université catholique de Louvain, Croix du Sud 4-5, B-1348 Louvain-la-Neuve, Belgium; schtickzelle@ecol.ucl.ac.be

We used movement paths of adult bog fritillary butterflies Proclossiana eunomia to study the consequences of behaviour at habitat patch boundaries on dispersal in two habitat networks differing in fragmentation and matrix quality. Butterflies systematically engaged in U-turns when they reached a boundary in the fragmented network while they crossed over boundaries in more than 40% of boundary encounters in the continuous one. Applying the Virtual Migration model (Hanski et al Ecology 2000) to capture-mark-recapture data collected in both networks, we showed (1) a lower dispersal rate and (2) a lower survival during dispersal in the fragmented network. This latter difference is likely to be the key biological process leading to behavioural avoidance of patch boundary crossings. Then we designed an individual-based simulation model to explore the relationship between patch area, boundary permeability and emigration rate. Predictions of the model fitted observed results of the effect of patch area on emigration rate according to fragmentation: butterflies are more likely to leave small patches than large ones in fragmented landscapes (where patch boundary permeability is low), while this relationship disappears in more continuous landscapes (where patch boundary permeability is high).

The influence of transmission modes, host wasp and host tree preference on the population structure of Amylostereum symbionts of siricid woodwasps

B Slippers, R Vasiliauskas, MJ Wingfield, DK Aanen, J Stenlid
Department of Forest Mycology and Pathology, Swedish University of Agricultural Sciences, Uppsala, Sweden; bernard.slippers@mykopat.slu.se

Siricid woodwasps (Hymenoptera) live in an obligate symbiosis with species of the fungus Amylostereum (Basidiomycotina). Wasps lay their eggs in softwoods together with a small inoculum of Amylostereum that causes a white-rot, where the wasp larvae develop. While there are many species of Sirex, only A. areolatum, A. chailletii and A. laevigatum are known to have symbioses with these insects. This difference in species numbers is reflected in specificity patterns: while a single wasp species typically is associated with one species of symbiotic fungus, the fungal species can be shared between different wasp species. Wasp species carrying the same fungal species commonly display different host tree preference. For example, S. juvencus and S. noctilio overlap in regional occurrence and both live in associations with A. areolatum. However, the former species preferentially breeds in Picea, while the latter shows a preference for Pinus. Here we studied the population structure of the Amylostereum symbionts of different wasp species, using phylogenetic and population genetic markers. We specifically determined genetic differentiation of symbionts between host wasps, host trees and geographical areas and inferred symbiont transmission modes. Transmission of the fungus between generations is usually thought to be strictly vertical from mother to offspring. However, the fact that various wasp species share the same fungal symbiont implies that horizontal transmission does occur, at least on evolutionary time scales. The observation of oviposition of wasps in the vicinity of previous Siricid and Amylostereum infections also suggests the possibility of both horizontal and vertical transfer.

Host range and population dynamics of greenhouse whitefly, Trialeurodes vaporariorum (Westwood) in North-Western Indian Himalayas

AK Sood, S Sood
Himachal Pradesh Agricultural University, Palampur, Hp, 176062, India; Sood_Hpau@Yahoo.Co.In

Greenhouse whitefly, Trialeurodes vaporariorum (Westwood) (Homoptera: Aleyrodidae) has become a major pest of ornamental plants and vegetable crops under protected (greenhouse) and open environment in the temperate regions of north-western Indian Himalayas. The host range investigated in the region revealed the presence of greenhouse whitefly on 44 hosts belonging to 20 plant families. T. vaporariorum remains active through out the year on most of the hosts, however in open environment it passes the winter months (November-February) on Lycopersicon esculentum, Fuchsia magellanica, Salvia officinalis and Erigeron canadensis. The adult activity monitored using yellow sticky traps revealed two peaks of trap catch, one during May, both under protected and open environment, and the other in second week of September (under protected environment) and second fortnight of November (under open environment). Seasonal dynamics studied on brinjal, Solanum melongena, showed the peak activity of greenhouse whitefly during mid-June and September under protected environment, and early June under open environment. In the absence of biotic mortality factors in the region, the abiotic factors of the environment alone exerted regulatory influences on pest abundance.

Weeds and wasps: the effect of bridal creeper on parasitic wasp assemblages

CJ Stephens, AD Austin, JM Facelli
Centre for Evolutionary Biology and Biodiversity, School of Earth And Environmental Sciences, The University of Adelaide, South Australia 5005; claire.stephens@adelaide.edu.au

The invasion of exotic plants can significantly change natural patterns of biodiversity. In most cases the effect of weed invasion is measured as a change in the abundance of a single trophic level, usually native flora. However, it is less known what impact environmental weeds have on native fauna such as terrestrial arthropods and their associated interactions and ecological functions. One major arthropod group are hymenopteran parasitoids. The evolution of parasitoid-host associations has resulted in specific relationships with both host taxa and habitat. This study investigated the effects of one of Australia's most serious environmental weeds, bridal creeper (Asparagus asparagoides), on parasitic wasp assemblages in remnant eucalypt woodland in South Australia. Results consider parasitic wasp abundance, diversity and functional groups based on host associations, and reveal that although bridal creeper invasion has a strong negative effect on native plant diversity it does not reduce wasp biodiversity and supports an overall different wasp assemblage than adjacent native habitat. Given that over 450 parasitic wasp morphospecies were recorded, this study also highlights the high levels of arthropod diversity that can occur in a remnant habitat and the conservation value of small reserves for terrestrial arthropods.

The effects of elevated CO2 on insect populations and communities

P Stilingm, T Cornelissen
Department of Biology, University of South Florida, 4202 East Fowler Avenue, Tampa, FL 33620, USA; pstiling@tampabay.rr.com

First, we present the results of a detailed study of the affects of elevated CO2 on different guilds of insect herbivores feeding on scrub-oak vegetation in Florida. Responses to elevated CO2 are compared both within guilds, for leafminers (6 species), gall insects (3 species), sap suckers (2 species), and chewing insects, and between guilds. Second, responses to elevated CO2 will be compared between and within guilds, and between habitats, using data from different elevated CO2 experiments at a variety of sites. We use meta-analysis for most of these comparisons. Finally, the effects of elevated CO2 is examined not just on selected populations, but on whole communities to see if insect community diversity is changed in elevated CO2. This analysis is based on newly collected data (2003-2004) from Kennedy Space Center and examines the effects of elevated CO2 on the diversity of plants, their herbivores, the herbivore's natural enemies, and the soil/litter dwellers. Because this is probably the only long term experiment examining the effects of elevated CO2 on a natural community, the results provide a unique opportunity to examine the effects of global change, in this case elevated CO2, on whole communities, not just populations of selected species.

Evolution in a community context: selection from herbivores and pollinators on plant traits

SY Strauss
Section of Evolution and Ecology, UC Davis, 2320 Storer Hall, One Shields Ave, Davis, CA 95616 USA; systrauss@ucdavis.edu

All species are part of multi-species communities and the traits they express are shaped by selective pressures generated by the web of direct and indirect interactions among community members, along with the effects of abiotic factors. Understanding the diverse and simultaneous pressures experienced by species within a community may provide insights not readily gathered from the study of pair-wise interactions between species. Moreover, since the strength and direction of selection is altered by stochastic, abiotic factors that vary from year to year, a simultaneous examination of multiple selective forces carried out over many seasons is required to assess evolution in a community context. Continued experimental field manipulations of putative selective agents are combined with observational demographic data and with greenhouse experiments in this long-term study of the diverse agents acting on flower color in Raphanus sativus. Flower color and foliar glucosinolate expression are correlated, and thus both pollinators and herbivores may act as selective agents on both traits. In addition, to date, the effects of these agents appear to act in opposition, and vary in both strength and direction among years. In understanding how communities influence component species, we appreciate the contributions of biodiversity not only to ecological processes like ecosystem function, but also to the evolutionary trajectories of species. These trajectories are often shaped by the compromises imposed by simultaneous, diverse selective pressures.

How variable are responses of insects in the same region to climate change?

RW Sutherst
CSIRO Entomology, 120 Meiers rd, Indooroopilly, QLD Australia 4068; Bob.Sutherst@csiro.au

Global environmental change is non-linear and impacting on insect management and conservation. The challenge for researchers is how best to identify the key issues that should drive management decisions on pest and non-pest species. Management decisions are usually site-based, and there are tensions caused by the desire to vary the emphasis put on each species. The response of a species to climate change or invasions by alien species will depend on its physiological, genetic and ecological attributes, and these will vary for each species at the same location. In addition, options for adaptation may be restricted by such constraints as pesticide resistance and non-target effects of pesticides such as endocrine disruption. A number of these attributes are identified and their implications discussed.

Molecular and ecological evidence for small-scale isolation by distance in an endangered damselfly

DJ Thompson, JR Rouquette, IJ Saccheri, PC Watts
School Of Biological Sciences, University Of Liverpool, Crown Street, Liverpool, L69 7zb, Uk; D.J.Thompson@Liv.Ac.Uk

Coenagrion mercuriale (Charpentier) is one of Europe's most threatened damselflies and is listed in the European Habitats directive that requires member states to designate Special Areas of Conservation for its protection. We combined an intensive mark-release-recapture study with a genetic analysis of 14 microsatellite loci for C. mercuriale from the Itchen Valley in the UK as part of an effort to understand the dispersal characteristics of this protected species with respect to its landscape. MRR data indicate that adult damselflies are highly sedentary. This restricted dispersal leads to significant genetic differentiation throughout most of the Itchen Valley, except between areas of continuous habitat, even though the core populations are separated by less than 10 km; this leads to a strong pattern of isolation by distance. Individual damselflies are positively autocorrelated at short distance classes reflecting fine-scale genetic clustering. A genetic patch size of 1.5 km is consistent with the distribution of movement events recorded by direct observation. These data are further discussed with respect to possible barriers to dispersal within the study site and the ecology and conservation of C. mercuriale. To our knowledge, this is the first report of fine-scale genetic structuring in any zygopteran species.

Invertebrate bioindicators to assess sustainability in vineyards

LJ Thomson, AA Hoffmann
CRCV Cooperative Research Centre for Viticulture, CESAR Centre for Environmental Stress and Adaptation Research, Biological sciences Building II, La Trobe University, Bundoora Victoria 3086 Australia; L.Thomson@latrobe.edu.au

The influence of management practices on invertebrates of economic interest and biodiversity in general provides important information for the development of sustainable agriculture. Invertebrates were sampled at ground level and in the canopy using three methods: pitfall traps and two types of sticky trap, to determine the effects of variation in two common vineyard practices (type of ground cover and level of irrigation). Earthworms were sampled by hand sorting soil samples. Results indicate that invertebrate taxa at the order level respond to management treatments. Order level biodiversity was increased with straw as a ground cover but was not affected by decreased irrigation. Ground cover (particularly straw) encouraged relatively larger populations of generalist predators and parasitoids as well as soil conditioning organisms such as Collembola and earthworms. Reduction in irrigation had a more limited effect, impacting on earthworm numbers and some generalist predators. However data also highlight some of the problems with the use of invertebrates for biomonitoring. In particular seasonal differences indicate the need for longitudinal studies incorporating a number of seasons.

Multitrophic plant-insect interactions and biodiversity at different spatial scales

T Tscharntke
Agroecology, Georg-August University of Göttingen, Waldweg 26, D-37073 Goettingen, Germany; ttschar@gwdg.de

The focus in ecology is changing from the traditional study of simple interaction types to direct and indirect interactions among populations of multiple trophic levels. Such consideration of the complexity found in nature includes the realization that landscape structure directly affects local interactions and community structure and the need to study populations at different spatial scales. In fragmented landscapes, the disruption of habitat continuity may be accompanied by a loss of species and a disruption of interaction strength between species, showing the functional significance of biodiversity. Local abundance of functional groups may depend on different spatial scales of the surrounding landscapes, and I will test whether populations of higher trophic levels are influenced by a smaller or larger diameter of the surrounding landscape circles, i.e. by a different spatial scale. In my talk, I will present results form experiments performed in our agroecology research group that include plant-herbivore-parasitoid as well as plant-pollinator interactions.

Plant-mediated interactions between below- and above-ground processes: decomposition, herbivory, parasitism and pollination

T Tscharntke, K Poveda, I Steffan-Dewenter, S Scheu
Agroecology, Georg-August University of Göttingen, Waldweg 26, D-37073 Goettingen, Germany; ttschar@gwdg.de

Traditionally, below-ground and above-ground communities have been investigated separately even though both systems show high interdependence. The interactions between above- and belowground organisms have only recently become a major field of study. Many of these studies focus on the effects of decomposers and below-ground herbivores on plant growth and above-ground plant-insect interactions, but their effect on plant reproduction is hardly studied. Further, the relative importance and the combined effects of below-ground and above-ground herbivores on plant performance, plant-herbivore, herbivore-parasitoid and plant-pollinator interactions is almost unknown. For this presentation and book chapter we will shortly review plant-mediated interactions between below- and above-ground processes. We will show results of our factorial experiments with potted mustard where we manipulated root and leaf herbivores as well as decomposers to analyze effects on plant-growth changes, herbivory, parasitism, flower visitation, fruit set and overall plant fitness. In these experiments we focus on the real-world complexity of direct and indirect interactions that only recently have been acknowledged by ecologists. By integrating our work with that from other published studies we will show that the traditional study of simple communities and interactions need to take such multitrophic-level interactions into account.

On the coexistence of thelytokous and arrhenotokous populations of Venturia canescens

JJM van Alphen, C Bernstein, I Amat, M Ney-Nifle
P.O. Box 9516, NL2300RA Leiden, Netherlands; alphen@rulsfb.leidenuniv.nl

Venturia canescens is an important model for laboratory studies on behaviour and physiology of parasitoids. However, little was known about its field ecology. Studies in Mediterranean France have revealed that sexually reproducing V.canescens occur together with thelytokous ones. Thelytoky is not caused by PI-Wolbachia, and extended genetic studies have shown that successful exchange of genes between sexual and thelytokous populations is extremely rare or absent. This raises the question how populations of the two reproductive modes can co-exist. We will show the results of field studies on distribution and laboratory studies on behaviour and life–history traits to show that important ecological differences exist between the two modes. A population model will be presented showing that the two reproductive modes can co-exist, even when the sexual form is competitively inferior, when dispersal of the sexuals is better, or when sexuals are better in host finding under natural conditions.

Butterfly metapopulation dynamics from the parasitoid's perspective

S van Nouhuys
Metapopulation Research Group, Department of Biological and Environmental Sciences, PO Box 65 (Viikinkaari 1), FIN-00014 University of Helsinki, Finland; sdv2@cornell.edu

The spatial population dynamics of parasitoids, including their persistence, is influenced by the dispersion and population dynamics of their hosts. Here I contrast the spatial scales at which host distribution and dynamics are important for two parasitoid species sharing a single host butterfly species, using data from field surveys, experiments and molecular markers. The host, Melitaea cinxia, lives as a classical metapopulation in the Åland islands of SW Finland. Local populations occupy about 400 of the 4000 habitable meadows in an area of 50 by 70 km. One parasitoid, Hyposoter horticola, is extremely dispersive, finding most hosts and parasitizing a practically uniform fraction of them at all spatial scales. This wasp has very little spatial population structure of it's own and does not appear to experience the metapopulation structure of the host. It contributes to host population dynamics only by equally reducing the size of each host population. In contrast, the parasitoid Cotesia melitaearum is sedentary and has strong spatial population structure. It can influence host metapopulation dynamics but is limited, by it's dispersal ability, to a few tightly clustered host populations. Presently C. melitaearum is at risk of regional extinction.

Spatially explicit host-parasitoid relationships: density dependence revisited

R Veldtman, MA McGeoch
Department of Zoology & Entomology, University of Pretoria. Current postal address: Department of Conservation Ecology, University of Stellenbosch, Private Bag X01, Matieland 7602, South Africa; rveldtma@sun.ac.za

Species typically have aggregated distributions. Aggregation in species abundance may also cause aggregation at higher trophic levels, e.g. parasitoids responding to their host. Methods of quantifying aggregation differ in the way physical position is incorporated, i.e. their degree of spatial explicitness. Traditionally, methods used to detect 'spatial density dependence' have not considered spatial references when quantifying aggregation in either the host or parasitoid attack rate. Host-parasitoid relationships warrant reconsideration with spatially-explicit approaches. First, the spatial non-independence of host-abundance counts dictate that their spatial position must be considered in statistical analysis. Second, because parasitoids specifically respond to the spatial pattern of aggregation of their host's abundance, a spatial, biologically relevant description of aggregation is important. Using a wild silk moth (Gonometa postica: Lasiocampidae) and its parasitoids, we test if spatial density dependence is detected using a spatially-explicit analysis and compare the results with traditional approaches. Spatially non-explicit methods found limited evidence for density dependent parasitism, while the spatially-explicit approach found several cases. Therefore, at the between-plant scale, the failure to consider spatial pattern in the host and parasitoid attack rate may cause spatial density dependence to go undetected, while its inclusion increases the power and biological relevance of analyses.

How microhabitat and watertype differ seasonally in their importance for aquatic invertebrates

WCEP Verberk, H Esselink
Bargerveen Foundation/Department of Animal Ecology, Faculty of Science, Mathematics and Computing Science University of Nijmegen (KUN). POBox 9010, 6500 GL Nijmegen; wilcov@sci.kun.nl

Why does a species occur at a certain place? Species occurrence can be linked to habitat characteristics operating on different spatial and temporal scales. For aquatic insects, the occurrence can depend for example on the presence of floating vegetation for egg deposition, nutrient availability or historical glaciation events. In addition, the suitability of a place can change seasonally. Therefore the importance of habitat characteristics can vary seasonally and between different life stages. To study the relative importance of habitat (waterquality, depth, size) and microhabitat (vegetation structure, food availability) macroinvertebrate assemblages in three permanent ponds differing in acidity, nutrient availability and vegetation were studied. All microhabitats present in the three ponds were sampled separately on four occasions (spring, summer, autumn, winter). Detritivore, herbivore and carnivore abundance differed seasonally for the different watertypes and microhabitats, indicating differences in resource quality and quantity. These changes either force species to migrate to suitable places or have their life cycle synchronised to suitable periods. Therefore knowledge on the habitat and microhabitat use of species provides insight in a species life history.

Plant defence: linking above- and belowground multitrophic interactions

LEM Vet
Netherlands Institute of Ecology (Nioo-Knaw), P.O.Box 1299, 3600 Bg Maarssen, The Netherlands; l.vet@nioo.knaw.nl

Plants form the major link between above- and belowground multitrophic interactions. Research on multitrophic interactions aims at identifying the forces that regulate populations of species and structure communities. The study of direct and indirect plant defence is central to multitrophic theory. Direct plant defence relates to bottom up forces while indirect defence, where plants enhance herbivore control by natural enemies, can be considered an integration of bottom up and top-down forces. Recent results show that plant defensive chemicals can be vertically transferred through the food web, affecting organisms several trophic levels higher. The majority of plant defence work has focussed on aboveground interactions, while plants are challenged to defend themselves against both above and below-ground attackers. As yet we know very little of the ecological and evolutionary consequences of plant defence in an above-belowground multitrophic setting. However, there is increasing evidence that underground herbivory can induce aboveground plant defence responses (e.g. the level and distribution of plant defensive chemicals and foliar extrafloral nectar production), thereby affecting the performance of aboveground herbivores and that of higher trophic levels. Including belowground interactions in future research on multitrophic level interactions may shed a more realistic light on the role of plant defence in community ecology.

The use of functional groups to investigate community response to environmental changes.

W Voigt
Institute of Ecology, University of Jena, Dornburger Str. 159, 07749 Jena, Germany; winfried.voigt@uni-jena.de

Independent studies of single species neglect indirect environmental effects mediated by species interactions, and so often fail to produce significant ecological insights. To deal with interactions in multispecies communities approaches covering all trophic levels have to be applied. Complex community data can be condensed without substantial loss of important information by reducing species composition to functional-group composition. Assuming that such functional groups differ in their response to environmental changes, links between environmental patterns and ecosystem functions can be revealed. We used empirically defined functional groups of plants (based on life-form traits), invertebrate herbivores, predators and detritivores (based on life-form and resource acquisition traits) derived from long-term data of two grassland communities to asses the impact of climate variation and anthropogenic disturbance by a phosphate fertilizer factory. Multivariate statistical techniques were used (redundancy analysis, simple and partial Mantel tests) to extract ecologically significant information from patterns in functional groups. This analysis resulted in two important findings: (a) trophic levels differed in their sensitivity to climate variation and (b) disturbance reduced the amount of interactions (connectance) in grassland communities. Thus, functional groups can be a useful generalization tool to study environmental effects on ecological communities. Optimum choice of traits to allocate species to functional groups by objective methods (e.g. statistical grouping techniques) might produce even clearer results.

Spruce budworm biotype reactions to forest and climate characteristics

WJA Volney, RA Fleming
Natrl. Resour. Canada, 5320-122 St., Edmonton, AB, Canada T6H 3S5; jvolney@NRCan.gc.ca

We review the population dynamics of eastern and western biotypes of the spruce budworm, Choristoneura fumiferana [Lepidoptera: Tortricidae]. These biotypes differ in the spatio-temporal patterns of their population dynamics as revealed by long-term defoliation histories. Examination of several population parameters revealed that western biotypes are more critically dependent on host synchrony than eastern types. Egg weights and survival to the feeding stage are critical parameters determining population success in the west. In the east, survival of large larvae and pupae determine generation trend. We relate these differences to two key (and interacting) environmental drivers: forest and climate characteristics. The forest characteristics include species composition, stand age distribution, and forest continuity over the landscape. Climate is important throughout the life cycle, but it is differences in the severity and consequent effects of late spring frosts that have had particularly dramatic effects on the insect species' population dynamics. In our concluding synthesis, we discuss the degree to which differences in the population dynamics of the two biotypes are rooted in genetics or environment. We also comment on the Pleistocene history of populations and discuss possible Neopleistocene changes to ranges of the insects in North America.

Invasive insects and climate change.

NL Ward, GJ Masters, ST Murphy
CABI Bioscience, Bakeham Lane, Egham, TW20 8LW, UK; n.ward@cabi.org

Alien invasive species have been identified as a significant component of environmental change and intense international effort has been directed at their exclusion and control. Invasive insects can have major impacts on both natural and agricultural ecosystems as well as on health. However, the identity and impact of invasive species may alter under the influence of another component of environmental change, climate change. It is therefore imperative that prevention measures take these future interactions into account. Research has suggested that climate change may favour species with certain sets of traits. Therefore, we have attempted to identify broad generalities in the characteristics of invasive insect species found in several distinct case-study areas covering a range of climates. Information collected on the insects was subjected to a simple meta-analysis. We compare the results from the different regions to assess the affects of climate and also predict which characteristics may be favoured by climate change in the future. The possible implications this may have for prevention and management of alien insect species are outlined.

Using a mesocosm to test pattern and process in a Drosophilidae assemblage

M Warren, MA McGeoch, SL Chown
Department of Zoology and Entomology, University of Pretoria, Pretoria, 0002, South Africa; mwarren@zoology.up.ac.za

Spatial analysis is a tool whereby mechanistic hypotheses may be generated regarding spatial pattern. We investigated the spatial patterns of an assemblage of vinegar flies (Diptera: Drosophilidae) inhabiting a mesocosm to determine the mechanisms generating pattern. The mesocosm comprised a heterogeneous environmental surface differing in microclimatic temperature. Multiple spatial methods were used to quantify pattern and generate mechanistic hypotheses. Although only 21-36 % of the variability in the species and assemblage variables was spatially structured, the detected periodic spatial pattern matched the predicted response of the flies to the environmental surface. Structuring resulted from a combination of colonisation preference by the flies for shaded plots and increased mortality in sun, compared to shade, plots. Autocorrelation analysis also detected structure resulting from oviposition by flies across adjacent fruit and this was strongest across two fruit neighbours. An additional hypothesis relating to within-fruit oviposition patterns arose from the results of spatially explicit (SADIE) analyses. Therefore, although the spatial pattern was relatively weak in some cases and clearly generated by multiple mechanisms, spatial methods were able to accurately detect pattern and generate hypotheses concerning the mechanisms structuring this assemblage. A spatial approach can thus contribute significantly towards understanding the mechanistic basis of assemblage structure.

Carabid abundance in disturbed and rehabilitated riparian habitats in eastern Washington State, USA.

TD Waters, DB Walsh, RS Zack, RP Wight
Washington State University, Department of Entomology, 24106 N. Bunn Rd, Prosser, WA, USA 99350; twaters@wsu.edu

Stream health and water quality are major regulatory concerns in the Pacific Northwestern United States. An integral component of rehabilitating disturbed waterways is the effective establishment of preferred vegetation in riparian buffers. We monitored three survey sites with varying degrees of ecological disturbance over a three year period in South Central Washington State. At each of the three survey sites, carabid beetle abundance was monitored in the riparian buffer corridor as well as in the adjacent orchard or vineyard. Our data shows that carabid beetle abundance is greater in highly disturbed plant communities comprised of exotic flowering plants. Plant communities comprised mostly of native vegetation with relatively low ecological disturbance contained fewer beneficial carabid beetles. Large stands of exotic flowering plants at ecologically disturbed sites hosted an abundance of pest insects. We conclude that carabid beetle abundance was greatest in these disturbed sites due to greater prey availability. Carabid beetle abundance was low in each of the adjacent orchards and vineyards studied. Cultural practices and pesticide inputs reduced the abundance beneficial carabid beetles in orchards and vineyards regardless of the ecological state of the adjacent riparian plant community.

Genetic structure of the endangered damselfly, Coenagrion mercuriale, in the UK.

PC Watts, SJ Kemp, IJ Saccheri, DJ Thompson
The Biosciences Building, School of Biological Sciences, Liverpool University, Crown Street, Liverpool, L69 7ZB. UK.

Coenagrion mercuriale (Charpentier) (Odonata: Zygoptera) is one of Europe's most threatened damselflies and is listed in the European Habitats directive that requires member states to designate Special Areas of Conservation for its protection. We have genotyped over forty of the major UK populations of C. mercuriale at 17 microsatellite loci as part of an effort to understand the genetic structure of this protected species with respect to its dispersal characteristics. There is significant genetic differentiation between most sites, even at small distance, that is consistent with MRR data that indicate this species is a poor disperser; the effect of this is a general pattern of isolation by distance. Gene flow (and presumably dispersal) is, however, enhanced by habitat connectivity whilst isolated populations, by contrast, can show marked skew in allele frequency, possible due to a founder event and/or bottleneck. These data are further discussed with respect to differences in genetic variation between populations and the conservation and management of this species.

Predicting the dynamics of new invasions based on fungal associates of exotic pine infesting bark beetles

MJ Wingfield, ZW de Beer, X Zhou, BD Wingfield
Forestry And Agricultural Biotechnology Institute (Fabi), University Of Pretoria, Pretoria, 0002, South Africa; mike.wingfield@fabi.up.ac.za

At least five species of pine infesting bark beetles (Coleoptera: Scolytidae) have been introduced into exotic plantations of the Southern Hemisphere. The best known of these are Orthotomicus erosus, Ips grandicollis, Hylurgus ligniperda, Hylastes ater and Hylastes angustatus. All but one of these species is native to Europe and I. grandicollis is native in North and Central America. Each of these bark beetles have been introduced into their new environments with a relatively large number of symbionts including a suite of fungi, most notably Ophiostoma spp. and their anamorphs. Studies on the taxonomy and population biology of the Ophiostoma spp. associated with introduced pine-infesting Scolytidae are revealing fascinating patterns relating to their introductions. These for example suggest that only a small portion of the mycoflora of the beetles in their native range, accompany them as exotics. Furthermore, overlapping niches of the insects in the exotic environment have led to changes relating to the fungi most commonly associated with them. These studies have shown clearly that further comparisons of the fungi associated with Scolytidae in their native and exotic environments are likely to be scientifically profitable.

Life system analysis of two coexisting Melitaenie butterflies in a patch network

RM Xu, GC Lei, YF Wang, RJ Wang, JJ Chen, WH Liu
College of Life Sciences, Beijing Normal University, Beijing, 100875, China; xurumei@bnu.edu.cn

Two species of melitaeine butterflies coexisted in a patch network in Hebei, China. Based on analysis on butterfly mobility, genetic differentiation and population dynamics, Euphydras aurinia can be considered as a classical metapopulation while Melitae phoebe as a source-sink metapopulation. M. phoebe and E. aurinia, feed exclusively on their specific larval host plants Stemmacantha uniflora (Compositae) and Scabiosa tschiliensis (Dipsacaceae) respectively. The contrasting metapopulation structures and dynamics of the two butterfly species were determined by the interaction of the butterflies' behavior with the abundance and distribution of their specific host plants. The topographic features of the system (patch aspect and slope), sub-regional vegetation may explain the occurrence and distribution of the two butterfly species in the patch network. Parasitism does not play an important regulatory role in this system. Moderate grazing and patches embedded with small and discontinuous croplands promote patch occupancy and densities of larval groups. However, climatic variation (especially, drought in the early spring) is the main cause for the population fluctuations between years.

The conservation genetics of endangered mutualisms: increased genetic differentiation and reduced effective population sizes in specialist bees

A Zayed, L Packer
Department of Biology, York University, Toronto ON, M3J 1P3, Canada; azayed@yorku.ca

Complimentary sex determination in the haplodiploid Hymenoptera leads to the production of diploid males when diploid progeny are homozygous at the sex-determining locus. Diploid males are either inviable or effectively sterile, and their production increases the genetic load and drains hymenopteran populations of females. Fragmentation is expected to decrease gene flow within hymenopteran metapopulations resulting in reduced effective population sizes and increased levels of diploid male production. We explore the effects of diploid male production on the extinction of isolated hymenopteran populations, using bees as examples.

Average longevity of nymphal instars and hatching dates of grassland natural population of three species of grasshoppers

I Chaírez-Hernández, C García-Gutiérrez, JN Gurrola-Reyes, E Rivera-García
CIIDIR-IPN Unidad Durango. Sigma s/n . Fracc. 20 de Noviembre II. CP. 34220. Durango, Dgo México; ichairez@hotmail.com.

Grasshoppers population was surveyed from June to December 2003 in grassland area in Durango Mexico, the most abundant species; Phoetaliotes nebrascensis (Thomas), Melanoplus lakinus (Scudder) and Boopedon nubilum (Say) were sorted by instar development and survey data. Exponential population models were obtained, taking dependent variable as grasshopper density and independent variables y and x as instar development and surveyed date ($P < 0.0001$). Midpoint in days of every nymphal instar was determined as the quotient of the integral of times x over the integral of , hatching periods were calculated as the integral limits of the exponential function over x with y equal to one, instar length ,of each specie was the slope the in linear regression of midpoints of presence of each instar and mean stages . The study showed a of 8.746, 13.142 and 5.861 days and hatching date on 16 July, 7 July and 27 July for P. nebrascensis, M. lakinus, and B. nubilum respectively. Mean values of life length were 15, 16, and 30 August for P. nebrascensis, B. nubilum and M. lakinus respectively, the bigger was 42 days for M. lakinus followed by 32 and 16 days for P. nebrascensis and B. nubilum.

Effects of fire on terrestrial invertebrates in buttongrass moorlands, Tasmania

MM Driessen
Nature Conservation Branch, Department of Primary Industries Water and Environment, PO Box 44, Hobart, 7001, Tasmania, Australia;
Michael.Driessen@dpiwe.tas.gov.au

Buttongrass moorland is a significant landscape feature of western Tasmania. It is a unique ecosystem of world heritage value, poorly represented on mainland Australia and absent elsewhere. Buttongrass moorland is very inflammable, with a long history of firing by Aborigines. Since European settlement fire regimes have been substantially altered, and the role of fire in maintaining biodiversity in this ecosystem is largely unknown. The invertebrate fauna of buttongrass moorlands has not been well studied. Using pitfall trapping and sweep sampling, I found a terrestrial invertebrate community numerically dominated by Collembola, Diptera, Araneae, Acarina, Formicidae and Orthoptera. The most bio-diverse groups were Diptera (36 families, 290 species/morphospecies), Araneae (29, 214), Coeloptera (25, 98) and Acarina (35, 68). Using a before-after-control-impact experiment, I found that fire had little effect on species diversity, but a number of taxa showed significant numerical responses. Taxa that declined are those that inhabit the sparse emergent overstorey (eg Araneae: Thomisidae) or decaying vegetation (eg Amphpoda: Talitridae); these habitats recover slowly following fire. Taxa that increased include Orthoptera: Gryllidae, Coleoptera: Alticinae, Diptera: Chloropidae; these groups are probably responding to herbs and grasses that increased after fire. I will also present preliminary data on the effects of fire on population parameters (sex ratio, growth and reproductive success) for selected species.

So what are the impacts of environmental change on insect management and conservation?

TH Jones, R Harrington, GJ Masters
Cardiff School of Biosciences, Cardiff University, PO Box 915, Cardiff, CF10 3TL UK; jonesth@caerdydd.ac.uk

The main objective of this Symposium has been to examine the extent to which responses of insects to environmental changes are likely to be predictable. Speakers have attempted to consider and assess the possibility of approaching the issue by defining traits or combinations of traits that allow generalisation. To do this a range of comparative studies involving more than one species has been used. In this summary session we will attempt to answer a series of questions including: (i) if closely related species respond differently, why might this be?; (ii) if they respond similarly, can the generalisation be taken further? (iii) can we help each other, or are we on our own?; and (iv) what are the merits, drawbacks and complementarities of the range of methodologies that have been presented.

Impact of global warming and land-use change on insect management and conservation in temperate Asian area

K Kiritani
Loisir 3-503, Futo 1020-292, Itou, Shizuoka 413-0231, Japan; kiritanik@ybb.ne.jp

Different agroecosystems are inhabited by insect groups with different traits; resident/migrant, native/exotic, diapause/non diapause, uni/multi-voltine, and bisexual/parthenogenetic. The strategy of pest management contrasts sharply between greenhouse culture and rice. Greenhouse culture is a newly created habitat for temperate insects with short daylength and high temperature during winter. This may represent a model of an agroecosystem under global warming. Half of the pest species are exotic invasive pests originating in the tropics/subtropics, resulting in a great increase in insecticide applications. International trading has homogenized the fauna worldwide. Consequently there exist no targets to be conserved. Interception of alien pests by plant quarantine followed by IPM is needed. Paddy rice is not only the habitat of the rice arthropod community, but it is also an alternative habitat to the lost natural wetland for many endangered aquatic insects. Therefore, the management strategy should strike a balance between IPM and conservation, which is referred to as IBM (Integrated Biodiversity Management) (Kiritani 2000). In general, global warming may work in favor of natural enemies (except for spiders) by increasing the number of generations more than their host species. Biological control is expected to become a more important control tactic in the future.

Role of aphid bacterial symbionts in resistance to parasitism

KM Oliver, NA Moran, MS Hunter
University of Arizona, Dept. of Entomology, 410 Forbes Building, Tucson, Arizona, U.S.A. 85721-0036; kmoliver@u.arizona.edu

Molecular diagnostic tools have recently shown that bacterial symbionts of arthropods are extremely common, yet the effects of these symbionts on their hosts are largely unknown. In addition to the well-characterized obligate primary symbiont, Buchnera aphidicola, which supplies nutrients lacking in the plant sap diet, the pea aphid, Acyrthosiphon pisum, harbours diverse facultative or 'secondary' symbionts (SS). Pea aphids may harbour combinations of at least five vertically transmitted SS, including three independent lineages in the ?-proteobacteria designated as the R-, T- and U –types, a Rickettsia, and a Spiroplasma. Two of the three types of symbionts tested (R- and T-type) confer resistance to the braconid parasitoid, Aphidius ervi, by causing mortality of developing wasp larvae. The consequences of infection with both resistance conferring symbionts (R and T-types) on the aphid host and developing parasitoid will be discussed. These findings will be related to the distribution of SS in natural aphid populations. This interaction between a symbiotic bacterium and a host natural enemy provides a mechanism for the spread and persistence of these bacteria, and may be an important component of the widespread variation in susceptibility of pea aphid clones to parasitoid attack.

The effect of salivary gland secretions on behavior of larval *Ephestia kuehniella* Zell (Lepidoptera: Phycitidae).

DN Akhaev
119992, Russia, Moscow, Leninskie gori 1, Department of Entomology, Moscow State University; ahaeff@mail.ru

The mediterranean flour moth, *Ephestia kuehniella* Zell. is one of the most cosmopolitan pest-species of insects and can be found in stored products and in the field. When the larvae meet they deposit a secret, which can regulate the oviposition behavior (Corbet, 1973a). In this communication it is shown that the extract of the larvae salivary glands secretions can have an effect on the larvae behaviour. In our investigation of the larvae behavior and the roles of taste and olfaction modalities in this were the Y-olfactometer and the method of repellent barrier used. First-, third- and fifth-instars larvae were used for experiments. The results show that the secretions of salivary glands has some active compounds, which can be felt by all instars larvae using taste and olfaction reception. The method of repellent barrier shows that in high concentrations the secretions of salivary glands acts as a repellent and causes escape behavior in all larvae instars. The olfaction experiments show behavior distinction between larvae instars. While in high concentrations of the secretions all instars show escape behavior, in low concentrations the first instar larvae has attractive response, stimulated by the secretion. As a result, these secretions can contribute to the regulation of larvae population density.

Volatiles from plant glandular trichomes of *Cordia curassavica* & their attraction to the herbivorous beetle *Cratosomus flavofasciatus*

JMS Bento, JRP Parra, B Appezzato-da-Glória, PW Pare, AS Nascimento
Depto de Entomologia, Fitopatologia e Zoologia Agrícola, ESALQ, Universidade de São Paulo, Piracicaba-SP, 13418-900, Brazil, E-mail:
jmsbento@esalq.usp.br

Glandular trichomes are epidermal plant appendages that accumulate a variety of low molecular weight chemicals, including monoterpenes and sesquiterpenes and have been recognized to serve in defense against herbivory. Behavioral, physiological and chemical evidences indicate that glandular trichomes on the New World species *Cordia curassavica* (Jacq.)(Boraginaceae) function in the attraction of the herbivorous beetle, *Cratosomus flavofasciatus* Guerin (Coleoptera: Curculionidae), especially at times of heavy plant transpiration. The emission of this plant volatiles may be an unavoidable byproduct of the transpiration process, is exploited by certain herbivores in locating their food source.

Host-orientation behaviors of *Lygus hesperus* (Heteroptera: Miridae) in response to visual and olfactory cues from plants and insect prey

JL Blackmer, JA Byers
WCRL-ARS-USDA, 4135 E. Broadway Rd, Phoenix, AZ 85040; jblackmer@wcrl.ars.usda.gov

Lygus hesperus, the western tarnished plant bug, is found throughout the western United States and Canada, where it can cause serious damage to many agricultural crops. Interestingly, this insect can also serve as a facultative predator, and with this flexible feeding behavior it is possible that plant visual and volatile cues, as well as cues associated with potential prey may mediate host location and selection. A better understanding of the factors involved in host choice could facilitate the development of novel trapping techniques. To investigate the role of these various cues we tested nymphs and adults to headspace volatiles associated with host plants (alfalfa and/or cotton) singly or in combination with a visual plant cue (simulated by a green light-emitting diode) with or without potential prey (whiteflies or beet armyworm [BAW]). Laboratory bioassays were conducted with a Y-tube olfactometer and selected visual-volatile combinations were tested under field conditions. Headspace volatiles were identified by GC-MS analysis. Nymphs and female *L. hesperus* were most often attracted to plant volatiles; males were only attracted to volatile-visual cue combinations or to BAW-infested plants. Plant phenology, time of day, *Lygus* feeding and prey feeding habit influenced headspace chemical profiles.

Calling of sterile male Mediterranean fruit fly, *Ceratitis capitata*: effects of protein in the diet or exposure to ginger root oil.

VG Bosco, CJ Smallridge, DC Hopkins
GPO Box 397, Adelaide, South Australia, Australia, 5001, bosco.vanessa@saugov.sa.gov.au

South Australia has recently incorporated the sterile insect technique (SIT) into its eradication programs for Mediterranean fruit fly, *Ceratitis capitata* (medfly) incursions. The possibility of improving sterile male Mediterranean fly performance through protein diets or exposure to ginger root oil (GRO) was investigated in laboratory observations on calling frequency of the Vienna7/Mix99 mediterranean fly strain. The experiments involved the use of cages containing either 10 males that were untreated controls, or 10 treated males. For the protein diet experiment, two trials were conducted with emerging flies being allowed to feed *ad lib* on either sugar agar or sugar agar and a dish of protein hydrolysate. Calling frequencies at two time periods on three consecutive days, analysed with repeated measures ANOVA, were not significantly different between protein-fed and control groups. For the GRO experiment, two trials were conducted to compare the calling frequency of untreated flies with that of flies exposed to GRO for 16 hours at age day 1-2. Repeated measures ANOVA indicated that the difference between treatments was significant in both trials with the GRO-treated males having a consistently higher frequency of calling. Studies to further assess the effect of GRO on behaviour are continuing.

Sand as a medium for transmission of vibratory signals of prey in antlions (Myrmeleontidae)

D Devetak, B Mencinger Vracko, M Marhl, M Devetak
Department of Biology, University of Maribor, Koroska 160, SI-2000 Maribor, Slovenia; dusan.devetak@uni-mb.si

Two European pit-building antlion species (*Euroleon nostras* and *Myrmeleon formicarius*) detect their prey by sensing the vibrations that prey generates during locomotory activity. For small arthropods walking on the sand a few centimetres away, the antlion larvae can determine direction of the prey's location. To observe signal transmission through the substrate we measured some of the physical properties of substrate vibrations in sand. The vibratory signals of four arthropod species (*Tenebrio molitor, Pyrrhocoris apterus, Formica* sp. and *Trachelipus rathkei*) were recorded in a distance of a few centimetres from an accelerometer. Frequency range of the signals varied from 0.2 to 4.5 kHz and acceleration values from 400 $\mu m/s^2$ to 1 mm/s^2. Pit-building antlion larvae are capable of discriminating between areas of sand differing in particle size, constructing pits in a fine sand and avoiding coarser sand. In sand fractions with different particle sizes (with sand grains up to 2.2 mm in diameter) we measured damping coefficients of the sand fractions for artificial pulses. Damping coefficient at frequencies from 100 to 300 Hz varied from 0.2 to 2.6 dB/cm and was inversely proportional to sand particle size and positively correlated with the frequency of the pulses.

Unpalatability of European checkerspots (Nymphalidae: Melitaeinae)

M Tesarova, M Prokopova, R Fuchs, M Konvicka, Z Fric
School of Biological Sciences, University of South Bohemia, Branisovska 31, CZ-37005 Ceske Budejovice, Czech Republic, zdenek.fric@tix.bf.jcu.cz

Several Nearctic checkerspots butterflies, including the famous *Euphyyas editha*, are unpalatable to birds. In addition, checkerspots feed on plants with secondary metabolite with a protective function. However, palatability was never tested in Palaearctic Melitaeinae butterflies. We offered five species of checkerspots, *Euphyyas aurinia*, *Melitaea athalia*, *M. diamina*, *M. aurelia* and *M. didyma*, to Great tits (*Parus major*), using the satyrid *Aphantopus hyperanthus* as a control. The butterflies significantly differed in palatability (GLM, effect of species, $p < 0.01$). The difference was not between checkerspots and control, but within checkerspots. *M. aurinia* and *M. diamina* were eaten as often as control, *M. aurelia* and *M. didyma* were rejected. Wahlberg (Evolution 55: 522-537) showed that host plants of *aurinia* and *diamina* contain secoiridoids, while hosts of *aurelia* and *didyma* contain iridoids. Plant chemistry seems to be more important for palatability than phylogeny. However, a clear association between host chemistry and palatability is obscured by ambiguous results for *M. athalia* (iridoids). In any case, European checkerspots form a mimetic complex.

Protein expression in the reproductive organs of male German cockroach (*Blattella germanica*)

YL Fu, YY Yang, HJ Lee
Dept. Entomology, National Taiwan University, Taipei 106, Taiwan, lisafu@ms29.url.com.tw

Male accessory reproductive glands (ARGs) contain factors that are transferred with sperm during mating to the female. One such factor (sex peptide of Drosophila) inhibits female's receptivity to additional mating. Here, we analyzed ARGs protein content and pattern for males of the German cockroach (*Blattella germanica*). Lower protein mass were found in young males (<3day-day-old) when compared to older ones (3~10-day-old) by SDS-PAGE. This study shows the expression of genes in ARG was different with age, but the protein content of testis remained the same after adult emergence. In addition, western blot analysis and whole-mount immunohistochemistry were used to investigate sex peptide-like immunoreactivity in the reproductive organs of the male. Unexpectedly, the sex peptide-like substance was only found in the testis of *B. germanica*. The significance of this finding is currently under investigation.

Acoustic features of calling song in female mate choice in a field cricket, *Telleogryllus taiwanemma*

M Fukui, N Utsumi
Lab of Insect Physio., Kyoto University, Kyoto 606-8502, Japan, mfukui@kais.kyoto-u.ac.jp

Male field crickets, *Telleogryllus taiwanemma*, produce calling songs attract females. Variations in calling song phrase consisting of chirp sequences were recognized in Taiwan: phrases composed of single, double and seven chirps (Chow *et al.* 1990). However, Chow *et al.* did not show any relationship between the temporal structure in calling songs and behavioral significance, though variation in phrases may reflect, in part, male qualities. Using a Japanese cricket population having phrase variations in calling song, we tested whether females demonstrate preferences based on variations in calling song phrase using computer-synthesized songs. However, females did not discriminate between variations in calling song phrase consisting the same chirp rate. Females preferred higher calling song chirp rates; that is, the preference function shape was open ended. Preference function shape by females toward two other acoustic features of song chirp was also determined. Open-ended preference function was found in the pulse number of chirps, and unimodal preference was shown toward carry frequency, but which features correlate with male qualities remains unclear.

Pollinator responses to mimicry by sexually deceptive orchids

AC Gaskett, ME Herberstein
Department of Biological Sciences, Macquarie University, NSW 2109; agaskett@bio.mq.edu.au

Deceptive orchids mimic insect signals to attract pollinators without providing a reward. Orchid flowers may resemble food, oviposition sites, or female insects. Insects that respond, by attempting to mate with or feed from orchid flowers for example, collect and distribute orchid pollinia. Deceived insects may incur costs, e.g. time and energy wasted travelling to and interacting with orchids, and loss of sperm during pseudocopulation. Such costs may encourage the evolution of behavioural strategies that allow insects to avoid deceptive orchids. In sexually deceptive orchids, male pollinators are initially attracted by scents identical to female insect sex pheromones. Short-range cues eliciting pollinator contact with the flower may include visual cues such as colour and shape, and structural or tactile features that resemble female insect bodies. Investigation of the relative importance of chemical, visual, and structural cues, and the interaction between, long- and short-range cues should be rewarding. The Australian orchid genus *Cryptostylis* is an excellent study subject because all five species attract the same male wasp pollinator despite obvious differences in flower shape and colour. Here I introduce this intriguing study system and present some initial observations of pollinator behaviour and interactions between pollinator learning and the dimensions of orchid patches.

Characterization of the mandibular glands in different classes of adults in *Scaptotrigona postica* colonies

LF Gracioli, FC Abdalla, C Cruz-Landim
Depto de Biologia, Instituto de Biociências, UNESP, Campus de Rio Claro. Av. 24A, nº 1515. Cep. 13506-900. Rio Claro – S.P.; lucifg@rc.unesp.br

Scaptotrigona postica, a Brazilian stingless bee, has paired mandibular glands, placed in each lateral head side, and constituted by a bifid sac, whose wall is covered by class III secretory cells. In *S. postica* workers, the mandibular gland produce a trail pheromone used by foragers to mark the pathway between the colony and the food source. The present abstract briefly describes the results of the histological and the morphometrical investigation of the mandibular glands in newly-emerged, nurse and forager workers, as well as in virgin, physogastric queens, and mature males of *S. postica*. The histology showed differences of the secretory cells related to the task of the bee in the colony. The morphometry showed that the mandibular glands have a single secretory cycle, in which the cell size is greater in the nurse workers, due to the secretion accumulation into the cells. Comparing the different bee classes studied, the physogastric queens have the greatest cells and nuclear areas, contrary to the males, which present the smallest cells. These observations suggest that the synthesis of the secretion starts from newly emerged and finishes in nurse workers. The queen is the class of individuals with more active glands. Although the function of the secretion was unknown in this caste, the present results clearly signalize their importance for it, since the queens presents more developed glands than the workers.

Comparative study of pupae cuticular hydrocarbon of flour beetles associated with their cannibalism and predation vulnerability (Coleopterae: Tenebrionidae).

T Alabi, G Lognay, L Arnaud, E Haubruge
Gembloux Agricultural University, Department of Pure and Applied Zoology, B-5030 Gembloux, Belgium; haubruge.e@fsagx.ac.be

Cuticular hydrocarbon of pupae were extracted with n-hexane at room temperature and GC-MS (gas chromatograpy-mass spectometry) investigations were used to identify and compare pupae cuticular hydrocarbon composition of several species which have been previously quantified with n-eicosane as internal standard. The major components identified were n-C25; 3-Me-C25; n-C26; n-C27; 13-Me-C27; 3-Me-C27; n-C28; n-C29. However other molecules with low quantity were found in some species. Generally, qualitative and quantitative significant differences were observed in cuticular hydrocarbon found between the species. Cuticular hydrocarbon patterns seem to be correlated with cannibalism and predation vulnerability patterns. The most intriguing case was remarkably expressed by *T. brevicornis,* which pupae had the most of chemical compound found with the highest rate, but were unable to be cannibalised and predated by different perpetrators. This particularity rests on chemical signals, which could partly be due to variations in the proportion of certain cuticular hydrocarbons.

Studies on the dorsal abdominal glands & exuviate of local scentless bugs, *Leptocoris abdominalis* (Fabricius) & *Leptocoris augur*

HY Ho, JZ Ho, LW Lo, YC Hsu, YC Chuang, YS Chow
Institute of Zoology, Academia Sinica, Taipei, Taiwan, 115

Two dorsal abdominal glands (median and posterior glands) are found in the nymphs of two local scentless plant bugs (Rhopalidae), whereas only the median glands are found in exuviate of nymphs. Both median and posterior glands are functional in nymphs, however, only posterior glands are functional in adults for the two species. Monoterpenes are the major compounds in posterior glands, but alkenals are the major compounds in median glands. Possible reasons for the sole presence of alkenals in exuviate will be discussed.

Body-wax sex pheromones & their functions in reproductive behavior of the black-winged fungus gnat, *Bradysia paupra* (Diptera: Sciaridae).

Y Liu, H Honda
Inst. Agri. & Forest. Univ. Tsukuba, 1-1-1, Ten-Nodai, Tsukuba, Ibaraki, 305-8572, Japan; hhonda@sakura.cc.tsukuba.ac.jp

A typical male mating behavior sequence of *Bradysia paupra* is: 1) intermittent wing fanning, 2) walking in a zigzag approach while continuing to fan wings, 3) abdomen curling and opening claspers, 4) copulation. Bioassay results demonstrated that female body-wax lipids elicit a sex pheromonal activity in male flies. The active substances were located on all parts of the female body. Teneral females showed a potential to evoke mating responses from males and males responded even 30 min after eclosion. Effects of light intensity on *B. paupera* male mating behavior and upwind flight to pheromone source were assessed in cage and wind tunnel tests. Typical mating behaviors were not affected by light intensity. However, male upwind flight to the pheromone source was remarkably inhibited by low light intensity, which significantly depressed their flight activity. n-aldehydes (C7-C18), n-hydrocarbons (C13-C22) and 2-ketones (C16-C18) were the main components of female body-wax lipids. Several GC-EAD active components in the extracts were separated by preparative capillary-GC, followed by GC-MS analysis. Four n-aldehydes (C10-C13) showed prominent activity to males in cage assays. 2-ketones and n-hydrocarbons showed none or lower activity. Sex pheromonal activity of these aldehydes was also confirmed by trap tests in a mushroom cellar.

Evidence for chemical mediation of host range expansion & host shifts in papilionid butterflies

T Nakayama, K Honda, T Murakami, H Ômura
Faculty of Integrated Arts & Sciences, Hiroshima University, Higashihiroshima 739-8521 Japan; honce@hiroshima-u.ac.jp

Phytochemical constraints are thought to be one of the major determinants of host range evolution and host shift in phytophagous insects. Papilionid butterflies comprising over 560 species utilize, for larval growth, a limited range of plants in the families Aristolochiaceae, Annonaceae, Lauraceae, Magnoliaceae, Rutaceae or Apiaceae. Although a number of oviposition stimulants have so far been reported for papilionids, very little is known about phytochemicals that reasonably explain how they have accomplished drastic host shifts. We identified oviposition stimulants for a Rutaceae feeder, *Papilio polytes,* from *Toddalia asiatica, Citrus depressa*, and *Glycosmis citrifolia*, and also for a Magnoliaceae feeder, *Graphium doson*, from *Michelia compressa* and *Magnolia grandiflora*. Two compounds (*trans*-4-hydroxy-*N*-methyl-L-proline and 2-*C*-methyl-D-erythronic acid) identified from *T. asiatica* and *G. citrifolia,* and five compounds (stachyine, proline, quinic acid, synephrine, and choline) identified from *C. depressa* were regarded as important constituents which synergistically stimulate egg-laying by *P. polytes.* On the other hand, pinitol, identified from *M. compressa* and *M. grandiflora,* was found to be one of the key stimulants responsible for host recognition by *G. doson*. Based on our findings and previous data, we discuss a possible phytochemical-mediated pathway of host range expansion and host shifts in papilionids.

The repellency of hinokitiol against the cigarette beetle, *Lasioderma serricorne*

M Hori
Laboratory of Insect Science and Bioregulation, Graduate School of Agricultural Science, Tohoku University, Sendai 981-8555, Japan; hori@bios.tohoku.ac.jp

The repellency of 73 chemicals against the cigarette beetles was investigated with an olfactometer. Hinokitiol strongly repelled the beetles. The repellency of hinokitiol was evaluated in a semi-field test. The filter-paper tapes treated with hinokitiol were attached around the openings of the cardboard boxes containing cured tobacco. The hinokitiol tapes prevented the beetles from entering the boxes. However, in the olfactometer assay, the filter paper treated with hinokitiol did not show repellency after 48 hr. Hinokitiol sublimed rapidly and its 90% sublimed within 48 hours. Therefore, a repellent tape slowly releasing hinokitiol was developed. The tape consisted of a filter paper containing hinokitiol, a polyethylene film bag sealing the paper, an aluminium sheet on the backside of the bag and an adhesive tape on the aluminium sheet. The tape slowly released hinokitiol. In the semi-field test, the tapes attached around the openings of the cardboard boxes containing food attractant prevented the beetles from entering the boxes. The number of the beetles in the treatment boxes was less than 20% of that in the control boxes for 64 days. The effectiveness of the tape continued for 92 days.

The effects of dynamic experience of resource heterogeneity on oviposition behavior of the seed beetle, *Callosobruchus maculatus* (F.)

RL Yang, H Fushing, SB Horng
Institute of Entomology, National Taiwan University, No. 1, Sec. 4, Roosevelt Rd., Taipei, Taiwan 106; sbhorng@ntu.edu.tw

The effects of dynamic search experience in response to resource heterogeneity and its depletion on oviposition behavior of the seed beetle, *Callosobruchus maculatus*, are studied here through a longitudinal view and a new set of experimental design. Sixty-four adzuki beans, 16 from each of four sizes, were arranged into three designs of 2 ´ 2, 4 ´ 4, and 8 ´ 8 sub-lattices of increasing resource heterogeneity, thus making the dynamic experience of size change by the female significantly different. We assumed each bean size has equal encountering probability. The results showed that, the difference between proportions of eggs laid on large beans and small ones increased with increasing resource heterogeneity. While the female still maintains the egg-discrimination as the major host selection trait, we show that the trait of preferring larger hosts is maintained for the entire oviposition process only if enough stimuli of contrasting experience of resource heterogeneity are retained in the environment. These results imply that the seed beetle does compare bean quality experience in the information processing constituting her decision-making capability. We also tested whether the size information content employed by the female is the weight of the host bean instead of the surface-area.

Trail-pheromone perception in the eastern subterranean termite

XP Hu, A Appel
207 Extension Hall, Auburn University, Auburn, AL, USA 36849; xhu@aces.edu

The chemo-receptors responsible for trail-following behavior in *Reticulitermes flavipes* was investigated using behavior choice tests. The trail following behavior of worker, soldier, prealate, and young casts was examined as well. Termites were anesthetized on ice before being manipulated one of the six potential receptors, including antennae, labial palps, maxilla palps, and tarsi of pro-, meso-, and meta-thoracic legs. Results show that only termites with antennae manipulated showed no response to trail-following mimic, indicating the chemo-receptors are located mainly, if not solely, on antennae. Further tests revealed that only the distal ten flagellar segments perceive the trail-following substances. Additionally, there was a strong linear relationship between the number of flagellar segments removed and the time required to locate the trail and the distance traveled on the trail. All the four castes demonstrated trail-following behaviors. However, worker and prealate tended to locate the trail faster than soldiers and young. Interestingly, both worker and young displayed reversed trail-following, suggesting either recruitment behavior or reinforcement of the trail.

Seasonal changes in metabolic rate & water loss through the spiracles and cuticle in the goldenrod gall fly, *Eurosta solidaginis* **(Diptera, Tephritidae)**

JT Irwin, RE Lee Jr
Department of Biology, Bucknell University, Lewisburg, PA USA 17837; jirwin@bucknell.edu

The goldenrod gall fly, *Eurosta solidaginis*, overwinters as a diapausing third-instar larva within its gall on the stem of goldenrod (*Solidago* spp.). During the winter this is a severely environment and the diapausing larvae are highly resistant to water loss. We used flow-through respirometry to track decreases in metabolic rate and water loss (cuticular and spiracular) as the larvae moved into winter diapause. The anterior spiracles were more important to respiration as there was no change in metabolic rate or water loss when the posterior spiracles were blocked. Conversely, blocking the anterior spiracles caused CO_2 production to decrease by almost 50%, although the rate of water loss fell only slightly. The rate of water loss fell as larvae moved into diapause because of a decrease in metabolic rate and a reduction in the permeability of the cuticle. We conclude that there is a substantial drop in the rate of water loss and metabolic rate as the goldenrod gall fly enters diapause in the autumn. A high cuticular resistance to water loss and efficient spiracles contribute to this species' notably low rate of water loss.

Host plant orientation and feeding in the rice bug, *Leptocorisa chinensis* **(Dallas) in response to olfactory cues**

M Ishizaki, S Oku, T Yasuda, Y Suzuki
National Agricultural Research Center, Tsukuba 305-8666, Japan; imami@affrc.go.jp

The rice bug, *Leptocorisa chinensis* Dallas (Hemiptera: Alydidae) causing pecky rice is one of the most important pests in Japan. It has been difficult to investigate chemicals affecting its behavior because no proper bioassay systems were available. We developed a bioassay method using a two-choice test to assess the response of *L. chinensis*, nymphs to olfactory stimuli. Two plastic cups were placed on a board covered with wet quartz sand. Each of the cups was covered with mesh cloth in order to prevent visual stimuli of the odor sources tested. At the center of the board, a stick was erected to function as the releasing point for bugs tested. This two-choice test bioassay method was used to demonstrate the responses of *L. chinensis* nymphs to olfactory stimuli. As a result, host plant volatiles alone were not attractive to the bugs, whereas the number of responding bugs significantly increased when there were feeding nymphs of *L. chinensis* together with host plants. We also developed a bioassay method to assess feeding response of *L. chinensis* to host plant extracts.

Herbivore-induced volatiles from *Acer negundo* **and their defensive function against** *Anoplophora glabripennis*

Y Jin, J Li
PO Box 41, Beijing Forestry University, Beijing, 100083, China; youjujin@bjfu.edu.cn

Ashleaf maple (*Acer negundo*) is the highly preferred host of adult *Anoplophora glabripennis* Motsch (ALB). However, what will happen after ALB's feeding-damage? Attract or repel? We investigated the behavior responses of ALB to the feeding-damaged *Acer negundo* over post-infestation duration by Y-tube olfactometer. The data indicated that the intact *A. negundo* attract the ALB evidently, but the infested plant repelled the ALB significantly from 24h to 48h after feeding damage. The volatiles from the infested plant were analyzed by TCT-GC/MS. It showed that many chemicals were induced, and the emission amount of most volatiles reached the maximum at 48h after infestation, then reduced sharply at 72h. The behavior response data of ALB to individual artificial compounds showed the herbivore-induced volatiles, such as Ocimene, trans-Geranylacetone, 2-Methylbutyronitrile, syn-2-Methylbutylaldoxime, 1,3,3-Trimethyl-2-methylene-indoline, repelled the ALB intensively. The peak time of releasing amount of herbivore-induced volatiles were well matched with the time of high repellency to ALB, which well exhibited the defensive function of infested ashleaf maple to prevent the further attack from ALB, at least within 72h. The mechanical damaged ashleaf maple was investigated simultaneously which showed the similar repellent trend but less number of volatiles be induced.

Disruption of pheromone communication in *Choristoneura rosaceana* and *Pandemis limitata* (Lepidoptera: Tortricidae) using microencapsulated single and multi-component pheromone blends

GJR Judd, MGT Gardiner, B Lannard
Agriculture and Agri-Food Canada, Pacific Agri-Food Research Centre, 4200 Hwy 97S, Summerland, British Columbia, Canada V0H 1Z0; juddg@agr.gc.ca

Microencapsulated (MEC) pheromones are being developed to disrupt mating of Tortricid pests of pome fruits in western North America. Responses of male *Choristoneura rosaceana* (Harris) and *Pandemis limitata* (Robinson) to calling females in clean air, and air treated with their major pheromone component, (*Z*)11-tetradecenyl acetate (*Z*11-14:OAc), released from 3M Phase I microcapsules applied at doses of 1, 10 and 100 mg ai m^{-2} to a flight tunnel (= field rates of 10, 100, and 1000 g ai ha^{-1}) were compared. Disorientation in both species was dose-dependent. Relative to orientation to calling females in clean air, orientation of male *P. limitata* was disrupted 23.3, 46.3 and 71.3%, and orientation of *C. rosaceana* was disrupted 31.6, 37.7, and 45.8% by doses of 1, 10, 100 mg m^{-2}, respectively. Disruption lasted 26, 74, and 218 h in *P. limitata* and 30, 54, and 174 h in *C. rosaceana* at these doses, respectively. Disruption of *P. limitata* was greater than *C. rosaceana* and appeared correlated with species' differences in female pheromone release rates. Multi-component blends caused greater disruption in *P. limitata* than the main component, but only at the lowest application rate. Disruption mechanisms invoked by MEC pheromones are discussed.

Female sex pheromone & communication disruption in the rice leaf bug, *Trigonotylus caelestialium* (Kirkaldy) (Heteroptera: Miridae)

M Kakizaki, H Sugie
Hokkaido Dohnan Agri. Exp. Stn. Ohono, Hokkaido 041-1202, Japan; kakizams@agri.pref.hokkaido.jp

The rice leaf bug, *Trigonotylus caelestialium*, injures rice, wheat, maize, and gramineous forage grasses. Females attract conspecific males (Kakizaki and Sugie, 1997), and the female sex pheromone was identified as a mixture of *n*-hexyl *n*-hexanoate (H:H), (*E*)-2-hexenyl *n*-hexanoate (*E*2H:H), and *n*-octyl *n*-butyrate (O:B) by the GC-EAD method and GC-MS analyses. H:H and *E*2H:H are essential components in the sex pheromone, and O:B enhances the male attraction in combination with the essential 2-components (Kakizaki and Sugie, 2001). The suppression effects of *T. caelestialium* populations by communication disruption using the sex pheromone were examined. In small-scale field tests (100 m^2), the numbers of males captured by traps baited with a lure containing the sex pheromone were reduced to some degree by treatment with either H:H, *E*2H:H, or a 2-component mixture, furthermore, those baited with the lure or 3-virgin females were mostly reduced by the 3-component treatment. In large-scale field tests (10,000 m^2), the population densities and males catches by traps in the treated fields were lower than those in the untreated fields. However, the traps baited with females had slightly attraction activity in the treated field, further, it may indicate that unknown pheromone components are involved with male attraction processes.

Effective pheromone lures for monitoring the rice leaf folder moth, *Cnaphalocrocis medinalis* (Lepidoptera: Crambidae)

K Kawazu, T Kamimuro, H Kamiwada, K Nagata, T Matsunaga, H Sugie, T Fukumoto, T Adati, S Tatsuki
Graduate School of Agricultural and Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113-8657, Japan

Several factors affecting the attractiveness of traps baited with synthetic sex pheromone components of *Cnaphalocrocis medinalis* were examined in the laboratory and field. In the laboratory, among the four pheromone components, Z11-18: Ald, Z13-18:Ald, Z11-18:OH and Z13-18:OH, the major component, Z13-18:Ald, was shown to be an essential component for attraction and Z11-18:Ald was shown to be a potent synergist for the major component. The alcohols also showed an apparent synergistic effect in the laboratory bioassay when their mixture was combined with an aldehyde mixture. The addition of the geometric isomers of the four components at levels greater than 5% of the purified 4-component blend showed significant inhibitory effects on the pheromonal activity in the laboratory. In the field, no synergistic effect of the alcohols on the aldehydes was shown. A range of loadings of the pheromone rubber septa (0.01–3.42 mg) was tested and all remained attractive for at least one month with optimum attractiveness on 0.86 mg/septum. No significant effects were obtained when the ratio of Z11-18:Ald to Z13-18:Ald was changed. Rubber septa containing 0.86 mg of the four components (*E*-isomers 5%) at the natural ratio are being effectively used for monitoring.

An artificial blend of volatiles for attracting parasitic wasps

S Kugimiya, K Shiojiri, K Sano, Y Ohara, J Abe, S Urano, T Shimoda, J Takabayashi
Center for Ecological Research, Kyoto University, Kamitanakami Hirano-cho, Otsu 520-2113, Japan; kugi@ecology.kyoto-u.ac.jp

When damaged by herbivorous arthropods, plants are known to emit specific volatile compounds that attract the natural enemies of herbivores. If we can artificially mimic particular blends of volatiles, we may be able to use them in agroecosystems to enhance the effectiveness of pests' natural enemies. The objective of this study is to test this possibility in a tritrophic system consisting of cabbage plants, diamondback moth larvae (*Plutella xylostella*) and their specialist parasitoids, *Cotesia plutellae*. The specific volatile components emitted from cabbage plants infested by diamondback moth larvae were analysed using a gas chromatograph-mass spectrometer (GC/MS). By using a choice-chamber bioassay, we found that a mixture of four compounds (hereafter called blend) attracted the wasps. The blend was significantly attractive to parasitoids over a certain range of doses, but it was not attractive at higher and lower doses. We dissolved the blend in triethyl citrate, and added the solution to a glass instrument from which the blend was gradually vaporized in the air. By using this equipment, we tried to attract the parasitic wasps under both greenhouse and field conditions. Possible applications of the blend in agroecosystems will be discussed.

Sex pheromone composition of the diamondback moth, *Plutella xylostella* in Korea

S Lee, JH Song, KS Boo
Lab. Insect Physiology, Seoul National University, Seoul 151-742, South Korea, bms77@hanmail.net

The diamondback moth (DBM), *Plutella xylostella,* is one of the most widely distributed moths, and the most destructive pest on cruciferous crops throughout the world. Three components of DBM sex pheromone has been known: (*Z*)-11-hexadecenal (*Z*11-16:Al), (*Z*)-11-hexadecenyl acetate (*Z*11-16:Ac) and (*Z*)-11-hexadecenyl alcohol (*Z*11-16:OH). The pheromone gland extracts of female DBM in Korea were analyzed with Gas Chromatography (GC). Three components from DBM sex pheromone were identified: the highest peak was *Z*11-16:Al and the other two components also detected. To examine DBM male response to female sex pheromone, Electroantennogram (EAG) assay to the synthetic sex pheromone components of DBM and their analogues was done. In EAG assay the two sex pheromone compounds, *Z*11-16:Al and *Z*11-16:Ac, elicited significant antennal response, but the response to the other compounds tested was weak, except for *Z*11-14:Ac and *Z*11-16:OH. In blend assays, the blend of Z11-16:Al and Z11-16:Ac showed strong response at the ratios of 5 : 5 to 7 : 3. In field trapping tests conducted at Chinese cabbage fields in Korea, DBM males were attracted mainly to 7: 3 blend.

The effects of photoperiods on the daily locomotion pattern of the German cockroach, *Blattella germanica* (L.)

HF Li, HJ Lee
Dept. of Entomology, National Taiwan Univ., 1, Roosevelt Rd. Sec. 4, Taipei 106, Taiwan, m480@ccms.ntu.edu.tw

The locomotion of the German cockroach, *Blattella germanica* (L.) can be entrained by light dark (LD) cycles, but the following constant darkness (DD) can cause a free-running rhythm on the locomotion. When cockroaches were entrained to various light-dark regimes, they showed typical locomotor pattern of nocturnal insects by concentrating their locomotion in the scotophase of the photoperiod. When the scotophase became extremely short (2 hours long), the locomotion pattern did squeeze in but the pattern was quite different from the one that was exposed to longer scotophase. Interestingly, the locomotor patterns did change during free-running condition after exposing to the different Zeitgebers. This change only showed in the distribution pattern of locomotion rather than in the length of circadian period, because all the Zeitgebers were 24 hours. By superimposing the locomotor distribution patterns of the same individuals under DD following two different Zeitgebers along the circadian time, the after effect was shown in the phase shifting. The locomotion pattern was also analyzed to understand the interaction between the circadian clock and locomotion.

Effects of herbivore-induced plant volatiles & previous foraging experiences on the residence time of the predatory mite *Amblyseius womersleyi* in a prey patch

T Maeda
National Institute of Agrobiological Sciences, 1-2 Ohwashi, Tsukuba, Ibaraki 305-8634; Japan, tarom@affrc.go.jp

It is important for predators to make optimal decisions on how long to stay in a prey patch. We investigated the effects of herbivore-induced plant volatiles, previous foraging experiences of predators, and the current patch condition on the residence time of *Amblyseius womersleyi*. The longest residence time was observed when the predators were in a heavily infested-patch. Neither prey eggs alone nor herbivore-induced plant volatiles alone emitted from the currently inhabiting patch affected the residence time. Satiated predators that had previously experienced starvation stayed longer in a patch than those that had not experienced starvation. When *A. womersleyi* had previously experienced a prey-rich patch, it showed approximately the same residence time irrespective of the number of prey in a patch. By contrast, *A. womersleyi* that had previously experienced a prey-poor patch stayed longer in a patch of high prey density than in one of low prey density. The residence time was also affected by herbivore-induced plant volatiles from outside the prey patch. *A. womersleyi* stayed significantly shorter in the volatiles-airflow than in the control-airflow. Thus, *A. womersleyi* appears to determine its residence time based on these multiple information about its foraging habitats.

Foraging & energy balance in *Pachydiplax longipennis* (Odonata: Libellulidae): implications for reproductive success

JM Baird, ML May
Dept. of Entomology, Rutgers University, 93 Lipman Drive, New Brunswick, NJ 08901, U.S.A.; may@aesop.rutgers.edu

Food intake, flight duration, and an estimate of prey availability at feeding areas were quantified for the dragonfly, *Pachydiplax longipennis*, by observing focal individuals on artificial perches. From these data we constructed activity budgets and thence have calculated approximate energy budgets. The latter indicate that average energy costs of foraging are small, and most individuals are in positive short-term energy balance. Nevertheless, these dragonflies probably have to feed 9-14 h per day to maximize reproductive success, and energy requirements may limit the time that males can spend at mating territories. Because of the energy requirements of territory defense by males and egg production by females, energy demands on both sexes appear to be high and roughly similar. Consequently, males may be relatively risk prone in foraging owing to high variance in male reproductive success.

Ecophysiological screening of necrotizing spiders in Korea using nonradioactive sphingomyelinase assay

MJ Moon, JS An, YS Choi
Department of Biological Sciences, Dankook University, Cheonan 330-714, Korea; moonmj@dankook.ac.kr

Spider bites cause a range of symptoms from simple swellings to disfiguring necrotic lesions, and occasionally death. There are now more than 40,000 identified spider species in the world, and considered about 100 species as actually dangerous to human. While spider bites are not a major medical problem in Korea, it would be of great value to know which species of spiders pose a threat to human health. A middle molecular weight protein, sphingomyelinase D, has been identified in the venom of the brown recluse spider and strong evidence suggests that they have a major role in spider bite necrosis (Tambourgi *et al.*, 1998). For the identification of necrotizing species, we have investigated using recently developed non-radioactive assay of sphingomyelinase for rapidly screening the necrotizing venoms. Here, we demonstrate the fetal toxicity of 47 species (34 genera within 15 families) among 622 identified spider species of Korea. It has been revealed that one species of the orb-weaving spider, *Araneus ventricosus*, and another species of wandering spider, *Dolomedes sulfureus* have the strongest positive activities among themselves.

Long chained acetates in the defensive secretion of Thysanoptera

PDG Tschuch, P Lindemann, A Niesen, R Csuk, G Moritz
M-Luther-Univ., Domplatz 4, 06099 Halle, Germany; tschuch@zoologie.uni-halle.de

Defensive secretions of several Thysanoptera species were found to contain mixtures of long chained acetates: saturated decyl, dodecyl, tetradecyl, hexadecyl and octadecyl acetate. If the saturated acetates are solid they are mixed with liquid long chained saturated alkanes, e. g. pentadecane. A further method is to dissolve solid saturated acetates in unsaturated acetates, e. g. (11Z)-11,19-eicosadienyl acetate. Those mixtures spread fast on surfaces and are especially designed to produce a long-lasting coating of sensory organs of potential predators like ants and mites. Furthermore unsaturated acetates act as repellents against ants. Similar mixtures, e g. (11Z)-11-eicosenyl acetate with octadecyl acetate, can be found in Thysanoptera and in some other insects species as well.

Secondary metabolites from sunflowers as oviposition stimulants for the banded sunflower moth, *Cochylis hospes*.

BD Morris, SP Foster, S Grugel, LD Charlet
Department of Entomology, North Dakota State University, PO Box 5346, Fargo, North Dakota 58105, USA; bruce.morris@ndsu.nodak.edu

The banded sunflower moth, *Cochylis hospes* (Walshingham) (Lepidoptera: Cochylidae) (BSFM), is a specialist species on sunflowers (*Helianthus* spp.). Its larvae are restricted to feeding on sunflower heads and are a significant pest of cultivated sunflowers in the USA. Extracts of sunflower head surface chemicals stimulated oviposition by *C. hospes* when applied to an artificial substrate in an egg-laying bioassay. The major compounds in these extracts were epicuticular waxes (long chain aldehydes and alcohols) and monoterpenes, primarily α-pinene. Also present were a number of sesquiterpenes, sesquiterpene lactones, and diterpenoid acids and alcohols previously characterized in studies of *Helianthus* secondary metabolites. Fractionation of head extracts by column chromatography and HPLC resulted in the isolation of several compounds which stimulated oviposition by females in the bioassay, and are apparently responsible, at least in part, for host acceptance by female *C. hospes*. Chemical characterization and indication of the final purity of active compounds used in bioassays was carried out by GC-MS and NMR spectroscopy.

Feeding responses of a dampwood termite, *Zootermopsis nevadensis* to various wood extracts

W Ohmura, M Ozaki, R Yamaoka
Forestry and Forest Products Research Institute, Tsukuba, Japan, murasan@ffpri.affrc.go.jp

A dampwood termite, *Zootermopsis nevadensis* **(Hagen) is regarded to be introduced into Japan with imported timbers from North America. It locally distributes in Kansai region and inhabits in fallen pinewoods (***Pinus densiflora* **(Sieb et Zucc.)). In the present study, we focused the feeding preference of** *Z. nevadensis* **to the sapwood extracts and investigated the behavioral and electrophysiological responses to the extracts of five softwoods and one hardwood (***P. densiflora*, *Picea jezoensis* **Carr.,** *Abies sachalinensis* **Fr.Schm.**, *Larix leptolepis* **Gord.,** *Cryptomeria japonica* **D.Don,** *Fagas crenata* **Blume). According to the two-choice feeding tests,** *Z. navedensis* **tended to prefer in this order,** *A. sachalinensis> C. japonica*, *P. densiflora, P. jezoensis, F. crenata > L. leptolepis*. **Contact chemoreceptor neurons in taste hairs on the labial and maxillary palps generate less adaptive impulses to these extracts. However, parallel relationships between the behavioral and electrophysiological results would not be clear. Probably, different cells were fired by different extracts, and/or olfactory stimuli may effect on the feeding preference of** *Z. navedensis*.

Electrophysiological & behavioural activity of chocolate volatiles: attractants for the pyralid moths *Ephestia cautella* **&** *Plodia interpunctella*

POC Olsson, O Anderbrant, C Löfstedt, AK Borg-Karlson, I Liblikas
"Department of Ecology, Lund University, Sölvegatan 37, SE-223 62 Lund, Sweden. "

The use of food odours to monitor females in pest populations would be a valuable complement to pheromone-based methods. In a chocolate factory stored product moths were observed flying in the vicinity of containers with chocolate-based products. We tested three chocolate-based products in flight tunnel experiments and found that they all attracted males and mated females of the pyralids *Ephestia cautella* and *Plodia interpunctella.* The substances in chocolate-based products were isolated by two different extraction methods to; steam distillation and head space collection. GC-EAD experiments revealed several electrophysiologically active substances in the different products. The extracts and headspace samples were analysed with GC-MS and the substances identified. The electrophysiological activity of the corresponding synthetic samples was investigated by EAG, and two components with a positive dose-relationship were detected for both species and sexes, phenylacetaldehyde and nonanal. These two compounds were also behaviourally active when tested individually in a flight tunnel, as was a third substance, ethyl vanillin. A blend of the three components induced landing rates corresponding to the levels found when testing chocolate-based products, suggesting that we had found the chemicals mediating the attraction to chocolate. Field tests with the blend are now running to evaluate the potential use in monitoring traps.

Oviposition behavior of *Stenoma catenifer* **Walsingham: chemical & physical stimuli & time of egg-laying**

DE Nava, JRP Parra, JMS Bento
ESALQ/USP, 13418-900, Piracicaba-SP, Brazil, jrpparra@esalq.usp.br

The influence of chemical and physical stimuli on the oviposition behavior of *Stenoma catenifer* Walsinghan (Lepidoptera: Elachistidae), as well as time of egg-laying were investigated aiming for biological control studies with *Trichogramma* spp. The experiments were carried out in the laboratory (25±2ºC temp., 60±20% RH and 14-h photophase), using 5 couples per cage. To evaluate the chemical stimulation, the cages were internally coated with paper towel with the different treatments: 1 and 2) fruits of cultivar Margarida and Breda; respectively 3) artificial fruit; 4) fruitless (natural or artificial). In order to evaluate the physical cues we used hollowed paper towel, non-hollowed paper towel and a smooth sheet of paper. The number of eggs in all treatments including the avocado fruit was statistically higher than the remaining ones. Likewise, the number of eggs on the hollowed paper towel was statistically higher in comparison with the non-hollowed paper towel and smooth sheet of paper. The peak of egg laying in laboratory was from 8PM to 12PM. Thus, we verified that achieving eggs on *S. catenifer* required coating the cage with a hollowed paper towel (physical cue) including the avocado fruit (chemical stimulation).

Biochemistry & evolution of floral scent

E Pichersky
Department of Molecular, Cellular and Developmental Biology, University of Michigan, 830 N. University, Ann Arbor, MI 48109-1048, USA; lelx@umich.edu

Floral scents of plants are often complex mixtures of volatiles derived from several metabolic pathways. The number of presently known volatile compounds from flowers is approaching a thousand, and new compounds are constantly being discovered in various plant species. Closely related species have distinct volatile profiles that can be discriminated by specialized insect pollinators, thus limiting gene flow across species boundaries. The ability of related plant species to synthesize different volatiles in their flowers is sometimes due to differential gene expression. However, new enzymes that catalyze the formation of new floral scent components are constantly evolving through the process of gene duplication and divergence, allowing for the majority of floral scent divergence. It has been shown that very small changes in protein sequences can lead to the ability of the changed enzymes to catalyze the transformation of drastically different substrates, leading to the production of new floral scent compounds. Such evolution is facilitated by the presence of large gene families in plant genomes that already encode similar enzymes with slightly different substrate specificities; the large number of such genes makes genes duplications even more likely to occur.

The glucosinolate-myrosinase defence system in the cabbage aphid, *Brevicoryne brassicae*

L Tibbles, G Powell, J Rossiter
Department of Agricultural Sciences, Imperial College London, Wye campus, High Street, Ashford, Kent, UK TN25 5AH, g.powell@imperial.ac.uk

Cruciferous plants contain glucosinolates that are hydrolysed by myrosinase enzymes within the plant to produce volatile isothiocyanates which act as repellents for generalist pests but attractants for specialist crucifer feeders including the cabbage aphid, *Brevicoryne brassicae*. Specialist aphids also produce a myrosinase enzyme and assimilate high levels of plant glucosinolates. However, the biological role of the aphid enzyme has not been explored. It is likely that the aphid myrosinase and sequestered glucosinolates play a defensive role against predators and parasitoids. Aphid myrosinase is found only within muscle tissue of the head and thorax while the glucosinolates are most likely located in the haemolymph, a spatial arrangement suggestive of a defensive role. Recent research has concentrated on the dynamics of the glucosinolate-myrosinase system in aphids, particularly glucosinolate uptake, released volatiles and the biological role of this defensive system in *B. brassicae*.

Evidence of female sex pheromone in *Anoplophora versteegi* Ritsema (Coleoptera: Cerambycidae) – a serious pest of citrus in north eastern hill region of India

K Rajasekhara Rao, NSA Thakur, AN Shylesha
Division of Entomology, Indian Council of Agricultural Research (ICAR) complex for North Eastern Hill Region, Umroi Road, Umiam 793 103, Meghalaya, India, Koradarajasekhar@rediffmail.com & rao@icarneh.ren.nic.in

Severe epidemics of trunk borer *Anoplophora versteegi* Ritsema (Coleoptera: Cerambycidae) were noticed on mandarin (*Citrus reticulata* Blanco) in the North Eastern Hill Region of India for the last 15 years, which resulted in gradual decline of mandarin orchards to the extent of 10-15% every year. The olfactometer studies revealed that the extract from lower abdomen of female beetle possessed pheromone properties and attracted 100% adult males within 5 minutes when kept at 5 meters apart. The pheromone continued to attract males for more than 7 days in laboratory conditions. The extracted material kept at 20 meters apart in a control orchard increased the activity of male beetles on surrounding citrus trees. When antennae of the male beetles were removed, they continued to be attracted towards females and copulation took place indicated that males used visual cues in the absence of antennae for locating adult females. The pheromone extracted from gravid females was also found to attract the male beetles to a lesser extent evidenced by mating between males and gravid females. The chemistry, structure, activity and relationships of the pheromone were under progress. This is the first report about the presence of female sex pheromone in *A. versteegi* from India and also seems to be first in the world.

Expression & properties of ant apolipophorin-III

R Renthal, D Velasquez, JA Cassill
Dept of Biology, Univ of Texas at San Antonio, San Antonio, TX 78249, USA; RRenthal@UTSA.edu

Apolipophorin-III (apoLp-III) is present at relatively high levels in the antenna of the male red imported fire ant, *Solenopsis invicta* (Formicidae: Hymenoptera). PCR analysis shows that apoLp-III is expressed in the male antenna as well as in other male body segments, and it is also expressed in workers. ApoLp-III is known to be involved in transport of diacylglycerol through the hemolymph from fat body to flight muscle in locusts. However, male fire ants do not have a high fat content and probably do not use fat as a major fuel for flight. Additional known functions for apoLp-III include immune response and apoptosis, and lipophorins also carry cuticular hydrocarbons and pheromones in some insects. Therefore, we are investigating whether apoLp-III might have an olfactory function in fire ants. We expressed fire ant apoLp -III in *E. coli* and the purified recombinant protein was tested for hydrophobic ligand-binding properties, using the fluorescent dye ANS. We found that ANS binds to fire ant apoLp-III with a dissociation constant in the micromolar range, similar to ANS binding to intracellular lipid-binding proteins. We are currently testing the capacity of fire ant apoLp-III to bind endogenous ligands.

Host finding cues of *Platygaster demades*, parasitoid of apple leaf curling midge & pear leaf curling midge

M Sandanayaka, JG Charles
The Horticulture and Food research Institute of New Zealand, Private Bag 92169, Auckland New Zealand. msandanayaka@hortresearch.co.nz

Platygaster demades is an egg parasitoid of the apple leaf curling midge (ALCM), *Dasineura mali* and pear leaf curling midge (PLCM), *Dasineura pyri*. The response of one to two day old naïve female parasitoids to pear and apple plant odour cues was measured in a specially designed two armed Y-tube olfactometer. When the parasitoids were given a choice of odours of ALCM and PLCM egg-free apple or pear leaves or clean air, they preferred the plant cues, responding similarly to both apple and pear odours. The results indicate that *P. demades* utilises plant cues to locate the habitat of its host and then searches for host eggs to parasitise. The odour mediated responses to midge egg-free apple and pear leaves suggest that the odours are not host induced and also that *P. demades* is attracted to a cue common to both apple and pear leaves.

Diffraction gratings in insect cuticle & spectral iridescence in Coleoptera

A Seago
ESPM- Insect Biology, 201 Wellman Hall, University of California, Berkeley CA 94720-3112, USA; seago@nature.berkeley.edu

Iridescence in beetles is usually due to interference, in which light is scattered as it passes through cuticular layers of varying density. In a few families, however, iridescence is due to diffraction gratings formed by cuticular microsculpture. In these unusual taxa, patches of spectral iridescence are visible under incident light, usually at the elytral apices. Cuticular diffracting structures vary widely in form; some resemble flattened setae, while others take the shape of minute combs or tabs perpendicular to the surface of the cuticle. This iridescence may be a form of crypsis, an intraspecific cue, or may simply be an artifact of the plastron-like pubescence related to moist environments. This phenomenon has hitherto been observed only in Scarabaeidae, Carabidae, Gyrinidae, Phalacridae and Torridincollidae; recently, several iridescent species in Hydrophilidae and Leiodidae were discovered. In order to elucidate the evolutionary origins and possible functions of these diffraction gratings, representatives of each family were examined with both light photography and scanning electron microscopy. Cuticular diffraction gratings appear to be linked to moist or aquatic habitats, but are likely visual cues as well; most of the iridescent species are diurnal and occur near the equator, where the angle of incident light is very low.

Evolution of pheromone desaturases in primitive moths (Lepidoptera)

M Strandh, T Johansson, C Löfstedt
Chemical Ecology, Dept. of Ecology, Lund University, Ecology Building, SE-223 62 Lund, Sweden, maria.strandh@ekol.lu.se

Typical moth sex pheromones like unsaturated 12-, 14- or 16-carbon acetates and alcohols are produced in the female pheromone gland from palmitic/stearic acid that is modified in a few enzymatic steps: desaturation, oxidation and reduction. The diversity of pheromone components in different species is obtained by the specificity of the enzymes involved and from the reactions occuring in different order. In the primitive moths and in the sister group Trichoptera short-chain alcohols and ketones are used as pheromones, instead of the long-chain pheromones used in the rest of Lepidoptera. *Lampronia capitella* (Incurvariidae) is the most primitive moth for which a palmitic/stearic acid-derived pheromone is known whereas the primitive moth *Eriocrania semipurpurella* (Eriocraniidae) use a short-chain pheromone similar to Trichopteran pheromones. Based on DNA-sequences of pheromone desaturase-genes in *Eriocrania semipurpurella* and *Lampronia capitella* together with previously described desaturase-genes from higher moths, we have made a phylogenetic reconstruction of the evolution of the genes and describe how the pheromone production has evolved from the primitive to the more recent Lepidopteran species.

Multiple mating stimulates the oviposition but not the egg maturation in female seed beetle (*Callosobruchus maculatus* (Fabicius))

SF Tseng, SB Horng
Department of Entomology, National Taiwan University, No. 1, Sec. 4, Roosevelt Road, Taipei, Taiwan; sbhorng@ntu.edu.tw

In general females, compared to males, do not enhance reproductive success by mating multiply; however, an evolutionary inclination to mate multiply in females has been observed in a variety of insect species. In this study, we tried to determine the potential function of additional matings for female *Callosobruchus maculatus* by permitting them to mate either singly or doubly. The lifetime fecundity and weight loss were both higher in the doubly than singly mated females, while the longevity was not significantly different between treatments. In addition, there was an immediate increase of egg production on the remating day of doubly mated females. The dissection of ovaries carried out 24 hours after remating showed that the number of eggs unlaid was lower in doubly mated females, thus multiple mating did not directly stimulate egg maturation. Indirect driven hypothesis that states the increased egg maturation rate was driven under the approximate emptiness of ovaries was proposed. By depriving hosts of females for 3 days after remating to inhibit oviposition, we were able to support this hypothesis because the increase of egg production disappeared in doubly mated females due to the number of eggs unlaid remaining high. Therefore, in *C. maculatus*, multiple mating for females could contribute to reproductive success through direct effect of increasing ovisopistion and indirect effect of increasing egg maturation.

Effects of prey species & prey densities on the olfactory responses of a generalist predator to herbivore-induced plant volatiles (HIPV)

M Uefune, Y Nakashima, E Tagashira and M Takagi
Faculty of Agriculture, Kyushu University, Fukuoka, 812-8581, Japan, uefune@ecology.kyoto-u.ac.jp

To clarify the effects of prey species and prey densities on the long-distance prey finding by a generalist predator *Wollastniella rotunda*, we studied the olfactory response of the predators toward HIPV emitted from eggplants infested by thrips *Thrips palmi* versus those from eggplants infested by spider mites *Tetranychus kanzawaii* in a Y-tube olfactometer. When the number of each prey species was low per plant (200 individuals each), the females preferred the plants infested by *T. kanzawaii* over those infested by *T. palmi*. By contrast, when the number of each prey species was high (800 individuals each), the females showed the equal distribution between the two HIPV sources. When the number of prey per plant was different in two prey species, the females significantly preferred HIPV from plants infested by prey of high-density regardless of prey species. These results suggest that the effects prey densities on the quality and/or quantity of HIPV differ according to herbivore species, and the predator females would distinguish such differences to select the plants with higher prey densities. This behavior would increase the foraging efficiency of the generalist predator.

Role of leaf volatiles from two maize (*Zea mays* L.) cultivars in eliciting larval orientation of *Chilo partellus* (Swinhoe) (Lepidoptera: Pyralidae)

AK Varshney, AK Singh, HC Agarwal
"Dept. Of Zoology, University Of Delhi, Delhi-110 007, India; singhak@vsnl.net"

The effects of two maize cultivars, susceptible (Basilocal) and resistant (Kisan), and their methanol- and hexane- extracts in eliciting orientation of the first-instar *Chilo partellus* (Swinhoe) larvae were studied in the laboratory. When presented at one end of the orientation tunnel, leaf whorls of both the Basilocal and Kisan varieties, elicited higher orientational responses of stemborer larvae as compared to the blank end, the orientation preference (OP) of the larvae being + 72% and + 48%, respectively. Statistically, OP of larvae for Basilocal leaves was significantly higher than for Kisan leaves ($P<0.01$). Methanol extracts of both the Basilocal and Kisan leaves also attracted the neonate larvae, but the difference between the OP for the two was not significant. However, the attraction of larvae for hexane extractable chemicals of Basilocal (OP= 40%) was significantly higher than that for Kisan (OP = -32%). The observations indicate that difference in the orientational response of stemborer larvae for the two maize cultivars is due to non-polar semiochemicals, extractable in hexane. Identification of the chemicals in these maize cultivars can be useful in the behavioural management of this economically important insect pest of maize and sorghum.

Host plant preferences of diamondback moth (*Plutella xylostella* L.) in western Australia.

T Worthington, H Spafford Jacob, JK Scott, F Berlandier
School of Animal Biology (M085), The University of Western Australia, 35 Stirling Highway, Crawley WA 6009, Australia, wortht01@tartarus.uwa.edu.au

In Western Australia, diamondback moth (*Plutella xylostella* L.) has become a serious problem in canola (*Brassica napus*), having repeatedly reached outbreak levels in some regions. At present, the factors responsible for *P. xylostella* outbreaks in canola are poorly understood. Field surveys in Western Australia have established that *P. xylostella* is abundant on some weedy Brassicaceae, indicating that alternative hosts may be contributing to the problem on canola. Two experiments were conducted to assess the host plant preferences of gravid female diamondback moth when offered a number of Brassica host plants. The purpose of these experiments was to determine whether *P. xylostella* actively prefers canola over weedy or horticultural hosts, and whether this preference results in a larger egg loads on canola. The first experiment used a Y-tube airflow olfactometer to assess the immediate behavioural response of *P. xylostella* to volatiles from a range of host plants. The second experiment assessed the oviposition preferences of the moths when exposed to the same set of host plants over an extended time period. The results of the experiments were then compared to assess whether the oviposition preferences of *P. xylostella* reflected the observed olfactory responses.

When did the discovery of olfaction communication take place?

J Wüest,
Museum of Natural History, PO Box 6434, CH-1211 Geneva 6, Switzerland Jean.wuest@mhn.ville-ge.ch

It is generally agreed that the first published observations about communication between insects by olfaction were the fact of the French entomologist Jean-Henri Fabre, at the beginning of the 20th century. In fact, we discovered mentions of olfaction communication in the works of Charles Bonnet and Louis Jurine, two well-known 18th century entomologists from Geneva Switzerland. Bonnet noted that ants always follow the same routes. Rubbing that route with a finger interrupts it. Bonnet hypothesized that ants deposit a secretion which is perceived by olfaction. He so discovered the trail pheromones. Jurine reported, and noticed himself, that some great female moths attract males at long distances. The place where the female was is attractive even in the absence of the female. Jurine again was hypothesising an odour evaporated by the female, which attract the males by olfaction. Depriving males of their antenna do not allow them to find the females. The publications of these observations took place in 1779 for Bonnet, in his book on "Observations sur les Insectes". Jurine placed his account about moths in the beginning of his great book "Nouvelle manière de classer les Hyménoptères", published in 1807.

Assessing the pitfalls of insect repellent evaluation methodologies

SJ Moore, MM Cameron, N Hill, CR Davies
4D1, DCVBU, London School of Hygiene and Tropical Medicine, Keppel St. London WC1E 7HT, UK, sarah.moore@lshtm.ac.uk

Insect repellents provide useful protection from malaria, for high-risk groups including forest-workers; especially in the Amazon Basin where vectors are difficult to control through conventional means due to their exophily, crepuscular biting and forest-breeding. The WHO recommends that repellents are field-tested using human-landing catches, with individual collectors positioned >10m apart. However, it is still commonplace to perform tests using repellent treated "bait" and an unprotected "collector". This could overestimate repellent protection and longevity since mosquitoes will feed preferentially from the unprotected "collector", thus potentially exposing subsequent users to disease. Mosquito diversion from 15% deet (repellent) to 15% baby oil (control) was quantified utilising pairs of testers with each team situated >10m apart. Permutations of repellent repellent; control control; and repellent control were replicated over 18 nights with 6 pairs. Control individuals received 22.82% more bites when paired with repellent wearers, than untreated individuals (likelihood-ratio test Prob > chi2= 0.0485), and repellent wearers received 11% more bites when paired with other repellent wearers than controls (N.S.). In a further test with 25% lemongrass *(Cymbopogon citratus)* repellent, controls received 23.53% more bites when paired with repellent wearers, than with unprotected partners (N.S.). Thus it is recommended that repellents are field-tested using individuals and not pairs of collectors.

Assessing the pitfalls of insect repellent evaluation methodologies

S J Moore, MM Cameron, N Hill, CR Davies
4D1, DCVBU, London School of Hygiene and Tropical Medicine, Keppel St. London WC1E 7HT, UK, sarah.moore@lshtm.ac.uk

Insect repellents provide useful protection from malaria, for high-risk groups including forest-workers; especially in the Amazon Basin where vectors are difficult to control through conventional means due to their exophily, crepuscular biting and forest-breeding. The WHO recommends that repellents are field-tested using human-landing catches, with individual collectors positioned >10m apart. This could overestimate repellent protection and longevity since mosquitoes will feed preferentially from the unprotected "collector", thus potentially exposing subsequent users to disease. Mosquito diversion from 15% deet (repellent) to 15% baby oil (control) was quantified utilising pairs of testers with each team situated >10m apart. Permutations of repellent repellent; control control; and repellent control were replicated over 18 nights with 6 pairs. Control individuals received 22.82% more bites when paired with repellent wearers, than untreated individuals (likelihood-ratio test Prob > chi2= 0.0485), and repellent wearers received 11% more bites when paired with other repellent wearers than controls (N.S.). In a further test with 25% lemongrass *(Cymbopogon citratus)* repellent, controls received 23.53% more bites when paired with repellent wearers, than with unprotected partners (N.S.). Thus it is recommended that repellents are field-tested using individuals and not pairs of collectors.

Male-produced anti-sex pheromone in a plant bug.

QH Zhang, JR Aldrich
USDA-ARS-BARC Chemicals Affecting Insect Behavior Lab, Beltsville, Maryland USA 20705

In at least some plant bugs (Miridae) females produce sex pheromones in the metathoracic scent gland (MSG), which in most other true bugs (Heteroptera) is responsible for chemical defense. Females of a pine inhabiting mirid, *Phytocoris difficilis* Knight, contained predominantly hexyl, (*E*)-2-hexenyl and (*E*)-2-octenyl acetates in their MSG, while the latter two compounds were found only in trace amounts in males. This ternary acetate blend (2: 1.5 :1 by volume) constitutes the sex pheromone of *P. difficilis.* However, the possibility that the MSG secretion of male plant bugs plays a role other than defense has been largely overlooked. For *P. difficilis* we showed that hexyl butyrate and (*E*)-2-hexenyl butyrate are abundantly produced only in males, and demonstrated that these MSG compounds elicit strong antennal responses in conspecific males. Furthermore, physiologically relevant doses of these butyrates totally interrupted attraction of males to the female-produced sex pheromone in the field. Our results suggest that in some plant bugs the male MSG esters have a natural communicative function as anti-sex pheromones, probably to repel other males from further mating attempts. From a practical standpoint, synthetic anti-sex pheromones may be useful for mating disruption of economically important plant bugs.

Sex pheromones in Diprionidae & other Symphyta (Hymenoptera).

O Anderbrant
Department of Ecology, Lund University, Ecology Building, SE-223 62 Lund, Sweden: olle.anderbrant@ekol.lu.se

The most ancient group of Hymenoptera, Symphyta or sawflies, consists of around 8000 described species. The vast majority, are herbivorous and some species are important pests of agricultural crops or forest trees. Despite this, comparatively little is known about the chemical ecology within this group. I will present an overview of the sex pheromones identified so far in the different families, with emphasis on Diprionidae, the only well-studied group. In this family all active compounds discovered are saturated methyl-branched hydrocarbons with two to four chiral centres. The chiral configuration seems to be important for all species, whereas specificity regarding carbon chain-length or functional group (different esters) often is less distinct. The electrophysiologically and behaviourally active esters are released by the females together with their alcohol and carboxylic acid precursors. According to present knowledge, several sympatric species share the same sex pheromone, also with respect to stereoisomer, calling for more attention from chemical and evolutionary ecologists. In the other families the identified pheromones are different from those in Diprionidae, but there are too few sex pheromones identified for drawing any general conclusions.

Identification of volatile compounds from *Stenodema* (Heteroptera: Miridae) trigged by their natural predators.

M Apelqvist
Univiersity of Jönköping (HLK), Box 1026, S-551 11 Jönköping, Sweden; magnus.apelqvist@hlk.hj.se

Gland secretions in Heteroptera contain different compounds spanning from sex pheromones to allomones. Little is known about the structure and function of released defence substances, especially in Miridae, and studies of emissions from living species are rare. In this study, *Stenodema* Laporte specimens were exposed to predators and the trigged chemical response was recorded in vivo using solid-phase microextraction (SPME). Sexual immature adults from *S. calcarata* Fallén, *S. holsata* Fabricius and *S. laevigata* Linnaeus were tested and predators like spiders and Nabidae were introduced to provoke defence reactions. Each species of *Stenodema* released three substances in high amounts due to the confrontation. These compounds were absorbed on SPME-fibers and identified using GC-MS.

Behavioural interactions between a slug pest & a carabid beetle predator.

C Armsworth
Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ; clare.armsworth@bbsrc.ac.uk

The co-evolution in the responses of predators and their prey is an exciting area of research which has practical benefits for the development of biological control. My work is focussed on how an important slug pest detects and responds to a carabid beetle predator and whether this can be related to the spatial dynamics of the predation interaction in the field. The avoidance response of the slug *Deroceras reticulatum* (Müller) to the carabid beetle *Pterostichus melanarius* (Illiger) was investigated under laboratory and semi-field conditions. Slug responses to the presence of both beetles and beetle odour were measured, and the chemical constituents of the odour which elicited the response were identified. Beetle odour had both a repellent and an antifeedant effect upon slugs and elicited anti-predator behaviour such as increased velocity and movement and a reduction in the turning rate of slugs. The findings were related back to data from a previous study that showed there to be a strong spatial relationship between the two species, indicative of density dependant predation on the slugs by the carabid beetle predator. The implications of this work for the efficacy of *P. melanarius* as a natural biological control agent of slugs will be discussed.

Functional diversification of the material properties of orb-weaving spider silk.

TA Blackledge
Department of Biology, University of California, Riverside, CA 92521, USA; todd.blackledge@ucr.edu

Spider silks are exceptionally strong and can absorb more energy before breaking than high performance manmade fibers such as Nylon or Kevlar. The exceptional mechanical properties of spider silks are thought to have resulted in part from selection on the function of webs during prey capture, in particular upon aerial orb webs that must arrest fast-flying, high kinetic energy insect prey. However, orb-weaving spiders spin up to seven different types of silks, all of which are produced from distinct glands and are utilized in many different ways, from protecting eggs, to building retreats, to capture of prey. Here, we use the orb-weaving spider *Argiope argentata* to demonstrate that each of these silks, produced by distinct glands within a single spider, has a unique combination of material properties. Furthermore, these differences in mechanical performance reflect variation in the amino acid sequences of silk proteins. Thus, molecular evolution has played in important role in the evolution of the diverse toolkit of silks utilized by modern orb-weaving spiders.

Candidate pheromone receptors of the moth.

J Krieger, K Raming, YME Dewer, T Gohl, E Große-Wilde, H Breer
"University of Hohenheim, Institute of Physiology, 70593 Stuttgart, Germany; breer@uni-hohenheim.de"

The remarkable responsiveness of male moths to female released pheromones is based on the extremly sensitive and selective reaction of highly specialized sensory cells in the male antennae. These cells are supposed to be equipped with very distinct, male-specific receptors for pheromonal compounds; the nature of these receptors is still elusive. Using a combination of genomic sequence analysis and cDNA library screening of the tobacco budworm *Heliothis virescen***s led to the discovery of a divergent gene family encoding putative olfactory receptors. Comparing the encoded amino acid sequences of all candidate olfactory receptors emphasized their extreme diversity; however, a small family (identity > 40%) emerged, including the three receptor types HR14, HR15, HR16. RT-PCR-analysis revealed that all three subtypes were exclusively expressed in the antennae of male moths. More detailed** *in situ* **hybridization studies indicated that expression of these male-specific receptor types was confined to antennal cells located beneath sensillar hair structures which contain pheromone sensitive neurons. Moreover, two colour double** *in situ***-hybridization approaches in combination with laserscanning microscopy uncovered that each cell expressing one of these receptor type was surrounded by cells expressing pheromone binding proteins. These findings suggest that the novel receptor types may render neurons in male antennae responsive to pheromones.**

Influence of host footprints kairomone & past oviposition experience on the host location behaviour of *Trissolcus basalis.*

E Peri, MA Sole, E Wajnberg , S Colazza
S.En.Fi.Mi.Zo. Department - Section of Entomology, Acarology and Zoology – Università di Palermo, Viale delle Scienze, 13 90128 Palermo, Italy; colazza@unipa.it

During the host selection process insect parasitoid make flexible use of chemical information which can be directly or indirectly associated with the presence of their hosts. Wasp's response to a stimulus should be inversely related to its potential response and a change in wasp's response to stimuli can be the result of associative learning. In this view, influence of host indirect cues on the host location behaviour of the egg parasitoid *Trissolcus basalis* was investigated. *T. basalis* host selection behavior is mediated by chemical cues which are directly or indirectly associated with the presence of host egg mass of *Nezara viridula*. In particular, nymphs and adults footprints left on the substrate are known to play a role as indirect host-derived cues inducing an arrestment response in the parasitoid. We hypothesized that females which experienced the presence of host footprints kairomone without finding the host eggs should be less likely to respond to the same stimulus in the near future, while females that successfully located host egg masses would have shown reinforced responses. Results support our hypotheses. The significance of these findings for the manipulation of adult parasitoid behavior to enhance pest control and their implications for host selection by egg parasitoids are discussed.

Influence of direct mutual interference on patch time location in egg parasitoids.

E Wajnberg, C Curty, S Colazza
S.En.Fi.Mi.Zo. Department - Section of Entomology, Acarology and Zoology – Università di Palermo, Viale delle Scienze, 13 90128 Palermo, Italy; colazza@unipa.it

Direct mutual interference, i.e. the competition between parasitoid females foraging simultaneously for hosts, has regularly been considered to have a strong influence on the population dynamics of host-parasitoid systems. Furthermore, patch time allocation has also always been presented as an important behavioral component that should be deeply involved in the demographic features of host-parasitoid interactions. Based on a detailed analysis of within-patch interactions between *Trissolcus basalis* females, the present study aimed at understanding accurately how direct mutual interference can influence patch time allocation in this species. *T. basalis* attacks patches of its host, the egg masses of the Southern Green Stink bug *Nezara viridula*. In this species, competition between females occurs through strong fights when they are foraging simultaneously on the same patch. Such mutual interference could modify drastically the time invested by the females on the host patches. Behavioral interactions between the females were analyzed using a Cox's proportional hazards model. Results first indicated that the competitive interaction (through contacts and fights) between females strongly influences their patch residence time. Also, all the corresponding patch-leaving decision rules adopted by the females appeared to be under a significant genetic variation in the population studied. Such a genetic variability likely corresponds to an intra-population genetic variation in females' susceptibility to interference. The population dynamics and evolutionary consequences of these results are discussed.

Investigation of pheromones of coffee stemborers (Coleoptera: Cerambycidae).

DR Hall, A Cork, Jayarama, R Naidu, D Kutywayo
Natural Resources Institute, University of Greenwich, ME4 4TB, UK; a.cork@gre.ac.uk

Stemborers (Coleoptera: Cerambycidae) are the most important insect pests of arabica coffee in Africa and Asia. In India and other countries of S.E. Asia, the main species is *Xylotrechus quaipes*. Adult males were previously shown to attract female beetles to traps in the field. Analysis of volatiles collected from virgin male beetles by gas chromatography (GC) linked to electroantennography (GC) showed three components accounting for over 90% of the volatiles, two of which elicited EAG responses from a female beetle. The major EAG-active component was identified as (*S*)-2-hydroxy-3-decanone (I) and the minor as (*S,S*)-2,3-dihydroxyoctane (II). The third component was 3-hydroxy-2-decanone (III). (*S*)-(I) was attractive to male *X. quaipes* in laboratory bioassays, but addition of (*S,RS*)-(III) at 10% of (I) reduced attractiveness. In field trials carried out in India with sticky, cross-vane traps, (*S*) and (*RS*)-(I) attracted male *X. quaipes* and addition of (*S,S*)-(III) at 10% of (I) reduced attractiveness. In Africa the main species is *Monochamus leuconotus*. Preliminary field studies have failed to show any attraction between the sexes, but collection and analysis of volatiles from male or female beetles has shown the males produce a compound not produced by the females and identification of this is in progress.

Chemical information in soil: tritrophic interactions between plants, insects & parasitic nematodes.

RWHM van Tol, MW Sabelis, WJ de Kogel
Plant Research International, PO Box 16, 6700 AA Wageningen, The Netherlands; willemjan.dekogel@wur.nl

Plants can protect themselves against insect herbivores by promoting the effectiveness of the herbivore's enemies. One way to do this is by releasing herbivore-induced volatiles that attract the herbivore's enemies. Most evidence for this phenomenon comes from studies on aboveground tritrophic interactions. We will discuss an example from underground tritrophic interactions: roots from a coniferous plant (*Thuja occidentalis*) release chemicals upon attack by weevil larvae (*Otiorhynchus sulcatus*). These chemicals attract parasitic nematodes (*Heterorhabditis megidis*) which are the natural enemies of the weevil larvae. We will discuss biological, chemical and exploitation aspects of this tritrophic interaction.

Collective foraging in an outbreaking forest pest.

E Despland
Concordia University, 7141 Sherbrooke W., Montreal, Québec, H4B 1R6, Canada; Despland@alcor.concordia.ca

Gregarious behaviour is common among outbreaking forest insects. The forest tent caterpillar (*Malacosoma disstria*) is an early spring feeder that attacks North American hardwoods. Colonies exhibit complex social behaviour, using pheromone trails to move together between temporary bivouacs and feeding sites. Colonies alternate together between periods of quiescence and foraging, and mass movement is facilitated by chemical communication: moving caterpillars spin a fine thread of silk from their mouthparts and mark it with a highly stable non-volatile sterol pheromone. We show that the presence of trails significantly influences the behaviour of individual caterpillars, especially in the early larval stadia: trails increase both amount of locomotor activity and speed of travel. Larvae find novel food sources faster in an arena coated with trails than in a bare environment. This translates into a significant effect of trails on individual performance: caterpillars consume more food, grow larger and develop faster in the presence of trails. Although forest tent caterpillars do not recruit colony-mates to new food finds, trails nonetheless improve foraging by increasing individual mobility. These findings suggest that group-living is integral to the biology of the forest tent caterpillar and has shaped many aspects of its behaviour and development.

Finding the needle in a smelly haystack: prey location by carnivorous arthropods.

M Dicke, JG de Boer, R Gols
Laboratory of Entomology, Wageningen University, P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands; Marcel.Dicke@wur.nl

Many natural enemies of herbivorous arthropods use herbivore-induced plant volatiles to locate their prey. These induced volatiles are sometimes referred to as 'SOS-signals' from plants and their composition is variable. The composition of a blend of herbivore-induced plant volatiles can vary with plant and herbivore species, and with other biotic and abiotic conditions. Carnivores have to cope with this variation to be able to locate their food. We investegated responses of a predatory mite to plant volatiles induced by its prey or by non-prey herbivores. The role of individual compounds from the volatile blend in the discrimination between different blends has been addressed, as well the importance of phenotypic plasticity in predator behaviour. Our data show that the predatory mite *P. persimilis* can locate their prey by using SOS-signals from the prey's host plant not only in setups that have no odour-background, but also when an odour-background consisting of other herbivore-infested plants is present. The induction of herbivore-induced plant volatiles is mediated by the phytohormone jasmonic acid. Application of this hormone can mimic the effect of spider mite infestation to some extent. Moreover, application of the phytohormone can increase the effect of spider mite infestations at low mite densities.

Interaction between olfactory & gustatory inputs in insect behavior.

JC Dickens, B Hollister
USDA, ARS, Beltsville Agricultural Research Center, Plant Sciences Institute, Chemicals Affecting Insect Behavior Laboratory, Beltsville, MD, USA 20705; dickensj@ba.ars.usda.gov

Behavior of insects is governed by chemical and physical signals impinging on specialized sensory organs. Volatile chemical signals are detected by the olfactory sense and result in upwind orientation by conspecifics receiving them. Detection of less volatile chemical signals by the gustatory sense results in behaviors such as copulation, biting and ingestion. However, seldom are these signals encountered in isolation; more often multiple chemical signals are detected simultaneously and the insect receiving them must process the information and appropriate a response. We investigated behavior of Colorado potato beetles challenged by simultaneous olfactory and gustatory stimuli. An open ambulatory Y-track olfactometer was used to measure insect preferences, number of turns made during orientation, and time to make a choice between stimuli. Olfactory stimuli were delivered to one-side of the device; gustatory stimuli were painted on the other side. Behavioral conflicts and preferences were discovered between stimulus pairs. For example, females took more time and made more turns when confronted with a volatile plant attractant and sucrose compared to the plant attractant and a male extract. We will examine behavioral hierarchies revealed by our studies and discuss how they may relate to reproduction and feeding.

Does the aggregation pheromone of *Riptortus clavatus* (Heteroptera: Alydidae) attract the *Piezodorus hybneri* (Heteroptera: Pentatomidae)?

N Endo, T Wada, Y Nishiba
National Agricultural Research Center for Kyusyu Okinawa Region, 2421 Suya, Kikuchi, Kumamoto, 861-1192, Japan; enobu@affrc.go.jp

The male of *Riptortus clavatus* releases an aggregation pheromone which attracts conspecific adults and nymphs. We found that the synthetic aggregation pheromone (a mixture of three components) of *R. clavatus* (Heteroptera: Alydidae) attracted nymphs and both sexes of adults of *Piezodorus hybneri* (Heteroptera: Pentatomidae) in soybean fields. Among the three components of the synthetic pheromone, (*E*)-2-hexenyl (*E*)-2-hexenoate (EE) showed the attractiveness to *P. hybneri* and the activity was almost equal to the aggregation pheromone. The other two components lacked the attractiveness. Thus, EE was considered to be the component which showed the attractiveness to *P. hybneri*. Since we could not detect a peak of EE with the GC-MS analysis in the hexane extracts of *P. hybneri* and soybean plants, *P. hybneri* seems to utilize the component of the pheromone of *R. clavatus*, which has a similar host range, as a kairomone to search for food plants. However, real male bugs of *R. clavatus* did not attract the *P. hybneri*. Now we are trying to explain this contradiction.

Fatty acid levels & triacylglycerol biosynthesis in the sex pheromone gland of *Heliothis virescens* Fabricius.

SP Foster
Department of Entomology, North Dakota State University, PO Box 5346, Fargo, North Dakota 58105, USA; stephen.foster@ndsu.nodak.edu

Most species of moths biosynthesize sex pheromone de novo in a specialized gland located between the 8th and 9th abdominal segments. As well as sex pheromone components, the gland contains large quantities of lipids, predominantly triacylglycerols. These triacylglycerols contain significant quantities of fatty acid precursors and other intermediates of the sex pheromone components. Despite the obvious role as a source of precursor acids for pheromone biosynthesis, the evidence in favor of this is equivocal; one particular problem is that insects using specific geometric isomer ratios for pheromone components tend to have very different ratios of the respective precursor acids. We believe that the glandular lipids have the role in pheromone biosynthesis of governing glandular fatty acid concentrations. When fatty concentrations are high (especially during high rate of pheromone biosynthesis), excess fatty acids are stored in the lipids; when concentrations low, fatty acids are mobilized from the lipids. This ensures the smooth production of pheromone during the sexually active period, which otherwise might be punctuated, for example, by high fatty acid concentrations inhibiting pheromone biosynthetic function. In this talk, we report the effect of glandular fatty acid levels on the biosynthesis of triacylglycerols in the pheromone gland of *H. virescens*.

Male mating behavior of the white-spotted longicorn beetle, *Anoplophora malasiaca* (Thomson) (Coleoptera: Cerambycidae) regulated by assorted female components.

M Fukaya, H Yasui, T Akino, T Yasuda, S Wakamura
Laboratory of Insect Behavior, NIAS, Tsukuba 305-8634, Japan; fukaya@affrc.go.jp

Male *A. malasiaca* dash towards and mount females, and bend the abdomen to copulate after contact with antennae or tarsi. Males make a similar mating attempt with glass dummies treated with the solvent extract of female elytra, indicating the presence of a female sex pheromone perceptible by physical contact. Chemical analysis of the pheromone components from female elytra revealed that at least three different groups of chemicals are involved: (1) long-chained alkanes, (2) ketones and (3) novel polar components. All three of these groups of chemicals are indispensable to evoke male mating behavior and work synergistically. Components within each group, however, complement each other. In addition to observation of the contact sex pheromone, we note the presence of volatile attractant produced by females in the near vicinity. Visual cues of females also appear to act synergistically with the volatiles in male mate location before direct contact by male antennae.

Control of sex pheromone precursor biosynthesis in adzuki bean borer *Ostrinia scapulalis.*

M Fukuzawa, S Tatsuki, Y Ishikawa
Laboratory of Applied Entomology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113-8657, Japan; aa26021@mail.ecc.u-tokyo.ac.jp

The adzuki bean borer *Ostrinia scapulalis* is one of the eight *Ostrinia* species found in Japan, and is an important pest of adzuki bean plant and hop. The sex pheromone of *O. scapulalis* is a blend of (*E*)-11- and (*Z*)-11-tetradecenyl acetates. These components are biosynthesized from common saturated fatty acids through chain shortening, desaturation, reduction and acetylation. The key enzyme in this cascade is the Δ11 desaturase that introduces a double bond into myristic acid to form E11-/Z11-tetradecenoic acid (fatty acyl pheromone analog, FAPA). It is known that one day-old females of *O. scapulalis* do not show calling behavior. We found that these females had little FAPA in their pheromone gland while sexually mature 3 day-old females accumulated a substantial amount. As decapitated females did not synthesize FAPA, it appeared that a signal from cephalic organs is important for triggering FAPA biosynthesis. We further found that FAPA titer in the females maintained under a constant light condition is lower than that in the control females, suggesting that the light-off signal enhances FAPA synthesis. Since the expression level of Δ11 desaturase gene was constant regardless of FAPA titer, it was suggested that FAPA biosynthesis in *O. scapulalis* is under post-transcriptional regulation.

Relationship of visual & olfactory signal parameters in a food-deceptive flower mimicry system.

CG Galizia, J Kunze, A Gumbert, AK Borg-Karlson, S Sachse, C Markl, R Menzel
University of California, Entomology 383, Riverside CA 92521, USA; galizia@ucr.edu

Pollinators are attracted to flowers by their scent and visual display. While most flowers reward visits by providing pollen and/or nectar, some do not. Such mimicry relationships allow investigating the evolution of floral signals and their impact on pollinator behavior. We have reanalyzed a case of specialized food mimicry between *Orchis israelitica* and its model, the lily *Bellevalia flexuosa.* We characterized visual and olfactory signals of model, mimic, and of two phylogenetically related orchids. We mapped their visual signals to the perceptual space of honeybees and found a shift of the mimic's visual signals towards the model, confirming that visual mimicry is present. We analyzed flower odors using GC/MS. We related them to the perceptual space by testing them physiologically, using *in-vivo* optical recording. We found no evidence of olfactory mimicry. The results indicate that evolutionary processes altered *O. israelitica's* visual, but not olfactory, traits toward a higher similarity to its model. Apparently, odor mismatch does not prevent a bee from landing on a flower that has the expected visual display. The results therefore argue for the dominance of visual stimuli in short-distance flower choice. The orchid may still depend on long-distance olfactory attraction originating from neighboring model plants.

Pollinator responses to mimicry by sexually deceptive orchids.

AC Gaskett, ME Herberstein
Department of Biological Sciences, Macquarie University, N.S.W. 2109, Australia.

Deceptive orchids mimic insect signals to attract pollinators without providing a reward. Orchid flowers may resemble food, oviposition sites, or female insects. Insects that respond, by attempting to mate with or feed from orchid flowers for example, collect and distribute orchid pollinia. Deceived insects may incur costs, e.g. time and energy wasted travelling to and interacting with orchids, and loss of sperm during pseudocopulation. Such costs may encourage the evolution of behavioural strategies that allow insects to avoid deceptive orchids. In sexually deceptive orchids, male pollinators are initially attracted by scents identical to female insect sex pheromones. Short-range cues eliciting pollinator contact with the flower may include visual cues such as colour and shape, and structural or tactile features that resemble female insect bodies. Investigation of the relative importance of chemical, visual, and structural cues, and the interaction between, long- and short-range cues should be rewarding. The Australian orchid genus *Cryptostylis* is an excellent study subject because all five species attract the same male wasp pollinator despite obvious differences in flower shape and colour. Here I introduce this intriguing study system and present some initial observations of pollinator behaviour and interactions between pollinator learning and the dimensions of orchid patches.

Multimodal communication in the acoustic Lepidoptera: evolutionary pathways & biophysical constraints.

MD Greenfield
Department of Ecology & Evolutionary Biology, Univ. of Kansas, Lawrence, KS 66045 U.S.A.

Multimodal signaling, widespread among animal communications, may serve in conveying multiple messages, reaching different receiver categories, redundancy, and reliability. In Lepidoptera, sexual communication in various species involves male acoustic (ultrasonic) + chemical advertisement and female hearing + olfaction. These modalities operate during different stages of pair formation. Phylogenetic analysis indicates that olfaction is ancestral, with (male) chemical signaling and ultrasonic hearing (females, males) each evolving independently in multiple clades; hearing evolved as a response to predatory, echolocating bats. Finally, (male) acoustic signaling evolved in several clades possessing hearing. Dual use of the ultrasonic channel by acoustic Lepidoptera and bats indicates special problems for sexual communication in the former, as females must reliably distinguish male calls from bat echolocations. Moreover, they must distinguish these in flight and while perched, situations with exposure to different bats. Whereas multimodal communication may conceivably afford opportunities for adaptive response, studies of the pyralid moth *Achroia grisella* show that critical distinctions are made acoustically and via input from a third modality, proprioception: Females assess temporal characters of ultrasounds and respond appropriately in accordance with their assessment and situation, flying or in ground contact. This protocol may be particularly reliable, given the constraints of time and limitations of neural processing.

Patch leaving strategies & superparasitism: an asymmmetric generalized war of attrition.

P Haccou, P Glaizot, C Cannings
Institute of Biology, Leiden University, P.O. Box 9516, 2300 RA Leiden, The Netherlands; Haccou@rulsfb.leidenuniv.nl

When several competitors deplete a patch, it can be advantageous for each of them to stay provided that others leave, whereas, on the other hand, staying longer decreases the expected payoff for everyone. This situation can be considered as a generalized war of attrition. Previous studies showed that when competitors interfere optimal patch leaving strategies become stochastic and the expected leaving time is much larger than predicted by the marginal value theorem. The possibility of superparasitism, as occurs e.g. in parasitoids, induces such interference. In addition, it gives several complications. First, the payoff of females that have left the patch is affected by the ovipositions of the remaining individuals. Second, differences in arrival time of females cause payoff-relevant asymmetries, since females that arrived early have parasitised more hosts in a patch at the moment superparasitism starts than those that arrived late. We show that this can be modelled as an asymmetric generalized war of attrition, and derive global characteristics of the ESS for simultaneous decisions when to start superparasitism and when to leave a patch

Reproductive strategies of cerambycid beetles & the role of semiochemicals.

LM Hanks
Dept. of Entomology, 320 Morrill Hall, Univ. of Illinois at Urbana-Champaign, URBANA, IL 61801, USA; hanks@life.uiuc.edu

Reproductive strategies of adult cerambycid beetles, and the role of semiochemicals, are apparently associated with the condition of the host plant required by their larvae (whether hosts are alive, dying, or dead). For example, early studies have indicated that species whose larvae feed in living hosts are likely to use long-range pheromones, while those that feed in dying hosts typically rely on host plant volatiles to unite the sexes for mating. Nevertheless, more recent research has revealed evidence of long-range sex pheromones in dying-host species. There is also a growing body of evidence that mate recognition in species of both categories depends on contact chemoreception, and contact pheromones have been identified for several cerambycid species in recent years. Although the current state of cerambycid research documents considerable variation in reproductive strategy, the association with host plant condition provides structure for guiding future research.

Can female sex pheromones serve as a condition-dependent handicap trait?

AR Harari, T Zahavi, D Thiéry
Department of Entomology, the Volcani Center, Bet Dagan, 50250, Israel; ally@int.gov.il

The handicap principle predicts that secondary sexual characters may act as honest signals of the individual quality if the trait bears a cost and if its expression is phenotypically condition-dependent. The cost of increasing the trait should be tolerable for individuals in good condition, but not for those in poor condition, thus, providing an honest signal of quality. Sex pheromones have long been recognized as important cues in sexual selection, however, whether sex pheromones comprise a handicap is unknown. We used the moth *Lobesia botrana* to study the role of sex pheromones as honest indicators of female quality because (a) females release a sex pheromone which attracts mate-seeking males from a distance, (b) there is evidence that females' calling behavior is affected by their size, (c) it was suggested that the female sex pheromone's characteristics are inherited and (d) males invest in the females more than sperm. We show that the male moths choose females as mates according to sex pheromone-related cues. We demonstrate that exposure to female species-specific synthetic sex pheromones bear a cost for the females and may therefore act as a condition-dependent trait and therefore we suggest that pheromones honestly advertise females' quality.

Mass trapping of olive moths.

EM Hegazi, WE Khafagi
Faculty of Agriculture, Alexania University, Alexania, Egypt; eshegazi@hotmail.com

"A simple and inexpensive UV-trap was developed by the first author from materials generally available around the olive farm, to capture the main lepidopterous pests of olive trees. The trap consisted of a sticky-collecting device, two ultraviolet fluorescent tubes and tilted mirrors to increase light intensity by interference of reflected rays and spreading light reflection over a wider area. The trap was compared with delta-traps (baited with (Z)-Z-tetradecenol) and funnel traps (baited with (E)-11-hexadecenol and (E)-11-hexadecenyl-acetate) for monitoring the olive moth, *Prays oleae* and jasmine moth, *Palpita unionalis*, respectively. Sex pheromone catches (only males) were persistently lower in all collections of 2 successive olive seasons of 2002 & 2003 than those of UV-traps. *P. oleae* catches (males & females) in the UV-trap significantly ($P<0.01$) exceeded *P. unionalis* moths. The obtained results indicated that the UV-trap may represent an effective tool for mass-trapping of *P. oleae* and monitoring tool for *P. unionalis* and other species of moths in the area. The trap was so effective in trapping *P. oleae* even when adult population was low compared with sex pheromone trap. Some of non-target species may be protected from damage by placing a screen of proper sized mesh over the entrance of the trap. The UV-trap saved the fruit yield of a large olive farm without using any insecticides throughout the study period.
"

New approaches to find key compounds in tritrophic interactions – exploiting genetic variation & *in situ* modification of volatile profiles.

M Held, M D'Alessandro, C Tamo, T Turlings
Laboratoire d'Ecologie Animale et d'Entomologie, Rue Emile-Argand 11, Université de Neuchâtel, CH-2007 Neuchâtel, Switzerland; matthias.held@unine.ch

Odour blends that are released by plants after herbivore attack can act as indirect defense by attracting natural enemies of the herbivore. These blends consist of mixtures of volatile organic compounds (VOCs), but, as yet, for many tritrophic systems it remains unknown, which VOCs of such complex blends are the most attractive ones. One way of studying the importance of individual VOCs is to test the attractiveness of odour blends differing in their pattern of compounds. This approach was used to test the attraction of naive and experienced females of the parasitoid wasp *Cotesia marginiventris* to volatile blends of maize infested with *Spodoptera littoralis* larvae. We used olfactometers in which female wasps were offered choices among odour blends of different chemical composition. The different blends were obtained by either using different maize inbred lines or by installing selectively adsorbing filters between the odour source and the olfactometer arms. The data were analysed with multivariate statistical techniques and revealed the relative importance of some VOCs that are often underestimated because of their small quantities.

How parasitoids read the news: information use in a patchy world.

TS Hoffmeister, A Thiel, U Tölch, MF Kersch, JJ Piening
Institute for Ecology and Evolution, Dept. of Animal Population Ecology, University of Bremen, Leobener Str. D-28359 Bremen, Germany;
t_hoffmeister@web.de

Patch leaving decisions in insect parasitoids have mainly been studied as a function of host density and host encounters in single-patch experiments. From such experiments we know that parasitoids respond to host kairomones and encounters with unparasitized hosts. Yet, parasitoids often encounter unparasitized as well as parasitized hosts. Response to encounters with parasitized hosts has been debated, but experimental evidence has been equivocal. Moreover, how information on a given patch and patch encounter rate influence the patch time allocation on subsequent patches has largely remained unanswered. Using *drosophila* parasitoids, we investigated behavioural responses of wasps to information cues for estimating patch quality and habitat quality. In patch-quality experiments we tested responses towards staged encounters with unparasitized vs. parasitized hosts. In habitat-quality experiments we tested whether odour from neighbouring patches affect the patch-time, and the searching behaviour when leaving the patch. Further, we studied how encounters with good and poor quality hosts and their density influence the time allocation on subsequent patches. Finally, we tested how parasitoids respond to variation in patch encounter rates in their patch time allocation and patch exploitation level. We discuss our results with respect of the reliability of such cues for future foraging success.

Floral scent mediating the foraging behaviour of some papilionid & danaid butterflies.

K Honda
Faculty of Integrated Arts & Sciences, Hiroshima University, Higashihiroshima 739-8521, Japan; honce@hiroshima-u.ac.jp

In addition to visual stimuli, olfactory cues also play a significant role in the foraging behaviour of anthophilous butterflies. I investigated floral volatiles of *Citrus* flowers (white in colour) that stimulate flower-visiting by a papilionid butterfly, *Papilio protenor*, which shows innate colour preference for red, orange, and blue. To determine active compounds, odour components were first screened individually to assess their ability to evoke proboscis extension reflex (PER), and the actual attractancy of potential components was confirmed by free-flight experiments. Of 16 compounds identified from the flower, methyl anthranilate, 2-phenylethanol, and phenylacetonitrile were found most attractive to the butterfly, indicating that compounds with an aromatic ring serve as important olfactory cues in their flower-visiting. In Japan, flowers of *Eupatorium chinense* have been observed to strongly attract danaid butterflies in the genera *Parantica, Ideopsis, Euploea,* and *Salatura*. Although several volatile compounds detected from an isopentane extract of the flower showed weak to moderate PER-activities, none of them exhibited strong attractiveness to the danaids. However, floral nectar of the plant was found to contain a considerable amount of pyrrolizidine alkaloids. The major compound, identified as intermedine, strongly attracted some danaid species, suggesting that certain pyrrolizidine alkaloids *per se* function as attractants.

Molecular cloning of a putative PBAN receptor from pheromone glands of the silkmoth, *Bombyx mori*.

JJ Hull, R Kurata, MG Suzuki, K Moto, S Matsumoto
RIKEN, Wako, Saitama, 351-0198, Japan; joeythemarsupial@yahoo.com

Despite recent successes in elucidating the molecular components of sex pheromone biosynthetic pathways within the Lepidoptera, identification of the gatekeeper of the pathway, the PBAN receptor, has proven to be elusive. Given the sequence similarity between the active C-terminal regions of PBAN and neuromedin U, it was hypothesized that their respective receptors might also be similar in structure. Consequently, a homology-based molecular approach utilizing primers constructed from the conserved regions of insect neuromedin U receptor homologues was used to amplify a full-length 2777-nt clone from a *Bombyx mori* pheromone gland cDNA library. Conceptual translation of the ORF indicated that it encoded a 45.8 kDa 7 transmembrane protein with 82% identity to a GPCR that has been recently cloned from pheromone glands of *Helicoverpa zea*. Interestingly, the sequence identity decreases considerably within the amino terminus and the *Bombyx* receptor contains a 67 amino acid C-terminal extension. Tissue distribution analyses reveal that the receptor is specific to the pheromone gland where it undergoes significant up-regulation in the day preceding eclosion. In addition, when expressed in Sf9 cells the receptor not only exhibits specific binding to PBAN but also mobilizes calcium in a dose-dependent response.

Reception of floral odours by *Helicoverpa armigera* antennae.

CD Hull, JP Cunningham, CJ Moore, MP Zalucki, BW Cribb
Department of Zoology and Entomology, The University of Queensland, Brisbane, Qld, 4072, Australia; c.hull@ento.uq.edu.au

The antennal receptor cell complex of *Helicoverpa armigera*, that is used in detecting a range of floral and green leaf odours, was investigated with electrophysiological and behavioural methods. By using mixtures of odours at saturating levels, the electroantennogram method can produce useful information about the classes of receptor cells used in detecting plant odours. This methodology provides information that both differs from and augments that gained by single neuron recordings, and as such allows the testing of hypotheses related to receptor types. A range of volatiles was tested including those principally associated with flowering parts or leaves as well as volatiles common to both. The two enantiomers of the chemical μ-pinene were also investigated and results suggest a common receptor neuron type for these enantiomers. Behavioural experiments showed that conditioned learning of odours can influence the decisions of the insect.

Significance of male's licking female dorsum in matings of Cerambycidae (Coleoptera).

R Iwata, H Imazeki
Department of Forest Science and Resources, College of Bioresource Sciences, Nihon University, Fujisawa 252-8510, Japan; iwata@brs.nihon-u.ac.jp

In matings of, if not all, some coleopteran families including Cerambycidae, it has been often recognized that male, on female's back, lick her dorsum with his mouth parts. However, there has been only a very limited number of literature on this behavioral component. We therefore investigated the significance of each of the body parts in cerambycid mating sequence, focusing on males' dorsum-licking behavior. Adults of diurnal cerambycid species, *Dinoptera minuta* (Gebler) (Lepturinae) and *Chlorophorus quinquefasciatus* (Cerambycinae), were collected in the field, and each of the test animals was treated by mutilating antennae with scissors (male, female) or coating its compound eyes (male, female) or pronotum plus scutellum (female) with water-based white correcting fluid. A treated individual and an untreated partner were paired and their mating sequence followed. Untreated pairs initiated mounting directly upon male antenna's touching female's body or antenna. Antenna-mutilation of male caused severe hinance of mating. Blind males did not mount or copulate. Coating pronotum/scutellum-region of the female also caused copulation hinance. The last result suggests that female beetle possibly possesses in her pronotum/scutellum region a source of pheromone toward the male and/or a sensory organ admitting male's appeasement by his mouth parts while in copula.

Using synthetic herbivore-induced plant volatiles to enhance conservation biological control in crop ecosystems: field experiments in hops & grapes.

DG James, T Price
Department of Entomology, Washington State University, Irrigated Agriculture Research and Extension Center, 24106 North Bunn Road, Prosser, Washington 99350, USA; david_james@wsu.edu

The potential of using synthetic herbivore-induced plant volatiles to enhance conservation biological control of insects and mites in crop ecosystems is being researched in hops and grapes in Washington State. Results to date indicate that a number of natural enemy species in the families, Chrysopidae, Hemerobiidae, Anthocoridae, Geocoridae, Miridae, Coccinellidae, Syrphidae, Braconidae, Empididae and Mymaridae, are attracted to sticky traps baited with aqueous methyl salicylate (MeSA), hexenyl acetate, farnesene or octyl aldehyde. Further, hop yards and grape blocks baited with slow release sachet dispensers of MeSA appeared to recruit larger populations of some insect predators (e.g. *Stethorus punctum picipes, Orius tristicolor, Chrysopa nigricornis*) than unbaited areas, resulting in some instances, in improved biological control of spider mites. The use of synthetic plant-signalling compounds as 'Herbivore-Induced Plant Protection Odors' (HIPPOs) may provide a novel yet practical option for improving the efficacy and reliability of conservation biological control in a variety of agricultural ecosystems.

Mating behaviour of the New Zealand native leafroller *Cnephasia jactatana* Walker (Lepidoptera: Tortricidae).

A Jiménez-Pérez, Q Wang, N Markwick, R Arzuffi
Ceprobi-IPN. Apto. Postal 24, Yautepec, 62731, Morelos, Mexico; Aljimenez@ipn.mx

Cnephasia jactatana Walker is a pest of kiwifruit in New Zealand. The objective of this study was to provide information on its mating behaviour for the development of pest management measures. Sexual maturation period was 3 d for females and 2 d for males. More than 50% of eggs were laid within 3 d after mating. Female reproductive fitness was reduced by > 85% if mating was delayed for 4 d. Males actively approached and courted females before mating occurred and females appeared to be less active. Males used their antennae, labial palps and wings to touch females when courting. Virgin males performed more mating attempts than mated males when competing for females. Sexual selection in *C. jactatana* did not support Darwin's sexual selection theory where females are more selective and males suffer the sexual selection effects. In this species, males appeared to be more selective than females. Both sexes preferred virgin to mated mates for mating. Males preferred young to old females for mating while females did not discriminate the male age when choosing a mate. Male body weight did not confer any mating advantage. However, females preferred males with longer antennae for mating. Light- and average-weight males presented a size assortive-selection while heavy males did not show any preference.

Regulation of pheromone biosynthesis in moths: PBAN & a G-protein coupled receptor.

R Jurenka
Iowa State University, Department of Entomology, 3222 Science II, Ames, IA, 50011, U.S.A; rjurenka@iastate.edu

Pheromone biosynthesis in most moths is regulated by PBAN (pheromone biosynthesis activating neuropeptide). This hormone is produced by the subesophageal ganglion and can be released into the hemolymph to stimulate biosynthesis in pheromone glands. PBAN acts directly on pheromone glands using cAMP and calcium as second messengers. Biosynthesis is activated by stimulating acetyl-CoA carboxylase or a reductase. Pharmacological evidence indicated the presence of a G-protein coupled receptor. To identify the receptor we utilized the finding that *Drosophila* contains PBAN-like peptides and thus a receptor for the peptides. Three *Drosophila* receptors had sequence homology to neuromedin U receptors from vertebrates. Neuromedin U will stimulate pheromone biosynthesis in *Helicoverpa zea* and *H. armigera* indicating cross-reactivity of the peptide and functional homology of the receptors. Based on sequence homology to the receptors from *Drosophila,* the open reading frame of a gene was isolated from mRNA obtained from pheromone glands of *H. zea*. The PBAN-receptor was cloned and expressed in Sf9 cells and using a calcium mobilization assay responded to PBAN in a dose-dependent manner. Additional peptides produced by the PBAN family were also tested. This represents the first identification of a receptor for the PBAN family of peptides with a known function in female moths.

Herbivore-induced volatiles alter plant resistance.

R Karban
Department of Entomology, UC Davis, Davis, CA 95616 USA; rkarban@ucdavis.edu

In response to damage, several plants have been found to emit volatiles that make neighboring plants more resistant to herbivory. When sagebrush is damaged in the field, airborne volatiles cause neighboring conspecifics to change chemically and suffer less damage by naturally occurring herbivores. Emissions of methyl jasmonate increase in the headspace of damaged sagebrush, making it a leading candidate as a volatile cue mediating increased resistance. Since many plant species respond to methyl jasmonate, it seemed plausible that various neighbors might induce resistance when growing near damaged sagebrush. Damage to sagebrush in the field caused neighboring wild tobacco but not other naturally occurring plant species to become more resistant. Preliminary laboratory experiments suggest that methyl jasmonate is sufficient, but not necessary, as an airborne cue.

Effective pheromone lures for monitoring the rice leaffolder moth, *Cnaphalocrocis medinalis* **(Lepidoptera: Crambidae).**

K Kawazu, T Kamimuro, H Kamiwada, K Nagata, T Matsunaga, H Sugie, T Fukumoto, T Adati, S Tatsuki
Graduate School of Agricultural and Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113-8657, Japan

Several factors affecting the attractiveness of traps baited with synthetic sex pheromone components of *Cnaphalocrocis medinalis* were examined in the laboratory and field. In the laboratory, among the four pheromone components, Z11-18:Ald, Z13-18:Ald, Z11-18:OH and Z13-18:OH, the major component, Z13-18:Ald, was shown to be an essential component for attraction and Z11-18:Ald was shown to be a potent synergist for the major component. The alcohols also showed an apparent synergistic effect in the laboratory bioassay when their mixture was combined with an aldehyde mixture. The addition of the geometric isomers of the four components at levels greater than 5% of the purified 4-component blend showed significant inhibitory effects on the pheromonal activity in the laboratory. In the field, no synergistic effect of the alcohols on the aldehydes was shown. A range of loadings of the pheromone rubber septa (0.01–3.42 mg) was tested and all remained attractive for at least one month with optimum attractiveness on 0.86 ㎎/septum. No significant effects were obtained when the ratio of Z11-18:Ald to Z13-18:Ald was changed. Rubber septa containing 0.86 mg of the four components (*E*-isomers 5%) at the natural ratio are being effectively used for monitoring.

Experimental evolution of improved learning ability in *Drosophila.*

TJ Kawecki, F Mery
Department of Biology, University of Fribourg, Chemin du Musée 10, CH-1700 Fribourg, Switzerland; tadeusz.kawecki@unifr.ch

While fitness benefits of animal learning are well understood, other questions concerning the evolution of learning remain open. How easily can improved learning ability evolve? Does evolution act on "general intelligence", or rather on learning abilities specialized to particular tasks and situations? What are the costs of learning ability? To address these questions we have exposed replicated populations of *Drosophila melanogaster* to long-term selection for improved olfactory-gustatory learning in the context of oviposition substrate choice. After over 20 generations of selection the experimental populations evolved markedly improved learning ability. The improved learning ability generalized to other tasks, which involved different stimuli, reward rather than aversion learning, and classic rather than operant conditioning. The selected populations also showed better learning ability as larvae. This indicates that the response to selection was based on evolutionary changes in general aspects of the learning and memory, involved in many forms of learning. Furthermore, compared to control populations, larvae of the selected populations showed lower competitive ability. Additional data excluded inbreeding as a potential cause of reduced competitive ability. Therefore we believe that the lower competitive ability of the experimental populations indicates a genetic cost of learning ability.

Patch leaving decisions of *Cotesia rubecula*: a synthesis.

MA Keller
Plant & Pest Science, Waite Campus, The University of Adelaide, SA 5005 Australia; mike.keller@adelaide.edu.au

Cotesia rubecula (Hymenoptera: Braconidae) is a solitary endoparasitoid of larval *Pieris rapae* (Lepidoptera: Pieridae). Adult P. *rapae* lay single eggs on a range of *Brassica* species (Brassicaceae) and other plants, and their larvae develop as individuals on host plants. *C. rubecula* parasitises first through fourth instars of *P. rapae.* A series of laboratory and field experiments has examined patch-leaving decisions of Australian *C. rubecula.* A range of factors has been shown to influence patch-leaving tendency of this parasitoid including host stage and density, the amount of plant damage by the host, recent oviposition experience of the wasp and the wasp's feeding status. Decisions are also influenced by the spatial distribution of host plants. This paper will develop a synthesis of experimental results and aims to identify the selective factors that have shaped the foraging behaviour of *C. rubecula.*

The infrared organ of the Australian "little ash beetle" ***Acanthocnemus nigricans*****: morphology of the specialised sensilla.**

E Kreiß, A Schmitz, H Schmitz
Rheinische Freich-Wilhelms-University Bonn, Institute for Zoology, Poppelsdorfer Schloß, D-53115 Bonn Germany; e.kreiss@uni-bonn.de

The Australian beetle *Acanthocnemus nigricans* (Coleoptera, Acanthocnemidae) approaches forest fires. The reason for this pyrophilous behaviour might be that larval development depends on burned wood. *A. nigricans* has a pair of infrared organs on the ventrolateral sides of its prothorax. Each organ consists of a cuticular "sensory disc"with a diameter of about 150µm. About 70 small cuticular sensilla were found mainly on the outer surface of the disc. The cone shaped cuticular peg of a sensillum is about 2µm in diameter. It has no pores and is surrounded by a cuticular wall. The single sensory cell of the sensillum shows some similarities to the "bauplan" of a mechanoreceptive sensory cell of a trichoid sensillum. However, three specialisations can be found: (i) the denitic outer segment is enveloped by a pronounced electron-dense structure, which most likely represents the hypertrophied denitic sheath. (ii) The membranes of the denitic inner segment and the soma show distinct infoldings which contain a high amount of mitochondria. (iii) No tubular body can be found.
As the cuticular disc responds to infrared radiation, it is likely that this specialised new type of insect sensillum may act as a thermoreceptor. Further examinations will have to test this hypothesis.

Pheromone response & mating activity in the consperse stink bug, *Euschistus conspersus.*

CH Krupke, VP Jones, JF Brunner
1100 North Western Ave., Wenatchee, WA 98801, USA ckrupke@wsu.edu

The consperse stink bug, *Euschistus conspersus* Uhler, has emerged as an important pest of pome fruit production in Washington state. My research has focused upon quantifying the behavioural response of this insect to its aggregation pheromone, methyl (2*E*,4*Z*)-decadienoate in an attempt to develop pheromone-based monitoring or management systems. I describe research investigating the pheromone-mediated aggregation behaviour in *E. conspersus* in the field and describe the subsequent development of a detailed diel activity profile for this insect. *E. conspersus* aggregations peaked at dusk, with mating occurring primarily at night. Sex ratios were equal in aggregations and both sexes were found to be polygamous, mating on successive nights but with different partners. Laboratory experiments were performed to investigate possible factors mitigating mate choice in this species. The significance of these findings with respect to the possible function of aggregation in this species is discussed, as well as the implications for management.

Molecular basis of pheromone binding, release, & inactivation.

WS Leal, Y Ishida
Department of Entomology, University of California-Davis, Davis CA 95616, USA; wsleal@ucdavis.edu

Insects perceive the world through small molecules - pheromones and other semiochemicals. Their odor-oriented navigation relies heavily on the ability of the olfactory system to selectively detect minute amounts of pheromones and reset the detectors in millisecond scale (by inactivating the chemical signals). Pheromone molecules enter the sensillar lymph through pore tubules in the sensillar wall, are solubilized upon being encapsulated by odorant-binding proteins (OBPs), and transported to the olfactory receptors (ORs). Upon interaction with negatively-charged sites at the denitic membrane, the OBP-ligand complex undergoes a conformational change that leads to the ejection of pheromone to activate the pheromone receptors. While bound to OBPs, pheromone molecules are protected from odorant-degrading enzymes (ODEs). In this presentation, we will (1) briefly discuss the molecular mechanisms of pheromone binding and release by focusing on the *Bombyx mori* system, i.e., how bombykol enters and leaves the binding cavity in BmPBP, (2) report the first odorant-degrading enzymes isolated from insect antennae to date, and (3) discuss the possible mechanism of enzymatic inactivation of pheromones.

Induction of preference for oviposition repellents originated from non-host plants by a specialist herbivore.

SS Liu, Y Li, Y Liu
"Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Road, Hangzhou 310029, China; shshliu@zju.edu.cn"

Repellents derived from non-host plants have been assumed to have a role to play in the behavioural manipulation of crop insect pests. However, behavioural responses to such repellents by insects have been rarely observed either in the laboratory or field. In laboratory and greenhouse experiments, we observed the responses of diamondback moth, *Plutella xylostella*, a special herbivore of crucifer plants to oviposition repellents derived from a non-host plant, *Chrysanthemum morifolium.* When provided with a choice between untreated Chinese cabbage and Chinese cabbage sprayed with an extract of *C. morifolium* in one arena, inexperienced females deposited 9-fold more eggs on the former than on the latter plant, demonstrating that the plant extract had substantial repellent effects on this insect. However, when the test adults were offered prior experiences of the plant extract and then exposed to the dual-choice of plants for oviposition, they laid significantly more eggs on the plant sprayed with the *C. morifolium* extract than that on the untreated plant. Further observations with neem-based materials also showed induction preference to these repellents by *P. xylostella.* Adult learning thus can render repellents derived from non-host plants to become ineffective or even attractive to this insect.

Non-host antifeedants in hylobius pine weevils: from lab to field applications.

F Schlyter, P Månsson, J Löfqvist, K Eriksson, K Sjödin, HE Högberg
"Chemical Ecology, Department Of Crop Sciences, Swedish University Of Agricultural Sciences, Po Box 44, Se-230 53 Alnarp, Sweden;
Per.Mansson@Vv.Slu.Se"

We searched for antifeedant activity in non-host woody plants to find new compounds for seedling protection of Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) against pine weevil feeding. In total, 38 species from 25 families were compared. The weevils removed less of both outer and inner bark in *Ilex*, *Evonymus*, *Populus*, *Syringa*, *Taxus*, *Tilia*, *Viburnum*, *Lonicera*, and *Sorbus* than on *Pinus*. In some plants, *Juglans*, *Fraxinus*, *Sambucus*, *Aesculus*, *Quercus*, *Corylus*, *Fagus*, *Salix*, *Alnus*, & *Acer*, the outer bark was removed by the insects but had an inner bark with antifeedant qualities. Bark of Linden, *Tilia cordata*, showed the best antifeedant qualities and was extracted and tested for antifeedant activity. The active extract was fractioned on silica gel. TLC and GC was used to trace chemical similarities between the fractions and resulted in merging the number of fractions down. The micro assay gave positive antifeedant activity in two adjacent fractions. These fractions were analyzed and nonanoic acid was found in both of them. Synthetic octanoic, nonanoic, and decanoic acid tested in the micro feeding assay had strong antifeedant activities against both sexes.

Characterization of genes encoding enzymes involved in bombykol biosynthesis.

S Matsumoto, K Moto
Riken, Wako, Saitama, 351-0198, Japan; smatsu@riken.jp

In the biosynthesis of class I-type Lepidopteran pheromone components, the key enzyme required to produce the oxygenated functional groups is pgFAR. This enzyme converts fatty-acyl pheromone precursors to their corresponding alcohols, which can then be, depending on the moth species, further modified via acetylation or oxidation reactions. In experiments designed to characterize the pgFAR in *B. mori*, we have isolated a cDNA clone encoding a protein homologous to a FAR from the desert shrub, *Simmondsia chinensis*, commonly known as jojoba. The deduced amino acid sequence of this clone predicts a 460 amino acid protein with a consensus NAD(P)H binding motif within the amino terminus. Northern blot analyses indicated that the 2-kb transcripts of this gene are specifically expressed in the pheromone gland at one day prior to adult eclosion. Functional expression of this gene in the yeast *Saccharomyces cerevisiae* not only confirmed the long-chain FAR activity but also indicated a distinct substrate specificity. Finally, the transformed yeast cells evoked typical mating behavior in male moths when cultured with the pheromone precursor fatty acid. We will also refer to a bifunctional desaturase utilized in the production of the conjugated diene system from which bombykol biosynthesis is dependent on.

"Come on baby light a fire": the reproductive biology of *Actebia fennica.*

JN McNeil, M Cusson, Everaerts, E Forcier, W Francke, T Tolasch
Department of Biology, University of Western Ontario, London, ON., Canada, N6A 5B7; jmcneil2@uwo.ca

Black army cutworm out breaks are associate recently burned areas, which are unpredictable in time and space. Our wind tunnel experiments showed that while females exhibit oriented, upwind flight in smoke plumes males do not. We also examined the effect of smoke volatiles the temporal changes in juvenile hormone biosynthesis and oocyte development, as well as on the age at which females first exhibited the behaviour associated with the emission of the sex pheromone. All data support the hypothesis that volatiles from burnt vegetation serve as " kairomones", accelerating sexual maturation in females. However, mated females, held in the presence of volatiles that stimulated sexual maturation, actually laid fewer eggs. An ecological hand-waving scenario will be proposed to explain the results obtained to date. We will also discuss how the recent identification of different smoke compounds detected by females might subsequently be used in management programmes for this pest species.

On the kairomonal attraction of adults & nymphs of *Elatophilus* spp. (Heteroptea: Anthocoridae) to sex pheromones of *Matsucoccus* spp. (Hemiptera: Matsucoccidae).

Z Mendel, D Ofer, M Branco, JC Franco, E Dunlkelblum
Department of Entomology, ARO, the Volcani Center, Bet Dagan, 50250, Israel; zmendel@volcani.agri.gov.il

While kairomonal response of insect predators to the sex pheromone of the insect prey has been rarely documented, our recent studies proved consistently that the female sex pheromones of *Matsucoccus josephi* , *M. feytaudi* and *M. matsumurae* are powerful long range attractants for *Elatophilus* spp. Examining the attraction to the pheromone and analogs of seven *Elatophilus* spp. revealed a clear species specific attraction displaying by these predators. Similarly to their conspecific adults the nymphs of *E. hebraicus, E. crassicornis* and *E. nigricornis* are also lured by the specific sex pheromone. It seems that sex pheromones of *Matsucoccus* serve *Elatophilus* spp. as aggregation kairomones and as sexual stimulants. *Elatophilus* spp. display courtship behavior and mate frequently in arenas baited with the pheromone. When the predator population is high, most of the females that congregated around a pheromone source were already mated but displaying none or few visible eggs in the ovaries. We suggest that the typical group movement displayed by the nymphs is determined by their attraction to the pheromone. This behavior may increase survival through "a better feed tracing" and "safety in numbers". Female first mating probably occur soon after molting within their own group before being lured to a pheromone source.

Odor perception & odor learning in honeybees.

R Menzel, CG Galizia, S Sachse, P Syzszka, M Weidert
Neurobiologie, Freie Universität Berlin, Königin-Luise-Str. 28-30, 14195 Berlin, Germany

Honeybees discriminate a large range of odors, and learn odors as signals for food. We have used optical imaging and intracellular recording techniques to examine the neural substrates of odor coding and memory formation in the antennal lobe (AL) and the mushroom bodies (MB). Odors elicit combinatorial patterns of activity in the glomeruli of the AL. Imaging of the input region of the mushroom bodies reveals that odors are represented in specific patterns of microglomerular activation. A comparison of the dynamics of the odor responses shows that mushroom body intrinsic neurons code odors in a sparse way with a small number of spikes per stimulus and a small number on activated Kenyon cells. Odor learning leads to an enhancement of the synaptic transmission at the input synapses to the Kenyon cells that respond to the trained odor (CS+), and a reduction of synaptic efficiency to the non trained odor (CS-). A model will be presented that captures the results of our electro- and optophysiological recordings, and assigns particular functions to the mushroom body in the bee brain.

Male-produced aggregation pheromone of *Neoclytus acuminatus acuminatus*.

JG Millar, ES Lacey, M Ginzel, LM Hanks
Dept. of Entomology, University of California, Riverside CA 92521, USA; jocelyn.millar@ucr.edu

The red-headed ash borer, *Neoclytus acuminatus acuminatus* (F.) (Coleoptera: Cerambycidae) is endemic to North America, where it infests a variety of hardwood trees. It also has been accidentally introduced into Europe and possibly New Zealand. In the field, we observed males performing a stereotyped calling behavior which provided the first indication of pheromone production by male *N. a. acuminatus*. This behavior has not been reported for any other cerambycid species. Insects of both sexes were attracted to caged males but not to females. We report the identification and field testing of a male-produced aggregation pheromone for this species. During field trials, females of another cerambycid species, *Curius dentatus* Newman, were attracted to traps baited with some of the test compounds, suggesting that one of more of the test compounds were also part of the sex pheromone of this relatively unknown species as well. These may be the first examples of cerambycid pheromones with an activity range of tens to a huned meters or more.

Pheromonal & vibrational signals of stink bugs in the genus ***Chlorochroa*****.**

JG Millar, G Bagwell, HS Ho
Dept. of Entomology, University of California, Riverside CA 92521, USA; jocelyn.millar@ucr.edu

Stink bugs in the genus *Chlorochroa*, similar to other phytophagous stink bugs, use a combination of pheromonal and substrate-borne vibrational signals in their reproductive behaviors. The pheromones are male-produced, and probably act as attractants over longer distances, whereas vibrational signals (songs) are produced by both sexes once the bugs are on the same plant. The vibrational signals are sex- and species specific, with males and females producing a repertoire of calling songs as orientation cues, and courtship songs once the bugs are close together or in contact. The pheromonal and vibrational signals will be compared and contrasted for three sympatric *Chlorochroa* species, and the roles of these signals in intraspecific communication will be discussed.

Fruitspotting bugs.

CJ Moore, GK Waite, JR Aldrich, A Zhang
Locked Bag 4, Moorooka, QLD, 4105, Australia; chris.moore@dpi.qld.gov.au

The fruitspotting bugs, *Amblypelta nitida*, and the closely-related *Amblypelta lutescens*, are serious pests of tropical and sub-tropical fruit and nut crops in Queensland and northern New South Wales. Current control relies on the frequent application of insecticides, with recent investigations focussing on promising soft-option strategies such as restricting insecticide application to fruitspotting bug hotspots, and the use of SurroundÒ to deter feeding. Behaviour-modification approaches are a legitimate component of clean-green management strategies, and to this end, investigations of the insects' semiochemistry were commenced 14 years ago. Despite early breakthroughs in the chemistry studies, subsequent progress has been sporadic. The major component of male-derived volatiles of *A. nitida* was shown to be a mono-epoxide of (E)-b-ocimene, having the trivial name, myroxyde; and of *A. lutescens*, (-)-(3R)-(E)-nerolidol. The absolute configuration of the former compound has been defined through the development of efficient synthetic strategies and the application of SPME sampling technology. Recent gas chromatography-electroantennography studies have confirmed myroxide, along with the minor compounds, nonanal and decanal, as stimulants of antennal response in *A. nitida*. The attractiveness of blends of racemic myroxyde and the aldehydes, using a new clear-plastic football-shaped trap, is being investigated.

Exposure to allelobiotic substances has a physiological effect on cereal plants, evidenced by significant changes in the pattern of biomass allocation and changes in leaf temperature.

Isolation & characterisation of a putative aggregation pheromone component for the striped cucumber beetle, *Acalymma vittatum* (F) (Coleoptera: Chrysomelidae).

BD Morris, RR Smyth, S Franke, W Francke, SP Foster, MP Hoffmann, WL Roelofs
Department of Entomology, North Dakota State University, PO Box 5346, Fargo, North Dakota 58105, USA; bruce.morris@ndsu.nodak.edu

Male-produced aggregation pheromones have previously been identified from a limited number of Chrysomelids; the hydroxy-ketones (*S*)-3,7-dimethyl-2-oxo-6-octene-1,3-diol from the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) [1], and (*E*)-8-hydroxy-6-methyl-6-octen-3-one from the cereal leaf beetle, *Oulema melanopus* L. [2]. Himachalene and cadinene sesquiterpenes from *Phyllotreta cruciferae* and three *Apthona* spp. of flea beetles were electrophysiologically active [3]. Field trapping studies showed that feeding male *A. vittatum* attracted significantly more congeners than feeding females, or undamaged cucumber plants, indicating that it may also use an aggregation pheromone [4]. GC-EAD studies were carried out using airborne collections from feeding beetles, or SPME collections, and male or female antennae. One component of male collections consistently gave a strong EAD response, and was absent from collections from female beetles. This putative pheromone was initially characterised by GC-MS and micro-reactions. More than 3000 beetle-days of collection on Porapak resulted in sufficient compound for extensive 1- and 2-D NMR spectroscopic studies, and FTIR. These allowed complete structural characterisation of the pheromone. The only closely related compounds are antibiotics of microbial origin, which were compared with the pheromone by NMR. Currently, efforts to synthesize the pheromone, and test for behavioural activity are in progress.

Sex pheromone of a carpenter moth, *Cossus insularis* **(Staudinger).**

K Nakamuta, X Chen, T Nakashima, F Mochiduki, T Fukumoto
PO Box 16, Tsukuba Norin Kenkyu Danchi-nai, Tsukuba, Ibaraki 305-8687, Japan; nakamuta@ffpri.affrc.go.jp

Cossus insularis (Staudinger) (Cossidae: Lepidoptera) is a woodborer found in Honshu, Kyushu and Tsushima Island of Japan. The larvae excavate their galleries in a group on twigs or trunks of the broad-leaved trees such as willow trees, pear trees, chestnut trees, and cause damage and often mortality of the trees. To utilize sex pheromone for monitoring or controlling the borers, sex pheromone of *C. insularis* was identified. Combined gas chromatography-electroantennographic detection (GC-EAD) analysis of airborne volatiles collected from unmated female moths by a solid-phase microextraction (SPME) showed that two volatile compounds elicited significant electroantennographic responses from the antennae of male moths. These two volatile compounds collected from female moths were identified as (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate by mass spectral and retention index comparisons with synthetic standards. In field bioassays, sticky traps baited with a lure of a 4:1 blend of synthetic (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate captured significantly large number of male moths, while unbaited traps captured no male moths. These results indicate that sex pheromone of *C. insularis* is a mixture of (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate.

Plant/plant communication-herbivores & their natural enemies: experiments with spring-sown barley.

V Ninkovic, R Glinwood, J Pettersson
Swedish University of Agricultural Sciences, Department of Entomology, Box 7044, 75007 Uppsala, Sweden; velemir.ninkovic@entom.slu.se

Experiments with a barley crop and weeds have shown that effects of chemical communication between plants can be traced in a tritrophic perspective as follows:
Exposing cereal plants to allelobiotic volatiles from neighbouring plants and root exudates from aggressive weeds decreases the acceptability of the exposed plants for aphids. This happens in interactions between different cultivars of barley (*intra-species*), and between cereals and a number of aggressive weeds (*inter-species*).
Exposure to allelobiosis from weeds causes barley plants to become more attractive to aphid natural enemies, a ladybird *Coccinella septempunctata.*
The results suggest that plant responses to allelobiosis is a preparation for coexistence with other plants and this is a basis for follow up effects in higher trophic levels. The positive effect on searching behaviour of polyphagous predators may increase the ecological success of "listening" plants in a mixed plant stand and, also have negative effects on herbivore plant acceptance.

Artificial substrate bioassay for testing oviposition of the southern green stink bug, *Nezara viridula* (L.) conditioned by soybean plant chemical extracts.

AR Panizzi, M Berhow, RJ Bartelt
Embrapa-Labex-USA, Crop Bio-Protection, USDA/ARS, 1815 North University Street, Peoria, IL 61604, USA; panizzia@ncaur.usda.gov

The southern green stink bug, *Nezara viridula* (L.) (Heteroptera: Pentatomidae) is effectively controlled with egg parasitoids, and egg production is an important component of this strategy. Therefore, a laboratory bioassay was developed for testing its oviposition preference toward chemicals extracted from soybean pods and leaves. An artificial substrate (cheesecloth) was stretched over a wooden ring (embroidery hoops), treated with plant extracts or chromatographic fractions, and then exposed to adult stink bugs to assess oviposition preference. Freeze-ied soybean leaves and pods were extracted with hexane, then with methanol, and finally with water. The organic solvent extracts were fractionated by liquid chromatography, on a C_{18} reverse phase column, on a normal phase silica column, and by thin layer chromatography (TLC) on silica gel. The methanol extract of pods showed the greatest bioassay activity. The most active reverse phase fraction derived from this extract was eluted with 20% methanol in water. After subjecting this fraction to chromatography, the greatest activity occurred in the fraction eluted with 60% methanol in methylene chloride. TLC gave no single fraction with demonstrated activity, but the recombined fractions were again active, indicating that multiple components elicit oviposition. Hairs (long and short) on the female genitalia might be involved in chemical and/or mechanical recognition of oviposition stimulants.

The chemistry of sexual deception in Australian orchids.

R Peakall, FP Schiestl, W Francke
School of Botany & Zoology, Australian National University, ACT, 0200 Australia; rod.peakall@anu.edu.au

Pollination by sexual deception is among the most intriguing of orchid pollination syndromes. Odors are well established as the primary stimuli for sexually attracting the male insect pollinators in these orchids, but we have only begun to discover how many, and which compounds are involved. Using gas chromatography with electroantennographic detection (GC-EAD), GC-mass spectrometry (GC-MS) and GC-IR-spectrometry we have determined that a single active compound, Chiloglottone, produced by both females of the wasp *Neozeloboria cryptoides* and flowers of the orchid *Chiloglottis trapeziformis* is active in antennal neurons of the pollinators, males of *N. cryptoides*. This compound, tested as synthetic copy, proved to be equally attractive to natural extracts of flowers and wasps. We are now determining the chemical identity of sexual attractants in other *Chiloglottis* orchids. GC-EAD and GC-MS analysis indicates only 1 or 2 active compounds are involved and these compounds are related to Chiloglottone. Pollinator specificity and associated reproductive isolation is therefore likely under simple genetic control in these orchids. Thus rapid sympatric speciation is possible. We will present an update of our multifaceted research program that is exploring this hypothesis of sympatric speciation.

Biochemistry & evolution of floral scent.

E Pichersky
Department of Molecular, Cellular and Developmental Biology, University of Michigan, 830 N. University, Ann Arbor, MI 48109-1048, USA; lelx@umich.edu

Floral scents of plants are often complex mixtures of volatiles derived from several metabolic pathways. The number of presently known volatile compounds from flowers is approaching a thousand, and new compounds are constantly being discovered in various plant species. Closely related species have distinct volatile profiles that can be discriminated by specialized insect pollinators, thus limiting gene flow across species boundaries. The ability of related plant species to synthesize different volatiles in their flowers is sometimes due to differential gene expression. However, new enzymes that catalyze the formation of new floral scent components are constantly evolving through the process of gene duplication and divergence, allowing for the majority of floral scent divergence. It has been shown that very small changes in protein sequences can lead to the ability of the changed enzymes to catalyze the transformation of drastically different substrates, leading to the production of new floral scent compounds. Such evolution is facilitated by the presence of large gene families in plant genomes that already encode similar enzymes with slightly different substrate specificities; the large number of such genes makes genes duplications even more likely to occur.

Herbivore-induced plant volatiles identified from interactions at higher trophic levels: persistent effects on plants in the laboratory & field.

TJA Bruce, JL Martin, JA Pickett, BJ Pye, LE Smart, LJ Wadhams
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom; john.pickett@bbsrc.ac.uk

In many cases, volatiles produced by plant defensive mechanisms during herbivory act directly to repel insect attack, and may have indirect effects by attracting predators and parasitoids of the pest insect. *cis*-Jasmone occurs as a component of flower volatiles, but can also be produced by damaged vegetative tissues. In an olfactometer bioassay, *cis*-jasmone was repellent to alatae of the grain aphid, *Sitobion avenae* (Homoptera: Aphididae). *cis*-Jasmone is a catabolite of the stress-produced jasmonic acid, which can induce plant defence, but had previously been considered only as a biological sink for the jasmonate pathway. However, bean plants, *Vicia faba*, exposed to *cis*-jasmone vapour were more attractive to the parasitoid *Aphidius ervi*. Moreover, wheat, *Triticum aestivum*, seedlings sprayed with formulated *cis*-jasmone 24 h previously were less susceptible to attack by *S. avenae* than control plants. In field simulator studies, significantly fewer alate *S. avenae* settled on *cis*-jasmone treated plants over a 24 h period. The intrinsic rate of population increase, r_m, of *S. avenae* apterae was reduced on *cis*-jasmone treated seedlings. In a series of small-plot experiments conducted over four years, *cis*-jasmone applications reduced cereal aphid populations infesting wheat in the field.

Polyphagy in *Helicoverpa armigera*: primary host plants, host-associated volatiles & neurosensory stimulation.

C Rajapakse, GH Walter, CJ Moore, C Hull, B Cribb
Department of Zoology and Entomology, School of Life Sciences, The University of Queensland, Brisbane, 4072, Queensland, Australia; s001370@student.uq.edu.au

Headspace volatiles of a subset of known host plants and non host plants of *Helicoverpa armigera* were screened by the use of Gas Chromatography linked with Electroantennography. Pigeon pea (*Cajanus cajan* L.) is one of the most attractive hosts to *H. armigera* in India, so was included as the primary reference plant to compare the presence and concentrations of electrophysiologically active chemicals across the test plants. Eight active compounds were identified in pigeon pea headspace volatiles in relatively higher concentrations. They include three green leaf volatiles ((E)-2-hexenal, Z-3-hexenylacetate and Z-3-hexenyl-2-methylbutyrate) and five monoterpenes (α-pinene, β-myrcene, Limonene (E) – β-ocimene, and linalool). The other known host plants have a small subset of these chemicals, whereas the non host plants contained even fewer. Green leaf volatiles were prominent in the host plants. The Australian *H. armigera* individuals used in this study did not respond to the group of sesquiterpenes present in pigeon pea headspace, and thus differ from their Indian counterparts. The physiological status and the sex of the moths had no effect on their responses to these chemicals. The study exemplifies how some host plants species are primary targets for searching moths, whereas the other host plants are likely to be incidental targets.

Experimental evidence of semiochemicals modulating the behavior of *Loxosceles intermedia* Mello-Leitão, 1934 (Araneae: Sicariidae).

EN Ramires, FA Marques, JD Fontana, GM Fraguas, LGC Santos, EM Silva
UTP, FACBS, Ciências Biológicas, Project SESA-CPPI-PRONEX-PR-Fundação Araucária-CNPq, RUA Marcelino Champagnat, 505, Curitiba, Paraná, 80710-250, Brazil; eduardo.ramires@utp.br

There is evidence of semiochemicals modulating the behavior of many species of spiders, but few reports regarding the isolation, chemical identification, and synthesis of semiochemicals in these arthropods. Our search is experimentally focused on the occurrence of volatile semiochemicals modulating the behavior *of L. intermedia*, a venomous spider that constitutes a serious public health problem in Curitiba, Brazil (3,334 people bitten in 2002). An olfactometer of rectangular arena was used. The individuals employed as stimuli were put in metallic cages, positioned against air flow. We tested all possible combinations of males and females as stimuli or test individuals. For each stimuli trial different individuals of *L. intermedia* were used. Tests were made on summer and winter 2003, and summer 2004. Only females tested during summer significantly attracted males, indicating a volatile pheromone produced during the summer season. Pheromone glands are not described for spiders, but we suppose the secretory cells are less active during winter. This is the first evidence of semiochemical in the *Loxosceles* genus. Studies involving the extraction and GC-MS identification of the putative semiochemical(s), as well as further experimental observations are being carried out.

Evolution of pheromone biosynthesis in moths.

W Roelofs, B Xue, A Rooney
Dept. Entomology, Cornell University, Geneva, NY 14456, USA wlr1@cornell.edu

In addition to their role in metabolism, acyl-CoA desaturases in moths play a key role in female sex-pheromone biosynthetic pathways. These atypical membrane-bound sex pheromone desaturases have evolved a wide range of regio- and stereospecificities. Recently, it was shown that changes in pheromone blends in moths of the genes *Ostrinia* result from unusual molecular mechanisms that influence the expression and evolution of sex pheromone desaturases. In this talk, an overview of sex pheromone desaturase evolution is presented that covers the phylogeny and evolutionary patterns of sex pheromone genes, the moth sex pheromone molecular clock, and genomics of sex pheromones.

Dynamic irritability in parasitoids.

BD Roitberg
Biological Sciences, Simon Fraser University, 8888 Univ. , Burnby, BC, Canada V5A 1S6;   roitberg@sfu.ca

Parasitoids may encounter other organisms while foraging on host-containing patches. Some of those organisms post direct threats to the foraging wasp. On the other hand, the patch provides resources that that can directly contribute to the parasitoid's reproductive success. Thus, the parasitoids must "decide" how to tradeoff threats versus benefits. Further complicating matters are several parameters that can affect costs and benefits, including: (1) the threatening organism may or may not attack, (2) the patch will diminish in value over time and (3) forager state, in particular, egg load, body mass and energy state. For example, heavier wasps may be less agile or slower in escape than light individuals. Here I consider 2 mutually exclusive decisions, continue foraging vs. abandon the patch as a function of the three aforementioned parameters. In my talk I will develop state-dependent theory and test some predictions from the theory as to conditions under which parasitoids will abandon patches following encounters with threats. I will show both theoretically and experimentally that sensitivity to threats are dynamic i.e. they depend upon parasitoid internal state and perception of danger.

Herbivore-induced volatiles: variability in production & variability in natural enemy response.

MW Sabelis, J Takabayashi, K Shiojiri, T Maeda, M Kant, B Sznajder, M van Wijk
Section Population Biology, Institute For Biodiversity And Ecosystem Dynamics, Universtiy Of Amsterdam, Kruislaan 320, 1098 Sm Amsterdam, The Netherlands; sabelis@science.uva.nl

Ecological interactions between plants and the enemies of their enemies are often mediated by information available as blends of volatile chemical compounds. Because the information is under control of the sender and the receiver cannot check its validity from a distance, the receiver has to base its decisions on previous experiences and this creates opportunity for the sender to cheat. Hence, we expect conflicts of interest between the sender and the receiver. We will present recent evidence for plants that cheat, i.e. produce amounts of chemical information that does not reflect the number of herbivores, so that the predators fail to select plants harbouring the highest densities of their prey. We will also present evidence showing that predatory arthropods can only partly cope with this plant-generated variability by associative learning. Based on theoretical models of the evolution of chemical languages and classic predator-herbivore-plant models extended with an information-perception interphase, we predict that the emergent non-linearities in plant-predator communication have dramatic consequences for the evolutionary and ecological dynamics of tritrophic interactions.

Influence of temperature on mechanosensory host location by vibrational sounding in parasitic wasps.

J Samietz, S Kroder, D Schneider, S Dorn
Swiss Federal Institute Of Technology Zurich (Eth), Applied Entomology, Clausiusstr. 25/Nw, Ch-8092 Zurich, Switzerland; joerg.samietz@ipw.agrl.ethz.ch

Although temperature is one of the most important environmental parameters, there are relatively few studies dealing with its influence on ecological processes between trophic levels, e.g. on host-location mechanisms of parasitoids. Certain parasitic wasps use self-produced vibrations transmitted on plant parts to locate their immobile hosts (lepidopteran pupae) by resonance signals. This mechanosensory mechanism, vibrational sounding, depends both on physical cues of the environment and physical activity of the parasitoid and, therefore, should depend on ambient temperature and the likely adaptation of the insects to their environmental temperature range. We analysed such influences by choice experiments with plant-stem models in the temperate ichneumonid *Pimpla turionellae* and the tropical relative *Xanthopimpla stemmator*. Our results show a substantial effect of temperature on host-location activity and on the success of the process. Outside optimum ranges, the performance of the wasps decreases both at low and high temperatures. The tropical and the temperate species show substantial differences in their temperature range for successful host location and also with respect to their performance at equal temperatures. Using laser Doppler vibrometry in *Pimpla turionellae* we can furthermore show a modification of the self-produced vibrational signals by the ambient temperature with respect to both frequency and intensity.

Hostile behavior to neighbors induced by encounter experience in the Japanese queenless ant, *Pristomyrmex pungens.*

S Sanada-Morimura
Laboratory of Animal Population Ecology, Department of Agriculture, Okayama University, 1-1-1 Naka, Tsushima, Okayama 700-8530, Japan; sanada@cc.okayama-u.ac.jp

Ant workers cooperate among nestmates within colonies while they perform strong hostile behavior against non-nestmates. It is likely that neighbors are competitors for adjacent resources while strangers are transients from distant colonies. It might be adaptive for a species having the powerful competitors to discriminate neighbors from strangers and selectively attack the former. I hypothesized therefore that the workers can distinguish members of neighboring colonies from those of distant colonies based on some presumable cues in the ant *Pristomyrmex pungens.* To test this hypothesis, I created neighbors and strangers by an experimental method and compared the ant's hostile behavior toward the neighbors and strangers. The ants which had direct encounter experience with the neighbors could distinguish the neighbors from the strangers and showed more strong hostile behavior toward the former. The recognition of the neighbors was maintained for at least ten days after the most recent encounter. Nestmates without the encounter experience showed no hostile behavior toward the neighbors. This finding suggests that information about neighbors (probably colony odor) is not transmitted to nestmates within colonies. Aggressiveness toward neighbors therefore appears to be caused and maintained on the basis of individual memories from direct contact.

Infrared sensory systems in pyrophilous buprestid beetles.

H Schmitz
Institute for Zoology, University of Bonn, D-53115 Bonn, Germany; h.schmitz@uni-bonn.de

Jewel beetles of the genera *Melanophila* (distributed nearly all over the world except Australia) and *Merimna* (with the only species *atrata*, endemic to Australia) approach forest fires. The reason for this pyrophilous behaviour is that their xylophagous larvae only can develop in burnt wood. Both genera have infrared (IR) receptors to cope with their thermal environment. However, IR receptors are totally different in *Melanophila* beetles and in *Merimna atrata*. In *Merimna* 1 to 3 pairs of IR receptor can be found on the ventrolateral parts of the abdominal sternites. Receptors are innervated by a large multiterminal thermoreceptive neuron and function according to the bolometric principle. In *Melanophila* beetles, two pairs of metathoracic pit organs can be found directly behind the coxae of the middle legs. Each pit organs houses about 70 cuticular sensilla which function according to a photomechanic principle. Physiological and behavioural data suggest that *Melanophila* beetles may use their IR receptor for the detection of remote fires. On the other hand, *Merimna* may use its receptors in the near range to prevent to land on a hot surface. The fundamentally different structure and function strongly suggest that IR receptors have evolved independently in the two pyrophilous buprestid genera.

Fire recognition on the basis of insect olfactory systems.

S Schütz
Institut für Forstzoologie und Waldschutz, Georg-August-Universität Göttingen, Büsgenweg 3, D-37077 Göttingen; stefan.schuetz@forst.uni-goettingen.de

Insect antennae are morphologically and physiologically highly specialised organs for odour perception. Their sensitivity, selectivity, and response time cannot be matched by any technical method of trace analysis. Utilisation of these unique abilities of insects for trace analytical purposes demands a thorough adaptation of technical devices to the special needs of insect antennae. Yet approaches using electroantennogram (EAG) techniques are highly sophisticated, however, detailed examination of sensitivity and cross-reactivity of antennal responses to binary mixtures of odours are needed. By providing these data, practical applications of biosensors on the basis of intact insect antennae as a sensitive odour detecting and recognizing device become more feasible. Besides sex pheromones, insect antennae are able to detect a broad range of odours specific to their habitat. The Black jewel beetle (*Melanophila acuminata*) as well as the Australian pyrophilic beetle *Merimna atrata* shows a very high sensitivity to wood-fire specific volatiles. The results of first field tests of the biosensor will be reported. Practical application and technical development of the biosensor in fire early warning systems will be discussed.

Fire recognition based on new technologies.

A Eberheim, P Schieberle, S Schütz, D Kohl
Institute of Forest Zoology and Forest Protection, Universität of Göttingen, Büsgenweg 3, D-37077 Göttingen; stefan.schuetz@forst.uni-goettingen.de

In Europe, huneds of human beings are killed and huneds of millions € damage to property are inflicted by fires in industrial, domestic or forestry areas every year. In many cases, losses of lives and property could have been prevented by efficient fire recognition and early warning systems. For this reason, development of fire recognition systems is a rapidly growing field integrating techniques as IR/vis- detection, inorganic and organic trace gas detection and aerosol analysis. Driven by results of biological research about fire recognition mechanisms used by animals, technical research and development was focussed to IR detection and organic trace gas detection i.e. "sensors for burnt smell". Especially tin oxide sensor elements showed favourable characteristics. Their high sensitivity and selectivity to hydroxylated and phenolic compounds in combination to low cross-reactivity with water and carbon monoxide mimics highly efficient biological fire detection systems. For sensor evaluation the HRGC/SOMMSA (High resolution gas chromatography/selective odorant measurement by multisensor array) approach has been established.

Pheromone trapping of *Halyomorpha halys* in the eastern USA.

PW Shearer, JR Aldrich, A Khrimian
Rutgers U. Ag. Res. & Ext. Ctr. 121 Northville Rd. Bridgeton, NJ 08302 USA; shearer@aesop.rutgers.edu

The brown marmorated stink bug, *Halyomorpha halys* (Heteroptera: Pentatomidae), is an introduced species in the USA; first being collected in eastern PA in 1996, and subsequently spreading to NJ and MD. We have observed this bug feeding on fruit, vegetables, soybeans, and many ornamental plants. Studies were initiated to evaluate the effectiveness of attracting and capturing *H. halys* in pheromone baited traps. Various purities of synthetic *Plautia stali* (2E,4E,6Z-1:COOMe) and *Thyanta pallidovirens* (2E,4Z,6Z-1:COOMe) (Heteroptera: Pentatomidae) aggregation pheromones were loaded onto rubber septa (2.5 mg/septum) along with a UV inhibitor and anti-oxidant. The first test was started on 12 September 2003. Individual treated septa were placed inside clear football-shaped traps that were hung in fruit trees near known *H. halys* infestations. *Halyomorpha halys* male and female adults and nymphs were captured in traps baited with *P. stali* or *T. pallidovirens* pheromone. A second test consisting of various purities (76, 88, and 94% pure) of *P. stali* aggregation pheromone and 2 types of traps was initiated on 6 October 2003. Football traps with the 76% purity pheromone captured more *H. halys* than traps with the 88 and 94% purity pheromone.

Chemical ecology of the house dust mite: a potential alternative to their control?

AC Skelton, MA Birkett, MM Cameron, JA Pickett
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ; Amanda.skelton@bbsrc.ac.uk

House dust mites (HDM) *Dermatophagoides farinae* and *Dermatophagoides pteronyssinus* are a significant health problem; their faeces are highly allergenic and can cause atopic diseases such as asthma, rhinitis, and dermatitis. Up to 85% of people with asthma in the UK (4.3 million) are sensitive to HDM allergens. Chemical acaricides and regular vacuuming are recommended to control HDM. However, areas which have been treated for HDM populations are frequently re-colonized. There is a basic understanding of HDM behaviour, but very little is known about their chemical ecology. Once identified, HDM-derived semiochemicals (behaviour-modifying chemicals) may be used as an alternative novel approach to control HDM populations in the home by manipulating their behaviour. Potential semiochemicals were extracted from *D. farinae* and *D. pteronyssinus*, and analysed using gas chromatography (GC), and mite-specific peaks were tentatively identified using coupled GC-mass spectrometry (GC-MS). A suitable bioassay was developed to test the mite-derived extracts. A Y-tube olfactometer was modified to accommodate the HDM, which has not previously been reported as a bioassay method. Extracts and components of these extracts were tested and behavioural activity was demonstrated.

Contextual control of learning in insects.

BH Smith
Department of Entomology, 318 W. 12th Ave., Ohio State University, Columbus, OH 43210; smith.210@osu.edu

Insects are very adept at learning the association of many types of stimuli with biologically important events such as the occurrence of food, a mate, or a predator. There are several behavioral mechanisms associated with this type of learning, and they all in general allow animals to prepare for the occurrence of the event – e.g., flee, fight, or feed. Insects are equally adept at learning, through two or more means, to ignore stimuli that are not associated with important events. This prevents overuse of limited processing capacity associated with attention. With either type of learning, single stimuli are rarely perfectly reliable. The probability of an event (e) given the occurrence of a stimulus (s) - $p[e|s]$ - might be above 0 but well below 1. But several stimuli together as a "context" might provide a more reliable predictor of an event. Associations among stimuli might underlie sensitive contextual control of a response. For example, in the context of S2 $p[e|S1]$ might be much closer to 1 than in the context of S3. Furthermore, the meaning of S1 might be entirely different in S2 and S3. The presentation will review evidence for this type of contextual control of learning in insects.

Optimal patch leaving decision rules for parasitoids in patchy environments: an individual based model.

T Spataro, C Bernstein
Ecologie des Populations et Communautés, Institut National Agronomique Paris-Grignon, 16 rue Claude Bernard, 75231 Paris cedex 05, France;
spataro@inapg.fr

Experimental results have shown that when foraging for hosts in heterogeneous environments, parasitoids use a wide diversity of patch-leaving decision rules. More than the environmental stimuli implicated, it is the way they are integrated that appears as a major component of this diversity. Previous theoretical models suggest that simple rules based on environmental cues can be optimal, and that resource distribution strongly influences which is the optimal rule. However, these results were obtained considering very specific environmental conditions. Others authors claim that strong interactions exist between the parasitoids' ability to assess host availability when arriving on a patch and the best way to use the information subsequently collected while foraging in this patch. We have built an individual-based model in which parasitoids use realistic patch-leaving decision rules. Considering a large range of scenarios (depending on host distribution, environment size, parasitoid density, etc), we identify the kind of rule that is adaptive in each case. This allows us to test and discuss the robustness of previous theoretical results and to confirm or invalidate hypotheses inferred from experimental work. We show that environmental conditions have a determinant influence not only on the reliability of the initial information but also on the best use of other sources of information.

Carrion mimicry in the dead horse arum.

MC Stensmyr, I Urru, AM Angioy, BS Hansson
Div. Chemical Ecology, SLU, Alnarp, Sweden; Marcus.stensmyr@vv.slu.se

Some plants rely on deception for pollination. These plants typically mimic a favourable insect resource. Attracted insects are subsequently exploited as unrewarded pollinators. Here we describe the multisensory targeting mimicry of the dead horse arum, *Helicodiceros muscivorus*. The arum produces a characteristic odor, most similar to a carcass. Odor collections from the plant and from carrion contain the same active odor components, eliciting identical antennal responses in blowflies. Addition of these odor components to scentless flowers restores their attractiveness to the same level as plants with a natural scent. The arum is furthermore thermogenic, i.e. it produces heat. The arum is capable of producing over 10°C above ambient. Although, heat production is a fairly well known phenomenon, few studies have provided direct experimental evidence as to what function heat plays. We have shown that the heat in the arum primarily serves as a behavioral altering stimulus, enhancing threefold the likelihood that the flies will enter the trap chamber of the plant. Accompanying the olfactory and thermal cues are also visual and tactile cues, reinforcing the overall carrion appearance. The dead horse arum serve as a striking example of how a plant during evolution can acquire the ability to mimic multiple aspects of complex objects.

Pheromone & visual factors contribute to catch of *Synathedon tipuliformis.*

DM Suckling
Hortresearch, Po Box 51, Lincoln, New Zealand; msuckling@hortresesearch.co.nz

Currant clearwing *Synanthedon tipuliformis* (Sessiidae) has been a pioneering and successful target of mating disruption in New Zealand, widely adopted since c. 1990. However, control failures led us to examine pheromone loading and coloured traps. Male attraction to yellow delta traps was equivalent to green delta traps but was greater than to red, black, blue or white traps. Fully yellow delta traps were more attractive than black traps with yellow stripes designed to mimic the insect, and it is suggested that yellow provides a supernormal stimulus (female abdomens have two yellow stripes). However, there was no catch in the absence of the pheromone lure, showing that colour alone was not a sufficient stimulus. Catch increased as a function of pheromone loading and trap colour, but the effect appeared to be additive. However, when plastic funnel traps were used, catch in yellow traps was highly significantly greater than in green plastic traps, indicating greater discrimination between these colours. Curiously, a composite coloured lid-funnel-base of green-yellow-white funnel traps was more attractive than fully yellow-yellow-yellow coloured funnel traps or composite green-yellow-green. These results suggest that the insect has a high degree of visual discrimination between colour shades and surface area. While significant improvements (c. 16-fold) to catch have now been achieved, with an additive combination of trap colour and pheromone loading, more work is needed to decipher the visual discrimination in this species.

Putative identification of the contact sex pheromone of the burnt pine longhorn, *Arhopalus tristis* (Coleoptera: Cerambycidae).

DM Suckling, A Gibb, V Heppelthwaite, LA Manning, AM El-Sayed
PO Box 51, Lincoln, 8152, New Zealand; msuckling@hortresearch.co.nz

The longhorn *Arhopalus tristis* (F) is a pest of pines, particularly those damaged by fire, and is a major export quarantine issue in New Zealand. In our project to develop an attractant to help in monitoring and management of this species, we have investigated the contact sex pheromone. Male burnt pine longhorn initiates copulatory responses to females only after sensing them with their antennae, providing evidence for contact sex pheromone in this species. When applied to a gelatine capsule, hexane wash of female's elytra elicited male copulatory attempts similar to the copulatory response elicited in males by live females. GC-MS analysis of male and female elytra extracts indicated that all of the compounds present in both extracts were saturated and branched hydrocarbons from 25Hy to 33Hy. The GC-MS analysis of the hexane extracts of male and female elytra revealed that the profile of compounds in both extracts was qualitatively similar, but different in the ratio of two peaks. These two peaks were identified as branched 28Hy hydrocarbons and a straight chain 29Hy. Further work is underway to test the activity of these compounds.

Genetic variation in learning ability may mask population-level effects of experience.

B Sznajder, M Egas, MW Sabelis
Kruislaan 320, 1098 SM Amsterdam, The Netherlands; sznajder@science.uva.nl

Variation in learning abilities has long been suspected to have a genetic basis and recently experimental evidence in support of this hypothesis is accumulating. In spite of these developments, in many studies of cognitive abilities such a variation is not controlled for, because populations of mixed or unknown genetic background are tested. We postulate that such an approach may confound the occurrence and/or magnitude of learning effects. We support this postulate with our results on learning in the predatory mite *Phytoseiulus persimilis*. *Phytoseiulus persimilis* responds to volatile chemicals released by plants following infestation by its prey, the two-spotted spider mite. The blend of induced volatiles is herbivore-specific and as such it serves as a signal of prey presence. It has therefore been predicted that learning of volatiles would be highly beneficial for this mite. We show that a collection of *P. persimilis* from natural populations on Sicily exhibits no significant change in responses to the volatiles following the experience. The same tests, however performed on iso-female lines from those populations show variation in learning ability among the lines. These as well as other results on variation in learning abilities raise the question what mechanism maintains such a variation.

Specificity of herbivore-induced volatiles in information transfer in multitrophic interactions.

J Takabayashi, R Ozawa, K Shiojiri
Center for Ecological Research, Kyoto University, Otsu, 520-2113, Japan;

"junji@ecology.kyoto-u.ac.jp

When infested by diamondback moth (DBM) (*Plutella xylostella*) larvae, cruciferous plants emit volatiles that attract a specialist parasitic wasp of DBM larvae, *Cotesia plutellae*. The wasps are not attracted to volatiles emitted by a crucifer plant infested by nonhosts [cabbage butterfly (CB) (*Pieris rapae*) larvae]. We identified specific volatile compounds emitted by cabbage plants with minor DBM larvae infestations, but not emitted by intact cabbage plants. When we compared the attractive properties of each chemical on an intact cabbage plant (treated plant) with that of the solvent alone (control plant), the wasps were equally distributed between the two plants. However, when a mixture of all the chemicals was used instead of each chemical alone, the wasps showed a significant preference towards the treated plants. These data suggest that a specific blend is important in the interaction between cabbage plants, which are infested by DBM larvae, and *C. plutella*. By comparing this tritrophic system with one consisting of cabbage plants, CB larvae, and their parasitoid *Cotesia glomerata*, the specificity of herbivore-induced volatiles in information transfer is investigated.
"

Cone thermogenesis & volatiles associated with specific pollinators of *Macrozamia* cycads.

I Terry, G Walter, C Moore, P Forster, C Hull
Univ. of Utah, 257 S 1400 E, Salt Lake City, UT 84112 USA; terry@biology.utah.edu

Macrozamia cycads, endemic to Australia, are associated with an unusual and diverse array of insect pollinators compared with other cycads. Some *Macrozamia* species are pollinated by *Tranes* weevils only, others only by thrips (*Cycadothrips)*, and some by both insect types. We show that these cycads' cones have chemical and metabolic traits that are associated strongly with their specific pollinator type. Species pollinated by *Tranes*- only have cones that heat and release volatiles during the early evening, whereas *Cycadothrips*-only cycads have cones that heat and release volatiles during the day. Cones of *Tranes*-pollinated species release volatiles comprising a few monoterpenes, primarily linalool and much lower levels of beta-myrcene, whereas "thrips-only" cycads lack linalool and release numerous monoterpenes, dominated by beta-myrcene emitted at very high rates. Insect movement between male and female cones occurs during the cone heating and volatile emission phase of their specific host. Preliminary evidence suggests that insects are attracted to their host's cone volatiles and they respond neurologically to specific components within the volatile mix.

Cuticular hydrocarbon patterns of termitophiles & their host.

CC Tsai, CS Chen
"Department of Biology, Tunghai University, No. 181, Section 3, Taichung-Kan Road, Taichung, Taiwan 407 chuntsai@mail.thu.edu.tw"

Termitophile can be defined as any animal other than a termite that is normally found in a termite nest. Termitophiles supposed to use "appeasement chemicals" to integrate into the social structure of termite colonies. Since cuticular hydrocarbons are caste- and species-specific, these mixtures may important to termite, possibly used as species recognition cues. Termitophiles were collected from termite nest or around termite galleries in Taiwan. Using gas chromatographic analysis to compare the cuticular hydrocarbons of some termitophiles and their hosts, the chromatograms show some cuticular hydrocarbon components of termites might be similar to those of their termitophiles. Termitophiles might utilize chemical mimicry to integrate into termite society. The similarity of cuticular hydrocarbon component between termitophiles and termite host might indicate the integration degree of termitophiles.

Perspectives for time allocation studies in the future.

JJM van Alphen, C Bernstein
"P.O.Box 9516, NL200RA Leiden, Netherlands; alphen@rulsfb.leidenuniv.nl"

The allocation of foraging time in insects has been a fruitful area blending empirical and theoretical research. About 100 papers with insects or mites as study subjects have appeared since 1990, the same number as for all other organisms (birds, fishes, mammals and gastropods). A survey of this literature and recent developments point to the following promising areas of research.
(A) Recent models on group foraging have not yet seen empirical tests
(B) Individual variation in behaviour has been amply documented. Three explanations have been forwarded to explain this variation: (1) information acquisition and learning, (2) differences in internal state and (3) genetic variation within and between populations. However, the relative importance of these sources of variation has not been investigated.
(B) Individual variation in behaviour has been amply documented. Three explanations have been forwarded to explain this variation: (1) information acquisition and learning, (2) differences in internal state and (3) genetic variation within and between populations. However, the relative importance of these sources of variation has not been investigated.
(C) The recent finding that symbionts, like bacteria and viruses, can change parasitoid behaviour raises the question, of which behaviours might be extended phenotypes of these symbionts, and to what extent conflicts between symbionts and their hosts occur.
(D) Host foraging, the most studied process in patch allocation is one facet of different trade-offs, such as searching for food and searching for hosts. Little is know on how these trade-off affect parasitoid foraging time and how the animals integrate the information of the presence of different resources.
(E) Up to now the study field of patch residence time is restricted to behavioural macroscopic, processes. Insect physiologist should be attracted to the field to unravel processes as the integration of different signals, how the time elapsed is integrated to patch leaving mechanisms, etc.

A maternal chemical cue affecting the behaviour of a parasitoid of aphids on emergence.

H van Emden, S Douloumpaka
Department of Agriculture, The University of Reading, Earley Gate, Reading, RG6 6AR, UK; h.f.vanemden@reading.ac.uk

A fully-defined artificial diet containing no secondary plant compounds produces aphid mummies which give emerging parasitoids no opportunity to learn plant volatiles of the plant on which they were reared. To improve parasitisation of the aphid *Myzus persicae* (Sulzer) by the generalist parasitoid *Aphidius colemani* (Viereck) on the diet, we allowed parasitisation on a host plant leaf for 48 h, after which the aphids were returned to the diet. We now needed to test that this procedure did not provide plant volatile cues to the emerging parasitoids. Unfortunately it did, but only when the plant from which the parent parasitoids had been reared was the same as that on which they had parasitised the aphids. Thus, if parasitisation has occurred on Brussels sprouts, the emerging daughters only preferred the odour of sprouts to cabbage if their parents had been reared on sprouts; if reared on cabbage, there was no olfactory preference for either brassica. The parasitoids clearly leave a maternal cue for their offspring when they oviposit, and we discuss what this might be, where it might be located in the parasitised aphid, how it affects the emerging offspring and why it is left.

Sexual behavior in *Nezara viridula* (L) (Heteroptera: Pentatomidae).

M Virant-Doberlet, A Cokl, M Renou, N Miklas, P Pavlovcic, M Zorovic
National Institute of Biology, P.O.B. 141, SI-1001 Ljubljana, Slovenia; meta.virant@nib.si

The southern green stink bug *Nezara viridula* (L.) (Heteroptera: Pentatomidae) has a complex sexual behavior. As a part of a specific mate recognition system, during courtship male and female exchange chemical and substrate-borne vibrational signals. Sexually mature males release a volatile sex pheromone that is regarded as a long-range attractant and serves to bring bugs to the same plant. When on a plant, both male and female emit several species and sex specific vibrational signals called songs. It seems that volatile chemical signal triggers the emission of the female calling song. Male responds to female calls with his songs and he locates the singing female on a plant using her vibrational signals as a directional cue. Male songs keep female singing for a longer time with a regular repetition rate while the female calling song modulates the emission of the male sex pheromone. Such feed-back modulatory mechanisms probably help to improve the synchronization of sexual activity and could also provide the sensory cues for sexual selection.

Mating behaviour of *Zorion guttigerum* (Westwood) (Coleoptera: Cerambycidae).

Q Wang, LY Chen
Institute of Natural Resources, Massey University, Private Bag 11222, Palmerston North, New Zealand; Q.Wang@Massey.Ac.Nz

Zorion guttigerum *(Westwood) is a diurnal cerambycine beetle endemic to New Zealand. Pair-bonding, mating, and adult feeding occur on flowers while larvae feed on dead tree twigs. Adults live for > 3wks and the male and female arrive at flowers independently, suggesting that long-range sex pheromones may not operate in mate location. Mean pair-bonding period is 22.7 ± 24.2 (mean ± SD)(ranged from 2.3 to 120.5) min during which time 1.8 ± 1.5 (ranged from 1 to 6) matings occur. Mating lasts an average of 4.7 ± 2.5 (ranged from 1.2 to 11.7) min. Overall operational sex ratio is male-biased (»1♀:1.5♂) but it becomes very highly male-biased (»1♀:9♂) when pair-bonding and feeding activities decrease to the minimum between 1400 and 1600 h, suggesting that females leave flowers for oviposition. It is probably true that for cerambycid species whose females oviposit alone and mating and oviposition occur on different plants or different parts of plants, the operational sex ratio varies significantly over time on the mating/feeding sites. Duration of pair-bondings also varies over time. Shorter pair-bondings in the morning may suggest a strong sexual selection process. After ca. 2-h selection, both sexes tend to engage in much longer pair-bonding and mate more times before females leave the mating and feeding sites for oviposition in the early afternoon.*

Towards the identification of contact pheromones of the fig longicorn, Agrianome spinicollis *(Macleay).*

AL Ward, CJ Moore
Trawalla, MSF 2058, Pallamallawa 2399 Australia; aneww@stahmann.com.au

Agrianome spinicollis is a cerambycid endemic to the eastern states of Australia and is a serious pest of pecan nut trees. Damage results from larvae feeding within the limbs and trunks of the trees, which ultimately results in the trees' collapse. Observations suggest that contact pheromones on the elytra of female beetles form an important component of the mate recognition system employed by male beetles. Experiments were conducted in which the cuticular hydrocarbons were removed from both male and female beetles. Such solvent-rinsing of females resulted in the loss of attractiveness towards males. The subsequent re-application of the hexane rinse, at concentrations as low as 0.1 female equivalents, was followed by mating attempts by males. Gas chromatographic analysis of the cuticular rinses revealed significant quantitative sex differences in shared components, and possibly qualitative differences. The male extract is dominated by mono-unsaturated hydrocarbons having 25, 27 and 31 carbons. The female extract, in contrast, is dominated by a single alkene, with 26 carbon atoms. As a result of the short range of efficacy of the compounds, these findings are unlikely to have any significant management implications.

Influence of lek size on female visitation in Queensland fruit fly (*Bactrocera tryoni* Froggatt) (Diptera: Tephritidae).

CW Weldon
Fruit Fly Research Centre, School of Biological Sciences A08, University of Sydney, NSW, 2006, Australia; cweldon@bio.usyd.edu.au

The lek mating system of Queensland fruit fly, *Bactrocera tryoni* (Froggatt) (Diptera: Tephritidae), may reduce the ability of this species to colonise new areas. The importance of lek size for female visitation at lek sites and initiation of male pheromone-calling was investigated in large cages using artificial leks. Female visitation at artificial leks was monitored to determine if females visited leks due to passive attraction or showed a preference for larger leks. Female *B. tryoni* display a preference for larger leks rather than being passively attracted to a greater perceived stimulus from large leks. Per capita success of males in attracting females was higher at larger leks than where there was a single male. Calling propensity of male *B. tryoni* was increased by the presence of conspecific males. Overall, female visitation at leks was only weakly associated with male calling, suggesting that lek size and the number of pheromone-calling males is not the only factor important in locating mates in this species.

Integration of multi-sensory information in orientation & navigation behavior.

MA Willis
Department of Biology, Case Western Reserve University, 2080 Adelbert Rd., Cleveland, OH 44106-7080 USA; maw27@po.cwru.edu

The ultimate goal of neuroethology is to describe the neural mechanisms that produce adaptive behaviors in freely moving animals. My lab has been using a virtual reality flight system that closely emulates realistic stimuli that occur during flight, and which produce robust flight behaviors in a tethered moth (*Manduca sexta*) that are similar to those seen in real flight. Concurrently we are able to utilize extracellular multi-unit electrodes to record activity in the region of the ventral nerve cord between the brain and the thoracic ganglia. This system allows us to investigate mechanisms by which *Manduca* responds to visual and olfactory stimuli that it may encounter during actual pheromone-guided flight, and how it might activate and control flight manoeuvres. Initial results reveal ensembles of neurons that show unique activation patterns associated with visual pattern movement associated with flight, and that these patterns are modulated during exposure to pheromone. Similarly, other unique ensembles of neurons are activated differentially when the preparation is in tethered flight or not flying. These experiments are aimed at understanding how multiple streams of information are integrated by the nervous system and how this is meshed with ongoing behavior. Pheromone-modulated orientation mechanisms in walking male cockroaches.

MA Willis
Department of Biology, Case Western Reserve University, 2080 Adelbert Rd., Cleveland, OH 44106-7080 USA; maw27@po.cwru.edu

Perhaps the most remarkable olfactory task achieved by insects is that of locating distant resources using airborne chemical cues. It is currently thought that two primary mechanisms underlie flying insects' ability to perform this behavior: 1) an odor-modulated, visually-mediated orientation to the wind direction and, 2) an odor-activated internal program of turns. The blending of these two mechanisms is thought to generate the upwind zigzagging paths that we observe from insects tracking odors in flight. It is not yet clear whether vision contributes significantly to the odor tracking behavior of walking insects. Recent results suggest that visual information may be very important, but not used in the same manner as flying odor tracking insects. Furthermore, the structure of the walking paths of pheromone tracking cockroaches look remarkably like those observed from flying insects, and thus may be governed by similar mechanisms. Our new results suggest that comparing the odor tracking behavior of walking and flying insects in similar environments may reveal important similarities and differences in how olfactory and other sensory information is used. Supported by: ONR-MURI No. N00014-01-1-0676.

Odor concentration & odor invariance in the olfactory system of the honeybee.

GA Wright
Mathematical Biosciences Institute, 231W. 18th Ave, Columbus, OH 43210; wright.571@osu.edu

Sensory systems have evolved to recognize stimuli over a range of stimulus intensities. A stimulus may be more intense, but it will still retain other qualities that make it classifiable along another dimension. When the qualitative representation of a stimulus remains the same over a specific range of intensity, the stimulus is defined as *invariant* over that range. In olfaction, it is often noted that increasing the intensity of an odorant affects its quality, such that odorants do not remain invariant as a function of their concentration in air. I will discuss how our experiments with honeybees reflect the extent that odorants remain invariant and the implications of failure of invariance for odor coding.

Local resource competition in the solitary parasitoid *Haplogonatopus atratus* **(Hymenoptera: Dryinidae).**

YY Yamada, Y Nishioka
Insect Ecology Laboratory, Faculty Of Bioresources, Mie University, Kamiha-Cho, Tsu, Mie 514-8507, Japan; yamada-y@bio.mie-u.ac.jp

This is the first study showing local resource competition (LRC) in parasitoids. Females of the parasitoid *Haplogonatopus atratus* are apterous, while males are alate. Individuals of the host, *Laodelphax striatellus* (Hemiptera Delphacidae), are distributed in clumps in paddy fields. These facts suggest the existence of LRC among female offspring of mother parasitoids, and that female parasitoids will produce a lower proportion of male offspring in patches with higher host density. Our laboratory experiments confirmed these predictions, as follows. A female parasitoid was placed in a glass pot with rice seedlings on which different numbers of planthoppers (10, 20, 40, or 80) were feeding. The female was allowed to oviposit freely until she left the seedlings. Sex ratios (male proportions) in emerging adults decreased with increasing host density. Moreover, the average number of eggs laid among parasitized hosts decreased as the host density increased, but hosts with different numbers of eggs laid in the same patch produced similar sex ratios. Host-quality models suggesting that male eggs are more likely to be laid in hosts of low quality (i.e., the parasitized hosts in this case) do not explain the above patterns in the sex ratio.

Identification of semiochemicals for the Asian longhorned beetle, *Anoplophora glabripennis*.

A Zhang
USDA, Agriculture Research Services, Chemicals Affecting Insect Behavior Laboratory, BARC-West, Beltsville, MD 20705, USA; zhanga@ba.ars.usda.gov

A series of long-chain hydrocarbons comprise the cuticular waxes of both sexes of ALB adults. Although for the most part the gas chromatographic profiles are similar for the two sexes, five monounsaturated compounds were consistently more abundant in samples from females than in those from males. These compounds were identified as (*Z*)-9-tricosene, (*Z*)-9-pentacosene, (*Z*)-7-pentacosene, (*Z*)-9-heptacosene, and (*Z*)-7-heptacosene in the approximate ratio of 1:2:2:8:1, respectively. Antennal contact to a micro-centrifuge tube coated with synthetic mixture of the five compounds stimulated copulatory behavior in males. This is the first time that monounsaturated hydrocarbons, (Z)-9-tricosene, (Z)-9-pentacosene, (Z)-7-pentacosene, (Z)-9-heptacosene, and (Z)-7-heptacosene, have been implicated as contact sex recognition pheromone components in the family Cerambycidae. Two male-specific beetle volatiles were found that elicited strong gas chromatographic-electroantennographic detection (GC-EAD) responses from both sexes of adult Asian longhorned beetle (ALB), *Anoplophora glabripennis*. The secretion consisted of a ~1:1 blend of functionalized dialkyl ethers, 4-(*n*-heptyloxy)butanal and 4-(*n*-heptyloxy)butan-1-ol. These compounds are chemically unusual natural products that are previously unknown from insects. Laboratory olfactometer studies showed that a blend of 10 µg of each synthetic compound on a filter paper strip was significantly attractive to ALB adults.

Identification of sex pheromones of ***Holcocerus hippophaecolus*** **(Lepidoptera: Cossidae) & biological activities.**

Z Zhong-ning, F Yu-ling, S Jiang-hua, Z Cheng-hua
Institute of Zoology, Chinese Academy of Sciences, Beijing 100080, China; zhangzn@panda.ioz.ac.cn

Holcocerus hippophaecolus Hua (Lepidoptera: Cossidae) is a destructive forest pest widely distributed throughout northern and western region of China. Its primary host-plant is sandthorn (*Hippophae rhamnoides* L.), which is a most widely planted shrub used for preventing from soil erosion and desert control, along the area of loess plateau in China. The fruit of sandthorn could be used for juice and Chinese medicine. Its plantation reached 180 million ha. About half million ha of plantations suffered severely attacking by the pest insect. Seven components were identified from female sex pheromone gland. These components were (*E*)-3-tetradecenyl acetate (E3-14:Ac), (*Z*)-3-tetradecenyl acetate (Z3-14:Ac), (*Z*)-7-tetradecenyl acetate (Z7-14:Ac) and related alcohols: E3-14:OH, Z3-14:OH, Z7-14:OH and (*Z*)-9-tetradecenyl acetate (Z9-14:Ac). Two major ones are as Z7-14:Ac and E3-14:Ac. EAG showed that Z7-14:Ac produced the strongest response and followed by E3-14:Ac in these seven compounds. The field trials showed that the combination of Z7-14:Ac and E3-14:Ac in a ratio of 1:1 could significantly catch much more males than others.

Different habitats, different habits? Information use in the parasitic wasp *Venturia canescens*

A Thiel, G Driessen and TS Hoffmeister
Institute for Ecology and Evolution, University of Bremen, Leobener Str. D-28359 Bremen, Germany, andrathiel@web.de

Different environments require different adaptations. Effective foraging strategies in one habitat can lead to a wastage of time or energy in another habitat. In the parasitoid *Venturia canescens* (Gravenhorst), wasps with two different reproductive modes occur under different ecological circumstances. We studied the use of foraging information by testing females from ten populations in multi-patch experiments. Only thelytokous (unisexual) females, that usually live in habitats with fluctuating host densities, readily responded to cues indicating the current abundance of host patches by a reduction in patch residence times. In contrast, no changes in patch time allocation could be detected when we tested arrhenotokous (bisexual) wasps from environments that are more stable with respect to host density. Additional experiments showed that the different response patterns were not produced by different learning abilities of the two wasp types but instead by different ways of how the information gained was dealt with by the searching females. From supplementary life history data we conclude that the observed differences in information use in *Venturia canescens* are more likely to have evolved in response to life history-specific needs of dispersal in arrhenotokous wasps that are irrelevant to thelytokous wasps rather than to habitat-specific fluctuations in host abundance.

Maternal care of 8 Costa Rican Weevils (Attelabinae, Attelabidae, Coleoptera)

K Sakurai,
"Laboratory for Human-Environmental Research, Junior College, Seijo University, 6-1-20, Seijo, Setagaya, Tokyo, 157-8511 JAPAN sakurai@seijo.ac.jp"

An ethological study was carried out in Costa Rica during the period from April 1999 to March 2000 in order to reveal the maternal behaviours of attelabin weevils endemic to Central and South America. The whole process of the cradle formation was analysed for 8 species of 4 genuses (*Euscelus elliptiguttatus* Voss, *E.* sp.1, *E.* sp.2, *Omolabus quadratus* (Sharp), *O. angulipennis* (Sharp), *Xestolabus conicollis* (Sharp), *X. corvinus* (Gyllenhal) and *Pilolabus rugiceps* Voss). *E.* sp.1 and *E.* sp.2 made two types of cradles; cradles of one type made of the periphery of a leaf showed similarity with the cradles of *Euops*. *X. corvinus* firstly cut at the basal part of a leaf as many species do, and secondary at the apical part it conducted additional cutting with which the apical portion were thrown away. Leaf rolling technique of *P. rugiceps*, which made spherical cradles, was unique and it appeared to be a set of restricted manner. I am grateful to INBio and the staff (especially A. Solis, C.M. Rodriguez and Q.M. Jimenez) for their help and for giving me an opportunity to study at INBio. I also thank Dr. D.H. Janzen for valuable information and Dr. W. Eberhard, Dr. P. Hanson and K. Nishida for their kindness.

The Pherobase: database of insect pheromones and semiochemicals

AM El-Sayed
"PO BOX 51, Lincoln, 8152, New Zealand, AEl-Sayed@hortresearch.co.nz"

The Pherobase is a database of insect pheromones and semiochemicals that has become available on the worldwide web since November 2003. The main objective of this database is to provide a guide to the literature published on chemicals signals involved in insect's chemical communication. The pherobase is not biased towards any insect order or any type of semiochemicals; it covers most insect orders and all types of semiochemicals. The database is extensively linked, user-friendly, easy to understand and to follow. Currently, there are over 5000 entries that cover most of the insect orders, around 1600 molecules, and over 16000 static html pages. In addition, mass spectral data collected from the literatures for more than 800 compounds are included. The Pherobase will be demonstrated electronically in this meeting and I would appreciate any inputs form Entomologists on its features, structure and how to proceed with it in the future?

Role of leaf volatiles from two maize (Zea mays L.) cultivars in eliciting larval orientation of Chilo partellus (Swinhoe) (Lepidoptera: Pyralidae)

AK Varshney, AK Singh, HC Agarwal
"Dept. Of Zoology, University Of Delhi, Delhi-110 007, INDIA; singhak@vsnl.net"

The effects of two maize cultivars, susceptible (Basilocal) and resistant (Kisan), and their methanol- and hexane- extracts in eliciting orientation of the first-instar Chilo partellus (Swinhoe) larvae were studied in the laboratory. When presented at one end of the orientation tunnel, leaf whorls of both the Basilocal and Kisan varieties, elicited higher orientational responses of stemborer larvae as compared to the blank end, the orientation preference (OP) of the larvae being + 72% and + 48%, respectively. Statistically, OP of larvae for Basilocal leaves was significantly higher than for Kisan leaves ($P<0.01$). Methanol extracts of both the Basilocal and Kisan leaves also attracted the neonate larvae, but the difference between the OP for the two was not significant. However, the attraction of larvae for hexane extractable chemicals of Basilocal (OP= 40%) was significantly higher than that for Kisan (OP = -32%). The observations indicate that difference in the orientational response of stemborer larvae for the two maize cultivars is due to non-polar semiochemicals, extractable in hexane. Identification of the chemicals in these maize cultivars can be useful in the behavioural management of this economically important insect pest of maize and sorghum.

Assessing the pitfalls of insect repellent evaluation methodologies

SJ Moore, MM Cameron, N Hill, CR Davies
4D1, DCVBU, London School of Hygiene and Tropical Medicine, Keppel St. London WC1E 7HT, UK, sarah.moore@lshtm.ac.uk

Insect repellents provide useful protection from malaria, for high-risk groups including forest-workers; especially in the Amazon Basin where vectors are difficult to control through conventional means due to their exophily, crepuscular biting and forest-breeding. The WHO recommends that repellents are field-tested using human-landing catches, with individual collectors positioned >10m apart. However, it is still commonplace to perform tests using repellent treated "bait" and an unprotected "collector". This could overestimate repellent protection and longevity since mosquitoes will feed preferentially from the unprotected "collector", thus potentially exposing subsequent users to disease. Mosquito diversion from 15% deet (repellent) to 15% baby oil (control) was quantified utilising pairs of testers with each team situated >10m apart. Permutations of repellent repellent; control control; and repellent control were replicated over 18 nights with 6 pairs. Control individuals received 22.82% more bites when paired with repellent wearers, than untreated individuals (likelihood-ratio test Prob > chi2= 0.0485), and repellent wearers received 11% more bites when paired with other repellent wearers than controls (N.S.). In a further test with 25% lemongrass *(Cymbopogon citratus)* repellent, controls received 23.53% more bites when paired with repellent wearers, than with unprotected partners (N.S.). Thus it is recommended that repellents are field-tested using individuals and not pairs of collectors.

Assessing the pitfalls of insect repellent evaluation methodologies

Thus it is recommended that repellents are field-tested using individuals and not pairs of collectors.

Do sensory detectors interact in the decoding of environmental signals?

RG Vogt
Department of Biological Sciences, University of South Carolina, Columbia SC 29208, USA, vogt@biol.sc.edu

In a multimodal context, there is presumably little or no interaction between sensory detectors. Rather, a multitude of detector phenotypes and sub-phenotypes exist to deconstruct a signal rich environment and to present these signals to the brain via diverse pathways. The brain integrates this horde of information, making use of what is interesting and discarding what is not. Or, perhaps, there is a great deal of interaction, and we've been ignoring it. Individual neurons may contain multiple receptor/transduction pathways responsive to different signals, integrating these signals at the biochemical level. Individual sensilla (sensory organs) may contain neurons which respond to different signals and when activated, alter properties of their sibling neurons. Sensory appendages (eyes, antennae, wings, legs) may contain sensory organs with modalities as diverse as the functions of the appendage itself. Developmental decisions establish these diverse detector arrays, and hormonal regulation may differentially modulate their individual activities. My presentation will focus on the potential interactions between diverse sensory detectors, striving to consider sensory detectors in ways not currently in vogue.

Male-produced anti-sex pheromone in a plant bug.

QH Zhang, JR Aldrich
USDA-ARS-BARC Chemicals Affecting Insect Behavior Lab, Beltsville, Maryland USA 20705

In at least some plant bugs (Miridae) females produce sex pheromones in the metathoracic scent gland (MSG), which in most other true bugs (Heteroptera) is responsible for chemical defense. Females of a pine inhabiting mirid, *Phytocoris difficilis* Knight, contained predominantly hexyl, (*E*)-2-hexenyl and (*E*)-2-octenyl acetates in their MSG, while the latter two compounds were found only in trace amounts in males. This ternary acetate blend (2: 1.5 :1 by volume) constitutes the sex pheromone of *P. difficilis.* However, the possibility that the MSG secretion of male plant bugs plays a role other than defense has been largely overlooked. For *P. difficilis* we showed that hexyl butyrate and (*E*)-2-hexenyl butyrate are abundantly produced only in males, and demonstrated that these MSG compounds elicit strong antennal responses in conspecific males. Furthermore, physiologically relevant doses of these butyrates totally interrupted attraction of males to the female-produced sex pheromone in the field. Our results suggest that in some plant bugs the male MSG esters have a natural communicative function as anti-sex pheromones, probably to repel other males from further mating attempts. From a practical standpoint, synthetic anti-sex pheromones may be useful for mating disruption of economically important plant bugs.

Sex pheromones in Diprionidae & other Symphyta (Hymenoptera).

O Anderbrant
Department of Ecology, Lund University, Ecology Building, SE-223 62 Lund, Sweden: olle.anderbrant@ekol.lu.se

The most ancient group of Hymenoptera, Symphyta or sawflies, consists of around 8000 described species. The vast majority, are herbivorous and some species are important pests of agricultural crops or forest trees. Despite this, comparatively little is known about the chemical ecology within this group. I will present an overview of the sex pheromones identified so far in the different families, with emphasis on Diprionidae, the only well-studied group. In this family all active compounds discovered are saturated methyl-branched hydrocarbons with two to four chiral centres. The chiral configuration seems to be important for all species, whereas specificity regarding carbon chain-length or functional group (different esters) often is less distinct. The electrophysiologically and behaviourally active esters are released by the females together with their alcohol and carboxylic acid precursors. According to present knowledge, several sympatric species share the same sex pheromone, also with respect to stereoisomer, calling for more attention from chemical and evolutionary ecologists. In the other families the identified pheromones are different from those in Diprionidae, but there are too few sex pheromones identified for drawing any general conclusions.

Identification of volatile compounds from *Stenodema* (Heteroptera: Miridae) trigged by their natural predators.

M Apelqvist
Univiersity of Jönköping (HLK), Box 1026, S-551 11 Jönköping, Sweden; magnus.apelqvist@hlk.hj.se

Gland secretions in Heteroptera contain different compounds spanning from sex pheromones to allomones. Little is known about the structure and function of released defence substances, especially in Miridae, and studies of emissions from living species are rare. In this study, *Stenodema* Laporte specimens were exposed to predators and the trigged chemical response was recorded in vivo using solid-phase microextraction (SPME). Sexual immature adults from *S. calcarata* Fallén, *S. holsata* Fabricius and *S. laevigata* Linnaeus were tested and predators like spiders and Nabidae were introduced to provoke defence reactions. Each species of *Stenodema* released three substances in high amounts due to the confrontation. These compounds were absorbed on SPME-fibers and identified using GC-MS.

Functional diversification of the material properties of orb-weaving spider silk.

TA Blackledge
Department of Biology, University of California, Riverside, CA 92521, USA; todd.blackledge@ucr.edu

Spider silks are exceptionally strong and can absorb more energy before breaking than high performance manmade fibers such as Nylon or Kevlar. The exceptional mechanical properties of spider silks are thought to have resulted in part from selection on the function of webs during prey capture, in particular upon aerial orb webs that must arrest fast-flying, high kinetic energy insect prey. However, orb-weaving spiders spin up to seven different types of silks, all of which are produced from distinct glands and are utilized in many different ways, from protecting eggs, to building retreats, to capture of prey. Here, we use the orb-weaving spider *Argiope argentata* to demonstrate that each of these silks, produced by distinct glands within a single spider, has a unique combination of material properties. Furthermore, these differences in mechanical performance reflect variation in the amino acid sequences of silk proteins. Thus, molecular evolution has played in important role in the evolution of the diverse toolkit of silks utilized by modern orb-weaving spiders.

Candidate pheromone receptors of the moth.

J Krieger, K Raming, YME Dewer, T Gohl, E Große-Wilde, H Breer
"University of Hohenheim, Institute of Physiology, 70593 Stuttgart, Germany; breer@uni-hohenheim.de"

The remarkable responsiveness of male moths to female released pheromones is based on the extremly sensitive and selective reaction of highly specialized sensory cells in the male antennae. These cells are supposed to be equipped with very distinct, male-specific receptors for pheromonal compounds; the nature of these receptors is still elusive. Using a combination of genomic sequence analysis and cDNA library screening of the tobacco budworm *Heliothis virescen***s led to the discovery of a divergent gene family encoding putative olfactory receptors. Comparing the encoded amino acid sequences of all candidate olfactory receptors emphasized their extreme diversity; however, a small family (identity > 40%) emerged, including the three receptor types HR14, HR15, HR16. RT-PCR-analysis revealed that all three subtypes were exclusively expressed in the antennae of male moths. More detailed** *in situ* **hybridization studies indicated that expression of these male-specific receptor types was confined to antennal cells located beneath sensillar hair structures which contain pheromone sensitive neurons. Moreover, two colour double** *in situ***-hybridization approaches in combination with laserscanning microscopy uncovered that each cell expressing one of these receptor type was surrounded by cells expressing pheromone binding proteins. These findings suggest that the novel receptor types may render neurons in male antennae responsive to pheromones.**

Influence of host footprints kairomone & past oviposition experience on the host location behaviour of *Trissolcus basalis.*

E Peri, MA Sole, E Wajnberg , S Colazza
S.En.Fi.Mi.Zo. Department - Section of Entomology, Acarology and Zoology – Università di Palermo, Viale delle Scienze, 13 90128 Palermo, Italy; colazza@unipa.it

During the host selection process insect parasitoid make flexible use of chemical information which can be directly or indirectly associated with the presence of their hosts. Wasp's response to a stimulus should be inversely related to its potential response and a change in wasp's response to stimuli can be the result of associative learning. In this view, influence of host indirect cues on the host location behaviour of the egg parasitoid *Trissolcus basalis* was investigated. *T. basalis* host selection behavior is mediated by chemical cues which are directly or indirectly associated with the presence of host egg mass of *Nezara viridula*. In particular, nymphs and adults footprints left on the substrate are known to play a role as indirect host-derived cues inducing an arrestment response in the parasitoid. We hypothesized that females which experienced the presence of host footprints kairomone without finding the host eggs should be less likely to respond to the same stimulus in the near future, while females that successfully located host egg masses would have shown reinforced responses. Results support our hypotheses. The significance of these findings for the manipulation of adult parasitoid behavior to enhance pest control and their implications for host selection by egg parasitoids are discussed.

Influence of direct mutual interference on patch time location in egg parasitoids.

E Wajnberg, C Curty, S Colazza
S.En.Fi.Mi.Zo. Department - Section of Entomology, Acarology and Zoology – Università di Palermo, Viale delle Scienze, 13 90128 Palermo, Italy; colazza@unipa.it

Direct mutual interference, i.e. the competition between parasitoid females foraging simultaneously for hosts, has regularly been considered to have a strong influence on the population dynamics of host-parasitoid systems. Furthermore, patch time allocation has also always been presented as an important behavioral component that should be deeply involved in the demographic features of host-parasitoid interactions. Based on a detailed analysis of within-patch interactions between *Trissolcus basalis* females, the present study aimed at understanding accurately how direct mutual interference can influence patch time allocation in this species. *T. basalis* attacks patches of its host, the egg masses of the Southern Green Stink bug *Nezara viridula*. In this species, competition between females occurs through strong fights when they are foraging simultaneously on the same patch. Such mutual interference could modify drastically the time invested by the females on the host patches. Behavioral interactions between the females were analyzed using a Cox's proportional hazards model. Results first indicated that the competitive interaction (through contacts and fights) between females strongly influences their patch residence time. Also, all the corresponding patch-leaving decision rules adopted by the females appeared to be under a significant genetic variation in the population studied. Such a genetic variability likely corresponds to an intra-population genetic variation in females' susceptibility to interference. The population dynamics and evolutionary consequences of these results are discussed.

Investigation of pheromones of coffee stemborers (Coleoptera: Cerambycidae).

DR Hall, A Cork, Jayarama, R Naidu, D Kutywayo
Natural Resources Institute, University of Greenwich, ME4 4TB, UK; a.cork@gre.ac.uk

Stemborers (Coleoptera: Cerambycidae) are the most important insect pests of arabica coffee in Africa and Asia. In India and other countries of S.E. Asia, the main species is *Xylotrechus quaipes*. Adult males were previously shown to attract female beetles to traps in the field. Analysis of volatiles collected from virgin male beetles by gas chromatography (GC) linked to electroantennography (GC) showed three components accounting for over 90% of the volatiles, two of which elicited EAG responses from a female beetle. The major EAG-active component was identified as (*S*)-2-hydroxy-3-decanone (I) and the minor as (*S,S*)-2,3-dihydroxyoctane (II). The third component was 3-hydroxy-2-decanone (III). (*S*)-(I) was attractive to male *X. quaipes* in laboratory bioassays, but addition of (*S,RS*)-(III) at 10% of (I) reduced attractiveness. In field trials carried out in India with sticky, cross-vane traps, (*S*) and (*RS*)-(I) attracted male *X. quaipes* and addition of (*S,S*)-(III) at 10% of (I) reduced attractiveness. In Africa the main species is *Monochamus leuconotus*. Preliminary field studies have failed to show any attraction between the sexes, but collection and analysis of volatiles from male or female beetles has shown the males produce a compound not produced by the females and identification of this is in progress.

Chemical information in soil: tritrophic interactions between plants, insects & parasitic nematodes.

RWHM van Tol, MW Sabelis, WJ de Kogel
Plant Research International, PO Box 16, 6700 AA Wageningen, The Netherlands; willemjan.dekogel@wur.nl

Plants can protect themselves against insect herbivores by promoting the effectiveness of the herbivore's enemies. One way to do this is by releasing herbivore-induced volatiles that attract the herbivore's enemies. Most evidence for this phenomenon comes from studies on aboveground tritrophic interactions. We will discuss an example from underground tritrophic interactions: roots from a coniferous plant (*Thuja occidentalis*) release chemicals upon attack by weevil larvae (*Otiorhynchus sulcatus*). These chemicals attract parasitic nematodes (*Heterorhabditis megidis*) which are the natural enemies of the weevil larvae. We will discuss biological, chemical and exploitation aspects of this tritrophic interaction.

Collective foraging in an outbreaking forest pest.

E Despland
Concordia University, 7141 Sherbrooke W., Montreal, Québec, H4B 1R6, Canada; Despland@alcor.concordia.ca

Gregarious behaviour is common among outbreaking forest insects. The forest tent caterpillar (*Malacosoma disstria*) is an early spring feeder that attacks North American hardwoods. Colonies exhibit complex social behaviour, using pheromone trails to move together between temporary bivouacs and feeding sites. Colonies alternate together between periods of quiescence and foraging, and mass movement is facilitated by chemical communication: moving caterpillars spin a fine thread of silk from their mouthparts and mark it with a highly stable non-volatile sterol pheromone. We show that the presence of trails significantly influences the behaviour of individual caterpillars, especially in the early larval stadia: trails increase both amount of locomotor activity and speed of travel. Larvae find novel food sources faster in an arena coated with trails than in a bare environment. This translates into a significant effect of trails on individual performance: caterpillars consume more food, grow larger and develop faster in the presence of trails. Although forest tent caterpillars do not recruit colony-mates to new food finds, trails nonetheless improve foraging by increasing individual mobility. These findings suggest that group-living is integral to the biology of the forest tent caterpillar and has shaped many aspects of its behaviour and development.

Finding the needle in a smelly haystack: prey location by carnivorous arthropods.

M Dicke, JG de Boer, R Gols
Laboratory of Entomology, Wageningen University, P.O. Box 8031, NL-6700 EH Wageningen, The Netherlands; Marcel.Dicke@wur.nl

Many natural enemies of herbivorous arthropods use herbivore-induced plant volatiles to locate their prey. These induced volatiles are sometimes referred to as 'SOS-signals' from plants and their composition is variable. The composition of a blend of herbivore-induced plant volatiles can vary with plant and herbivore species, and with other biotic and abiotic conditions. Carnivores have to cope with this variation to be able to locate their food. We investegated responses of a predatory mite to plant volatiles induced by its prey or by non-prey herbivores. The role of individual compounds from the volatile blend in the discrimination between different blends has been addressed, as well the importance of phenotypic plasticity in predator behaviour. Our data show that the predatory mite *P. persimilis* can locate their prey by using SOS-signals from the prey's host plant not only in setups that have no odour-background, but also when an odour-background consisting of other herbivore-infested plants is present. The induction of herbivore-induced plant volatiles is mediated by the phytohormone jasmonic acid. Application of this hormone can mimic the effect of spider mite infestation to some extent. Moreover, application of the phytohormone can increase the effect of spider mite infestations at low mite densities.

Interaction between olfactory & gustatory inputs in insect behavior.

JC Dickens, B Hollister
USDA, ARS, Beltsville Agricultural Research Center, Plant Sciences Institute, Chemicals Affecting Insect Behavior Laboratory, Beltsville, MD, USA 20705; dickensj@ba.ars.usda.gov

Behavior of insects is governed by chemical and physical signals impinging on specialized sensory organs. Volatile chemical signals are detected by the olfactory sense and result in upwind orientation by conspecifics receiving them. Detection of less volatile chemical signals by the gustatory sense results in behaviors such as copulation, biting and ingestion. However, seldom are these signals encountered in isolation; more often multiple chemical signals are detected simultaneously and the insect receiving them must process the information and appropriate a response. We investigated behavior of Colorado potato beetles challenged by simultaneous olfactory and gustatory stimuli. An open ambulatory Y-track olfactometer was used to measure insect preferences, number of turns made during orientation, and time to make a choice between stimuli. Olfactory stimuli were delivered to one-side of the device; gustatory stimuli were painted on the other side. Behavioral conflicts and preferences were discovered between stimulus pairs. For example, females took more time and made more turns when confronted with a volatile plant attractant and sucrose compared to the plant attractant and a male extract. We will examine behavioral hierarchies revealed by our studies and discuss how they may relate to reproduction and feeding.

Does the aggregation pheromone of *Riptortus clavatus* (Heteroptera: Alydidae) attract the *Piezodorus hybneri* (Heteroptera: Pentatomidae)?

N Endo, T Wada, Y Nishiba
National Agricultural Research Center for Kyusyu Okinawa Region, 2421 Suya, Kikuchi, Kumamoto, 861-1192, Japan; enobu@affrc.go.jp

The male of *Riptortus clavatus* releases an aggregation pheromone which attracts conspecific adults and nymphs. We found that the synthetic aggregation pheromone (a mixture of three components) of *R. clavatus* (Heteroptera: Alydidae) attracted nymphs and both sexes of adults of *Piezodorus hybneri* (Heteroptera: Pentatomidae) in soybean fields. Among the three components of the synthetic pheromone, (*E*)-2-hexenyl (*E*)-2-hexenoate (EE) showed the attractiveness to *P. hybneri* and the activity was almost equal to the aggregation pheromone. The other two components lacked the attractiveness. Thus, EE was considered to be the component which showed the attractiveness to *P. hybneri*. Since we could not detect a peak of EE with the GC-MS analysis in the hexane extracts of *P. hybneri* and soybean plants, *P. hybneri* seems to utilize the component of the pheromone of *R. clavatus*, which has a similar host range, as a kairomone to search for food plants. However, real male bugs of *R. clavatus* did not attract the *P. hybneri*. Now we are trying to explain this contradiction.

Fatty acid levels & triacylglycerol biosynthesis in the sex pheromone gland of *Heliothis virescens* Fabricius.

SP Foster
Department of Entomology, North Dakota State University, PO Box 5346, Fargo, North Dakota 58105, USA; stephen.foster@ndsu.nodak.edu

Most species of moths biosynthesize sex pheromone de novo in a specialized gland located between the 8th and 9th abdominal segments. As well as sex pheromone components, the gland contains large quantities of lipids, predominantly triacylglycerols. These triacylglycerols contain significant quantities of fatty acid precursors and other intermediates of the sex pheromone components. Despite the obvious role as a source of precursor acids for pheromone biosynthesis, the evidence in favor of this is equivocal; one particular problem is that insects using specific geometric isomer ratios for pheromone components tend to have very different ratios of the respective precursor acids. We believe that the glandular lipids have the role in pheromone biosynthesis of governing glandular fatty acid concentrations. When fatty concentrations are high (especially during high rate of pheromone biosynthesis), excess fatty acids are stored in the lipids; when concentrations low, fatty acids are mobilized from the lipids. This ensures the smooth production of pheromone during the sexually active period, which otherwise might be punctuated, for example, by high fatty acid concentrations inhibiting pheromone biosynthetic function. In this talk, we report the effect of glandular fatty acid levels on the biosynthesis of triacylglycerols in the pheromone gland of *H. virescens*.

Male mating behavior of the white-spotted longicorn beetle, *Anoplophora malasiaca* (Thomson) (Coleoptera: Cerambycidae) regulated by assorted female components.

M Fukaya, H Yasui, T Akino, T Yasuda, S Wakamura
Laboratory of Insect Behavior, NIAS, Tsukuba 305-8634, Japan; fukaya@affrc.go.jp

Male *A. malasiaca* dash towards and mount females, and bend the abdomen to copulate after contact with antennae or tarsi. Males make a similar mating attempt with glass dummies treated with the solvent extract of female elytra, indicating the presence of a female sex pheromone perceptible by physical contact. Chemical analysis of the pheromone components from female elytra revealed that at least three different groups of chemicals are involved: (1) long-chained alkanes, (2) ketones and (3) novel polar components. All three of these groups of chemicals are indispensable to evoke male mating behavior and work synergistically. Components within each group, however, complement each other. In addition to observation of the contact sex pheromone, we note the presence of volatile attractant produced by females in the near vicinity. Visual cues of females also appear to act synergistically with the volatiles in male mate location before direct contact by male antennae.

Control of sex pheromone precursor biosynthesis in adzuki bean borer *Ostrinia scapulalis.*

M Fukuzawa, S Tatsuki, Y Ishikawa
Laboratory of Applied Entomology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113-8657, Japan; aa26021@mail.ecc.u-tokyo.ac.jp

The adzuki bean borer *Ostrinia scapulalis* is one of the eight *Ostrinia* species found in Japan, and is an important pest of adzuki bean plant and hop. The sex pheromone of *O. scapulalis* is a blend of (*E*)-11- and (*Z*)-11-tetradecenyl acetates. These components are biosynthesized from common saturated fatty acids through chain shortening, desaturation, reduction and acetylation. The key enzyme in this cascade is the Δ11 desaturase that introduces a double bond into myristic acid to form E11-/Z11-tetradecenoic acid (fatty acyl pheromone analog, FAPA). It is known that one day-old females of *O. scapulalis* do not show calling behavior. We found that these females had little FAPA in their pheromone gland while sexually mature 3 day-old females accumulated a substantial amount. As decapitated females did not synthesize FAPA, it appeared that a signal from cephalic organs is important for triggering FAPA biosynthesis. We further found that FAPA titer in the females maintained under a constant light condition is lower than that in the control females, suggesting that the light-off signal enhances FAPA synthesis. Since the expression level of Δ11 desaturase gene was constant regardless of FAPA titer, it was suggested that FAPA biosynthesis in *O. scapulalis* is under post-transcriptional regulation.

Pollinator responses to mimicry by sexually deceptive orchids.

AC Gaskett, ME Herberstein
Department of Biological Sciences, Macquarie University, N.S.W. 2109, Australia.

Deceptive orchids mimic insect signals to attract pollinators without providing a reward. Orchid flowers may resemble food, oviposition sites, or female insects. Insects that respond, by attempting to mate with or feed from orchid flowers for example, collect and distribute orchid pollinia. Deceived insects may incur costs, e.g. time and energy wasted travelling to and interacting with orchids, and loss of sperm during pseudocopulation. Such costs may encourage the evolution of behavioural strategies that allow insects to avoid deceptive orchids. In sexually deceptive orchids, male pollinators are initially attracted by scents identical to female insect sex pheromones. Short-range cues eliciting pollinator contact with the flower may include visual cues such as colour and shape, and structural or tactile features that resemble female insect bodies. Investigation of the relative importance of chemical, visual, and structural cues, and the interaction between, long- and short-range cues should be rewarding. The Australian orchid genus *Cryptostylis* is an excellent study subject because all five species attract the same male wasp pollinator despite obvious differences in flower shape and colour. Here I introduce this intriguing study system and present some initial observations of pollinator behaviour and interactions between pollinator learning and the dimensions of orchid patches.

Multimodal communication in the acoustic Lepidoptera: evolutionary pathways & biophysical constraints.

Stausfield
Department of Ecology & Evolutionary Biology, Univ. of Kansas, Lawrence, KS 66045 U.S.A.

Multimodal signaling, widespread among animal communications, may serve in conveying multiple messages, reaching different receiver categories, redundancy, and reliability. In Lepidoptera, sexual communication in various species involves male acoustic (ultrasonic) + chemical advertisement and female hearing + olfaction. These modalities operate during different stages of pair formation. Phylogenetic analysis indicates that olfaction is ancestral, with (male) chemical signaling and ultrasonic hearing (females, males) each evolving independently in multiple clades; hearing evolved as a response to predatory, echolocating bats. Finally, (male) acoustic signaling evolved in several clades possessing hearing. Dual use of the ultrasonic channel by acoustic Lepidoptera and bats indicates special problems for sexual communication in the former, as females must reliably distinguish male calls from bat echolocations. Moreover, they must distinguish these in flight and while perched, situations with exposure to different bats. Whereas multimodal communication may conceivably afford opportunities for adaptive response, studies of the pyralid moth *Achroia grisella* show that critical distinctions are made acoustically and via input from a third modality, proprioception: Females assess temporal characters of ultrasounds and respond appropriately in accordance with their assessment and situation, flying or in ground contact. This protocol may be particularly reliable, given the constraints of time and limitations of neural processing.

Reproductive strategies of cerambycid beetles & the role of semiochemicals.

LM Hanks
Dept. of Entomology, 320 Morrill Hall, Univ. of Illinois at Urbana-Champaign, URBANA, IL 61801, USA; hanks@life.uiuc.edu

Reproductive strategies of adult cerambycid beetles, and the role of semiochemicals, are apparently associated with the condition of the host plant required by their larvae (whether hosts are alive, dying, or dead). For example, early studies have indicated that species whose larvae feed in living hosts are likely to use long-range pheromones, while those that feed in dying hosts typically rely on host plant volatiles to unite the sexes for mating. Nevertheless, more recent research has revealed evidence of long-range sex pheromones in dying-host species. There is also a growing body of evidence that mate recognition in species of both categories depends on contact chemoreception, and contact pheromones have been identified for several cerambycid species in recent years. Although the current state of cerambycid research documents considerable variation in reproductive strategy, the association with host plant condition provides structure for guiding future research.

Mass trapping of olive moths.

EM Hegazi, WE Khafagi
Faculty of Agriculture, Alexania University, Alexania, Egypt; eshegazi@hotmail.com

A simple and inexpensive UV-trap was developed by the first author from materials generally available around the olive farm, to capture the main lepidopterous pests of olive trees. The trap consisted of a sticky-collecting device, two ultraviolet fluorescent tubes and tilted mirrors to increase light intensity by interference of reflected rays and spreading light reflection over a wider area. The trap was compared with delta-traps (baited with (Z)-Z-tetradecenol) and funnel traps (baited with (E)-11-hexadecenol and (E)-11-hexadecenyl-acetate) for monitoring the olive moth, *Prays oleae* and jasmine moth, *Palpita unionalis*, respectively. Sex pheromone catches (only males) were persistently lower in all collections of 2 successive olive seasons of 2002 & 2003 than those of UV-traps. *P. oleae* catches (males & females) in the UV-trap significantly ($P<0.01$) exceeded *P. unionalis* moths. The obtained results indicated that the UV-trap may represent an effective tool for mass-trapping of *P. oleae* and monitoring tool for *P. unionalis* and other species of moths in the area. The trap was so effective in trapping *P. oleae* even when adult population was low compared with sex pheromone trap. Some of non-target species may be protected from damage by placing a screen of proper sized mesh over the entrance of the trap. The UV-trap saved the fruit yield of a large olive farm without using any insecticides throughout the study period.

"New approaches to find key compounds in tritrophic interactions – exploiting genetic variation & *in situ* modification of volatile profiles. "

M Held, M D'Alessandro, C Tamo, T Turlings
Laboratoire d'Ecologie Animale et d'Entomologie, Rue Emile-Argand 11, Université de Neuchâtel, CH-2007 Neuchâtel, Switzerland; matthias.held@unine.ch

Odour blends that are released by plants after herbivore attack can act as indirect defense by attracting natural enemies of the herbivore. These blends consist of mixtures of volatile organic compounds (VOCs), but, as yet, for many tritrophic systems it remains unknown, which VOCs of such complex blends are the most attractive ones. One way of studying the importance of individual VOCs is to test the attractiveness of odour blends differing in their pattern of compounds. This approach was used to test the attraction of naive and experienced females of the parasitoid wasp *Cotesia marginiventris* to volatile blends of maize infested with *Spodoptera littoralis* larvae. We used olfactometers in which female wasps were offered choices among odour blends of different chemical composition. The different blends were obtained by either using different maize inbred lines or by installing selectively adsorbing filters between the odour source and the olfactometer arms. The data were analysed with multivariate statistical techniques and revealed the relative importance of some VOCs that are often underestimated because of their small quantities.

How parasitoids read the news: information use in a patchy world.

TS Hoffmeister, A Thiel, U Tölch, MF Kersch, JJ Piening
Institute for Ecology and Evolution, Dept. of Animal Population Ecology, University of Bremen, Leobener Str. D-28359 Bremen, Germany; t_hoffmeister@web.de

Patch leaving decisions in insect parasitoids have mainly been studied as a function of host density and host encounters in single-patch experiments. From such experiments we know that parasitoids respond to host kairomones and encounters with unparasitized hosts. Yet, parasitoids often encounter unparasitized as well as parasitized hosts. Response to encounters with parasitized hosts has been debated, but experimental evidence has been equivocal. Moreover, how information on a given patch and patch encounter rate influence the patch time allocation on subsequent patches has largely remained unanswered. Using *drosophila* parasitoids, we investigated behavioural responses of wasps to information cues for estimating patch quality and habitat quality. In patch-quality experiments we tested responses towards staged encounters with unparasitized vs. parasitized hosts. In habitat-quality experiments we tested whether odour from neighbouring patches affect the patch-time, and the searching behaviour when leaving the patch. Further, we studied how encounters with good and poor quality hosts and their density influence the time allocation on subsequent patches. Finally, we tested how parasitoids respond to variation in patch encounter rates in their patch time allocation and patch exploitation level. We discuss our results with respect of the reliability of such cues for future foraging success.

Floral scent mediating the foraging behaviour of some papilionid & danaid butterflies.

K Honda
Faculty of Integrated Arts & Sciences, Hiroshima University, Higashihiroshima 739-8521, Japan; honce@hiroshima-u.ac.jp

In addition to visual stimuli, olfactory cues also play a significant role in the foraging behaviour of anthophilous butterflies. I investigated floral volatiles of *Citrus* flowers (white in colour) that stimulate flower-visiting by a papilionid butterfly, *Papilio protenor*, which shows innate colour preference for red, orange, and blue. To determine active compounds, odour components were first screened individually to assess their ability to evoke proboscis extension reflex (PER), and the actual attractancy of potential components was confirmed by free-flight experiments. Of 16 compounds identified from the flower, methyl anthranilate, 2-phenylethanol, and phenylacetonitrile were found most attractive to the butterfly, indicating that compounds with an aromatic ring serve as important olfactory cues in their flower-visiting. In Japan, flowers of *Eupatorium chinense* have been observed to strongly attract danaid butterflies in the genera *Parantica, Ideopsis, Euploea,* and *Salatura*. Although several volatile compounds detected from an isopentane extract of the flower showed weak to moderate PER-activities, none of them exhibited strong attractiveness to the danaids. However, floral nectar of the plant was found to contain a considerable amount of pyrrolizidine alkaloids. The major compound, identified as intermedine, strongly attracted some danaid species, suggesting that certain pyrrolizidine alkaloids *per se* function as attractants.

Molecular cloning of a putative PBAN receptor from pheromone glands of the silkmoth, *Bombyx mori*.

JJ Hull, R Kurata, MG Suzuki, K Moto, S Matsumoto
RIKEN, Wako, Saitama, 351-0198, Japan; joeythemarsupial@yahoo.com

Despite recent successes in elucidating the molecular components of sex pheromone biosynthetic pathways within the Lepidoptera, identification of the gatekeeper of the pathway, the PBAN receptor, has proven to be elusive. Given the sequence similarity between the active C-terminal regions of PBAN and neuromedin U, it was hypothesized that their respective receptors might also be similar in structure. Consequently, a homology-based molecular approach utilizing primers constructed from the conserved regions of insect neuromedin U receptor homologues was used to amplify a full-length 2777-nt clone from a *Bombyx mori* pheromone gland cDNA library. Conceptual translation of the ORF indicated that it encoded a 45.8 kDa 7 transmembrane protein with 82% identity to a GPCR that has been recently cloned from pheromone glands of *Helicoverpa zea*. Interestingly, the sequence identity decreases considerably within the amino terminus and the *Bombyx* receptor contains a 67 amino acid C-terminal extension. Tissue distribution analyses reveal that the receptor is specific to the pheromone gland where it undergoes significant up-regulation in the day preceding eclosion. In addition, when expressed in Sf9 cells the receptor not only exhibits specific binding to PBAN but also mobilizes calcium in a dose-dependent response.

Reception of floral odours by *Helicoverpa armigera* antennae.

CD Hull, JP Cunningham, CJ Moore, MP Zalucki, BW Cribb
Department of Zoology and Entomology, The University of Queensland, Brisbane, Qld, 4072, Australia; c.hull@ento.uq.edu.au

The antennal receptor cell complex of *Helicoverpa armigera*, that is used in detecting a range of floral and green leaf odours, was investigated with electrophysiological and behavioural methods. By using mixtures of odours at saturating levels, the electroantennogram method can produce useful information about the classes of receptor cells used in detecting plant odours. This methodology provides information that both differs from and augments that gained by single neuron recordings, and as such allows the testing of hypotheses related to receptor types. A range of volatiles was tested including those principally associated with flowering parts or leaves as well as volatiles common to both. The two enantiomers of the chemical μ-pinene were also investigated and results suggest a common receptor neuron type for these enantiomers. Behavioural experiments showed that conditioned learning of odours can influence the decisions of the insect.

Significance of male's licking female dorsum in matings of Cerambycidae (Coleoptera).

R Iwata, H Imazeki
Department of Forest Science and Resources, College of Bioresource Sciences, Nihon University, Fujisawa 252-8510, Japan; iwata@brs.nihon-u.ac.jp

In matings of, if not all, some coleopteran families including Cerambycidae, it has been often recognized that male, on female's back, lick her dorsum with his mouth parts. However, there has been only a very limited number of literature on this behavioral component. We therefore investigated the significance of each of the body parts in cerambycid mating sequence, focusing on males' dorsum-licking behavior. Adults of diurnal cerambycid species, *Dinoptera minuta* (Gebler) (Lepturinae) and *Chlorophorus quinquefasciatus* (Cerambycinae), were collected in the field, and each of the test animals was treated by mutilating antennae with scissors (male, female) or coating its compound eyes (male, female) or pronotum plus scutellum (female) with water-based white correcting fluid. A treated individual and an untreated partner were paired and their mating sequence followed. Untreated pairs initiated mounting directly upon male antenna's touching female's body or antenna. Antenna-mutilation of male caused severe hinance of mating. Blind males did not mount or copulate. Coating pronotum/scutellum-region of the female also caused copulation hinance. The last result suggests that female beetle possibly possesses in her pronotum/scutellum region a source of pheromone toward the male and/or a sensory organ admitting male's appeasement by his mouth parts while in copula.

Using synthetic herbivore-induced plant volatiles to enhance conservation biological control in crop ecosystems: field experiments in hops & grapes.

DG James, T Price
Department of Entomology, Washington State University, Irrigated Agriculture Research and Extension Center, 24106 North Bunn Road, Prosser, Washington 99350, USA; david_james@wsu.edu

The potential of using synthetic herbivore-induced plant volatiles to enhance conservation biological control of insects and mites in crop ecosystems is being researched in hops and grapes in Washington State. Results to date indicate that a number of natural enemy species in the families, Chrysopidae, Hemerobiidae, Anthocoridae, Geocoridae, Miridae, Coccinellidae, Syrphidae, Braconidae, Empididae and Mymaridae, are attracted to sticky traps baited with aqueous methyl salicylate (MeSA), hexenyl acetate, farnesene or octyl aldehyde. Further, hop yards and grape blocks baited with slow release sachet dispensers of MeSA appeared to recruit larger populations of some insect predators (e.g. *Stethorus punctum picipes, Orius tristicolor, Chrysopa nigricornis*) than unbaited areas, resulting in some instances, in improved biological control of spider mites. The use of synthetic plant-signalling compounds as 'Herbivore-Induced Plant Protection Odors' (HIPPOs) may provide a novel yet practical option for improving the efficacy and reliability of conservation biological control in a variety of agricultural ecosystems.

Mating behaviour of the New Zealand native leafroller *Cnephasia jactatana* Walker (Lepidoptera: Tortricidae).

A Jiménez-Pérez, Q Wang, N Markwick, R Arzuffi
Ceprobi-IPN. Apto. Postal 24, Yautepec, 62731, Morelos, Mexico; Aljimenez@ipn.mx

Cnephasia jactatana Walker is a pest of kiwifruit in New Zealand. The objective of this study was to provide information on its mating behaviour for the development of pest management measures. Sexual maturation period was 3 d for females and 2 d for males. More than 50% of eggs were laid within 3 d after mating. Female reproductive fitness was reduced by > 85% if mating was delayed for 4 d. Males actively approached and courted females before mating occurred and females appeared to be less active. Males used their antennae, labial palps and wings to touch females when courting. Virgin males performed more mating attempts than mated males when competing for females. Sexual selection in *C. jactatana* did not support Darwin's sexual selection theory where females are more selective and males suffer the sexual selection effects. In this species, males appeared to be more selective than females. Both sexes preferred virgin to mated mates for mating. Males preferred young to old females for mating while females did not discriminate the male age when choosing a mate. Male body weight did not confer any mating advantage. However, females preferred males with longer antennae for mating. Light- and average-weight males presented a size assortive-selection while heavy males did not show any preference.

Regulation of pheromone biosynthesis in moths: PBAN & a G-protein coupled receptor.

R Jurenka
Iowa State University, Department of Entomology, 3222 Science II, Ames, IA, 50011, U.S.A; rjurenka@iastate.edu

Pheromone biosynthesis in most moths is regulated by PBAN (pheromone biosynthesis activating neuropeptide). This hormone is produced by the subesophageal ganglion and can be released into the hemolymph to stimulate biosynthesis in pheromone glands. PBAN acts directly on pheromone glands using cAMP and calcium as second messengers. Biosynthesis is activated by stimulating acetyl-CoA carboxylase or a reductase. Pharmacological evidence indicated the presence of a G-protein coupled receptor. To identify the receptor we utilized the finding that *Drosophila* contains PBAN-like peptides and thus a receptor for the peptides. Three *Drosophila* receptors had sequence homology to neuromedin U receptors from vertebrates. Neuromedin U will stimulate pheromone biosynthesis in *Helicoverpa zea* and *H. armigera* indicating cross-reactivity of the peptide and functional homology of the receptors. Based on sequence homology to the receptors from *Drosophila,* the open reading frame of a gene was isolated from mRNA obtained from pheromone glands of *H. zea.* The PBAN-receptor was cloned and expressed in Sf9 cells and using a calcium mobilization assay responded to PBAN in a dose-dependent manner. Additional peptides produced by the PBAN family were also tested. This represents the first identification of a receptor for the PBAN family of peptides with a known function in female moths.

Herbivore-induced volatiles alter plant resistance.

R Karban
Department of Entomology, UC Davis, Davis, CA 95616 USA; rkarban@ucdavis.edu

In response to damage, several plants have been found to emit volatiles that make neighboring plants more resistant to herbivory. When sagebrush is damaged in the field, airborne volatiles cause neighboring conspecifics to change chemically and suffer less damage by naturally occurring herbivores. Emissions of methyl jasmonate increase in the headspace of damaged sagebrush, making it a leading candidate as a volatile cue mediating increased resistance. Since many plant species respond to methyl jasmonate, it seemed plausible that various neighbors might induce resistance when growing near damaged sagebrush. Damage to sagebrush in the field caused neighboring wild tobacco but not other naturally occurring plant species to become more resistant. Preliminary laboratory experiments suggest that methyl jasmonate is sufficient, but not necessary, as an airborne cue.

Effective pheromone lures for monitoring the rice leaffolder moth, *Cnaphalocrocis medinalis* (Lepidoptera: Crambidae).

K Kawazu, T Kamimuro, H Kamiwada, K Nagata, T Matsunaga, H Sugie, T Fukumoto, T Adati, S Tatsuki
Graduate School of Agricultural and Life Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113-8657, Japan

Several factors affecting the attractiveness of traps baited with synthetic sex pheromone components of *Cnaphalocrocis medinalis* were examined in the laboratory and field. In the laboratory, among the four pheromone components, Z11-18:Ald, Z13-18:Ald, Z11-18:OH and Z13-18:OH, the major component, Z13-18:Ald, was shown to be an essential component for attraction and Z11-18:Ald was shown to be a potent synergist for the major component. The alcohols also showed an apparent synergistic effect in the laboratory bioassay when their mixture was combined with an aldehyde mixture. The addition of the geometric isomers of the four components at levels greater than 5% of the purified 4-component blend showed significant inhibitory effects on the pheromonal activity in the laboratory. In the field, no synergistic effect of the alcohols on the aldehydes was shown. A range of loadings of the pheromone rubber septa (0.01–3.42 mg) was tested and all remained attractive for at least one month with optimum attractiveness on 0.86 mg/septum. No significant effects were obtained when the ratio of Z11-18:Ald to Z13-18:Ald was changed. Rubber septa containing 0.86 mg of the four components (*E*-isomers 5%) at the natural ratio are being effectively used for monitoring.

Experimental evolution of improved learning ability in *Drosophila.*

TJ Kawecki, F Mery
Department of Biology, University of Fribourg, Chemin du Musée 10, CH-1700 Fribourg, Switzerland; tadeusz.kawecki@unifr.ch

While fitness benefits of animal learning are well understood, other questions concerning the evolution of learning remain open. How easily can improved learning ability evolve? Does evolution act on "general intelligence", or rather on learning abilities specialized to particular tasks and situations? What are the costs of learning ability? To address these questions we have exposed replicated populations of *Drosophila melanogaster* to long-term selection for improved olfactory-gustatory learning in the context of oviposition substrate choice. After over 20 generations of selection the experimental populations evolved markedly improved learning ability. The improved learning ability generalized to other tasks, which involved different stimuli, reward rather than aversion learning, and classic rather than operant conditioning. The selected populations also showed better learning ability as larvae. This indicates that the response to selection was based on evolutionary changes in general aspects of the learning and memory, involved in many forms of learning. Furthermore, compared to control populations, larvae of the selected populations showed lower competitive ability. Additional data excluded inbreeding as a potential cause of reduced competitive ability. Therefore we believe that the lower competitive ability of the experimental populations indicates a genetic cost of learning ability.

Patch leaving decisions of *Cotesia rubecula*: a synthesis.

MA Keller
Plant & Pest Science, Waite Campus, The University of Adelaide, SA 5005 Australia; mike.keller@adelaide.edu.au

Cotesia rubecula (Hymenoptera: Braconidae) is a solitary endoparasitoid of larval *Pieris rapae* (Lepidoptera: Pieridae). Adult P. *rapae* lay single eggs on a range of *Brassica* species (Brassicaceae) and other plants, and their larvae develop as individuals on host plants. *C. rubecula* parasitises first through fourth instars of *P. rapae*. A series of laboratory and field experiments has examined patch-leaving decisions of Australian *C. rubecula*. A range of factors has been shown to influence patch-leaving tendency of this parasitoid including host stage and density, the amount of plant damage by the host, recent oviposition experience of the wasp and the wasp's feeding status. Decisions are also influenced by the spatial distribution of host plants. This paper will develop a synthesis of experimental results and aims to identify the selective factors that have shaped the foraging behaviour of *C. rubecula*.

The infrared organ of the Australian “little ash beetle” *Acanthocnemus nigricans*: morphology of the specialised sensilla.

E Kreiß, A Schmitz, H Schmitz
Rheinische Freich-Wilhelms-University Bonn, Institute for Zoology, Poppelsdorfer Schloß, D-53115 Bonn Germany; e.kreiss@uni-bonn.de

The Australian beetle *Acanthocnemus nigricans* (Coleoptera, Acanthocnemidae) approaches forest fires. The reason for this pyrophilous behaviour might be that larval development depends on burned wood. *A. nigricans* has a pair of infrared organs on the ventrolateral sides of its prothorax. Each organ consists of a cuticular “sensory disc”with a diameter of about 150µm. About 70 small cuticular sensilla were found mainly on the outer surface of the disc. The cone shaped cuticular peg of a sensillum is about 2µm in diameter. It has no pores and is surrounded by a cuticular wall. The single sensory cell of the sensillum shows some similarities to the “bauplan” of a mechanoreceptive sensory cell of a trichoid sensillum. However, three specialisations can be found: (i) the denitic outer segment is enveloped by a pronounced electron-dense structure, which most likely represents the hypertrophied denitic sheath. (ii) The membranes of the denitic inner segment and the soma show distinct infoldings which contain a high amount of mitochondria. (iii) No tubular body can be found.As the cuticular disc responds to infrared radiation, it is likely that this specialised new type of insect sensillum may act as a thermoreceptor. Further examinations will have to test this hypothesis.

Pheromone response & mating activity in the consperse stink bug, *Euschistus conspersus.*

CH Krupke, VP Jones, JF Brunner
1100 North Western Ave., Wenatchee, WA 98801, USA ckrupke@wsu.edu

The consperse stink bug, *Euschistus conspersus* Uhler, has emerged as an important pest of pome fruit production in Washington state. My research has focused upon quantifying the behavioural response of this insect to its aggregation pheromone, methyl (2*E*,4*Z*)-decadienoate in an attempt to develop pheromone-based monitoring or management systems. I describe research investigating the pheromone-mediated aggregation behaviour in *E. conspersus* in the field and describe the subsequent development of a detailed diel activity profile for this insect. *E. conspersus* aggregations peaked at dusk, with mating occurring primarily at night. Sex ratios were equal in aggregations and both sexes were found to be polygamous, mating on successive nights but with different partners. Laboratory experiments were performed to investigate possible factors mitigating mate choice in this species. The significance of these findings with respect to the possible function of aggregation in this species is discussed, as well as the implications for management.

Molecular basis of pheromone binding, release, & inactivation.

WS Leal, Y Ishida
Department of Entomology, University of California-Davis, Davis CA 95616, USA; wsleal@ucdavis.edu

Insects perceive the world through small molecules - pheromones and other semiochemicals. Their odor-oriented navigation relies heavily on the ability of the olfactory system to selectively detect minute amounts of pheromones and reset the detectors in millisecond scale (by inactivating the chemical signals). Pheromone molecules enter the sensillar lymph through pore tubules in the sensillar wall, are solubilized upon being encapsulated by odorant-binding proteins (OBPs), and transported to the olfactory receptors (ORs). Upon interaction with negatively-charged sites at the denitic membrane, the OBP-ligand complex undergoes a conformational change that leads to the ejection of pheromone to activate the pheromone receptors. While bound to OBPs, pheromone molecules are protected from odorant-degrading enzymes (ODEs). In this presentation, we will (1) briefly discuss the molecular mechanisms of pheromone binding and release by focusing on the *Bombyx mori* system, i.e., how bombykol enters and leaves the binding cavity in BmPBP, (2) report the first odorant-degrading enzymes isolated from insect antennae to date, and (3) discuss the possible mechanism of enzymatic inactivation of pheromones.

Induction of preference for oviposition repellents originated from non-host plants by a specialist herbivore.

SS Liu, Y Li, Y Liu
"Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Road, Hangzhou 310029, China; shshliu@zju.edu.cn"

Repellents derived from non-host plants have been assumed to have a role to play in the behavioural manipulation of crop insect pests. However, behavioural responses to such repellents by insects have been rarely observed either in the laboratory or field. In laboratory and greenhouse experiments, we observed the responses of diamondback moth, *Plutella xylostella*, a special herbivore of crucifer plants to oviposition repellents derived from a non-host plant, *Chrysanthemum morifolium.* When provided with a choice between untreated Chinese cabbage and Chinese cabbage sprayed with an extract of *C. morifolium* in one arena, inexperienced females deposited 9-fold more eggs on the former than on the latter plant, demonstrating that the plant extract had substantial repellent effects on this insect. However, when the test adults were offered prior experiences of the plant extract and then exposed to the dual-choice of plants for oviposition, they laid significantly more eggs on the plant sprayed with the *C. morifolium* extract than that on the untreated plant. Further observations with neem-based materials also showed induction preference to these repellents by *P. xylostella.* Adult learning thus can render repellents derived from non-host plants to become ineffective or even attractive to this insect.

Non-host antifeedants in hylobius pine weevils: from lab to field applications.

F Schlyter, P Månsson, J Löfqvist, K Eriksson, K Sjödin, HE Högberg
"Chemical Ecology, Department Of Crop Sciences, Swedish University Of Agricultural Sciences, Po Box 44, Se-230 53 Alnarp, Sweden;
Per.Mansson@Vv.Slu.Se"

We searched for antifeedant activity in non-host woody plants to find new compounds for seedling protection of Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) against pine weevil feeding. In total, 38 species from 25 families were compared. The weevils removed less of both outer and inner bark in *Ilex*, *Evonymus*, *Populus*, *Syringa*, *Taxus*, *Tilia*, *Viburnum*, *Lonicera*, and *Sorbus* than on *Pinus*. In some plants, *Juglans*, *Fraxinus*, *Sambucus*, *Aesculus*, *Quercus*, *Corylus*, *Fagus*, *Salix*, *Alnus*, & *Acer*, the outer bark was removed by the insects but had an inner bark with antifeedant qualities. Bark of Linden, *Tilia cordata*, showed the best antifeedant qualities and was extracted and tested for antifeedant activity. The active extract was fractioned on silica gel. TLC and GC was used to trace chemical similarities between the fractions and resulted in merging the number of fractions down. The micro assay gave positive antifeedant activity in two adjacent fractions. These fractions were analyzed and nonanoic acid was found in both of them. Synthetic octanoic, nonanoic, and decanoic acid tested in the micro feeding assay had strong antifeedant activities against both sexes.

Characterization of genes encoding enzymes involved in bombykol biosynthesis.

S Matsumoto, K Moto
Riken, Wako, Saitama, 351-0198, Japan; smatsu@riken.jp

In the biosynthesis of class I-type Lepidopteran pheromone components, the key enzyme required to produce the oxygenated functional groups is pgFAR. This enzyme converts fatty-acyl pheromone precursors to their corresponding alcohols, which can then be, depending on the moth species, further modified via acetylation or oxidation reactions. In experiments designed to characterize the pgFAR in *B. mori*, we have isolated a cDNA clone encoding a protein homologous to a FAR from the desert shrub, *Simmondsia chinensis*, commonly known as jojoba. The deduced amino acid sequence of this clone predicts a 460 amino acid protein with a consensus NAD(P)H binding motif within the amino terminus. Northern blot analyses indicated that the 2-kb transcripts of this gene are specifically expressed in the pheromone gland at one day prior to adult eclosion. Functional expression of this gene in the yeast *Saccharomyces cerevisiae* not only confirmed the long-chain FAR activity but also indicated a distinct substrate specificity. Finally, the transformed yeast cells evoked typical mating behavior in male moths when cultured with the pheromone precursor fatty acid. We will also refer to a bifunctional desaturase utilized in the production of the conjugated diene system from which bombykol biosynthesis is dependent on.

"Come on baby light a fire": the reproductive biology of *Actebia fennica.*

JN McNeil, M Cusson, Everaerts, E Forcier, W Francke, T Tolasch
Department of Biology, University of Western Ontario, London, ON., Canada, N6A 5B7; jmcneil2@uwo.ca

Black army cutworm out breaks are associate recently burned areas, which are unpredictable in time and space. Our wind tunnel experiments showed that while females exhibit oriented, upwind flight in smoke plumes males do not. We also examined the effect of smoke volatiles the temporal changes in juvenile hormone biosynthesis and oocyte development, as well as on the age at which females first exhibited the behaviour associated with the emission of the sex pheromone. All data support the hypothesis that volatiles from burnt vegetation serve as " kairomones", accelerating sexual maturation in females. However, mated females, held in the presence of volatiles that stimulated sexual maturation, actually laid fewer eggs. An ecological hand-waving scenario will be proposed to explain the results obtained to date. We will also discuss how the recent identification of different smoke compounds detected by females might subsequently be used in management programmes for this pest species.

On the kairomonal attraction of adults & nymphs of *Elatophilus* spp. (Heteroptea: Anthocoridae) to sex pheromones of *Matsucoccus* spp. (Hemiptera: Matsucoccidae).

Z Mendel, D Ofer, M Branco, JC Franco, E Dunlkelblum
Department of Entomology, ARO, the Volcani Center, Bet Dagan, 50250, Israel; zmendel@volcani.agri.gov.il

While kairomonal response of insect predators to the sex pheromone of the insect prey has been rarely documented, our recent studies proved consistently that the female sex pheromones of *Matsucoccus josephi* , *M. feytaudi* and *M. matsumurae* are powerful long range attractants for *Elatophilus* spp. Examining the attraction to the pheromone and analogs of seven *Elatophilus* spp. revealed a clear species specific attraction displaying by these predators. Similarly to their conspecific adults the nymphs of *E. hebraicus, E. crassicornis* and *E. nigricornis* are also lured by the specific sex pheromone. It seems that sex pheromones of *Matsucoccus* serve *Elatophilus* spp. as aggregation kairomones and as sexual stimulants. *Elatophilus* spp. display courtship behavior and mate frequently in arenas baited with the pheromone. When the predator population is high, most of the females that congregated around a pheromone source were already mated but displaying none or few visible eggs in the ovaries. We suggest that the typical group movement displayed by the nymphs is determined by their attraction to the pheromone. This behavior may increase survival through "a better feed tracing" and "safety in numbers". Female first mating probably occur soon after molting within their own group before being lured to a pheromone source.

Odor perception & odor learning in honeybees.

R Menzel, CG Galizia, S Sachse, P Syszka, M Weidert
Neurobiologie, Freie Universität Berlin, Königin-Luise-Str. 28-30, 14195 Berlin, Germany

Honeybees discriminate a large range of odors, and learn odors as signals for food. We have used optical imaging and intracellular recording techniques to examine the neural substrates of odor coding and memory formation in the antennal lobe (AL) and the mushroom bodies (MB). Odors elicit combinatorial patterns of activity in the glomeruli of the AL. Imaging of the input region of the mushroom bodies reveals that odors are represented in specific patterns of microglomerular activation. A comparison of the dynamics of the odor responses shows that mushroom body intrinsic neurons code odors in a sparse way with a small number of spikes per stimulus and a small number on activated Kenyon cells. Odor learning leads to an enhancement of the synaptic transmission at the input synapses to the Kenyon cells that respond to the trained odor (CS+), and a reduction of synaptic efficiency to the non trained odor (CS-). A model will be presented that captures the results of our electro- and optophysiological recordings, and assigns particular functions to the mushroom body in the bee brain.

Male-produced aggregation pheromone of *Neoclytus acuminatus acuminatus*.

JG Millar, ES Lacey, M Ginzel, LM Hanks
Dept. of Entomology, University of California, Riverside CA 92521, USA; jocelyn.millar@ucr.edu

The red-headed ash borer, *Neoclytus acuminatus acuminatus* (F.) (Coleoptera: Cerambycidae) is endemic to North America, where it infests a variety of hardwood trees. It also has been accidentally introduced into Europe and possibly New Zealand. In the field, we observed males performing a stereotyped calling behavior which provided the first indication of pheromone production by male *N. a. acuminatus*. This behavior has not been reported for any other cerambycid species. Insects of both sexes were attracted to caged males but not to females. We report the identification and field testing of a male-produced aggregation pheromone for this species. During field trials, females of another cerambycid species, *Curius dentatus* Newman, were attracted to traps baited with some of the test compounds, suggesting that one of more of the test compounds were also part of the sex pheromone of this relatively unknown species as well. These may be the first examples of cerambycid pheromones with an activity range of tens to a huned meters or more.

Pheromonal & vibrational signals of stink bugs in the genus *Chlorochroa*.

JG Millar, G Bagwell, HS Ho
Dept. of Entomology, University of California, Riverside CA 92521, USA; jocelyn.millar@ucr.edu

Stink bugs in the genus *Chlorochroa*, similar to other phytophagous stink bugs, use a combination of pheromonal and substrate-borne vibrational signals in their reproductive behaviors. The pheromones are male-produced, and probably act as attractants over longer distances, whereas vibrational signals (songs) are produced by both sexes once the bugs are on the same plant. The vibrational signals are sex- and species specific, with males and females producing a repertoire of calling songs as orientation cues, and courtship songs once the bugs are close together or in contact. The pheromonal and vibrational signals will be compared and contrasted for three sympatric *Chlorochroa* species, and the roles of these signals in intraspecific communication will be discussed.

Fruitspotting bugs.

CJ Moore, GK Waite, JR Aldrich, A Zhang
Locked Bag 4, Moorooka, QLD, 4105, Australia; chris.moore@dpi.qld.gov.au

The fruitspotting bugs, *Amblypelta nitida*, and the closely-related *Amblypelta lutescens*, are serious pests of tropical and sub-tropical fruit and nut crops in Queensland and northern New South Wales. Current control relies on the frequent application of insecticides, with recent investigations focussing on promising soft-option strategies such as restricting insecticide application to fruitspotting bug hotspots, and the use of SurroundÒ to deter feeding. Behaviour-modification approaches are a legitimate component of clean-green management strategies, and to this end, investigations of the insects' semiochemistry were commenced 14 years ago. Despite early breakthroughs in the chemistry studies, subsequent progress has been sporadic. The major component of male-derived volatiles of *A. nitida* was shown to be a mono-epoxide of (E)-b-ocimene, having the trivial name, myroxyde; and of *A. lutescens*, (-)-(3R)-(E)-nerolidol. The absolute configuration of the former compound has been defined through the development of efficient synthetic strategies and the application of SPME sampling technology. Recent gas chromatography-electroantennography studies have confirmed myroxide, along with the minor compounds, nonanal and decanal, as stimulants of antennal response in *A. nitida*. The attractiveness of blends of racemic myroxyde and the aldehydes, using a new clear-plastic football-shaped trap, is being investigated.

Isolation & characterisation of a putative aggregation pheromone component for the striped cucumber beetle, *Acalymma vittatum* (F) (Coleoptera: Chrysomelidae).

BD Morris, RR Smyth, S Franke, W Francke, SP Foster, MP Hoffmann, WL Roelofs
Department of Entomology, North Dakota State University, PO Box 5346, Fargo, North Dakota 58105, USA; bruce.morris@ndsu.nodak.edu

Male-produced aggregation pheromones have previously been identified from a limited number of Chrysomelids; the hydroxy-ketones (*S*)-3,7-dimethyl-2-oxo-6-octene-1,3-diol from the Colorado potato beetle, *Leptinotarsa decemlineata* (Say) [1], and (*E*)-8-hydroxy-6-methyl-6-octen-3-one from the cereal leaf beetle, *Oulema melanopus* L. [2]. Himachalene and cadinene sesquiterpenes from *Phyllotreta cruciferae* and three *Apthona* spp. of flea beetles were electrophysiologically active [3]. Field trapping studies showed that feeding male *A. vittatum* attracted significantly more congeners than feeding females, or undamaged cucumber plants, indicating that it may also use an aggregation pheromone [4]. GC-EAD studies were carried out using airborne collections from feeding beetles, or SPME collections, and male or female antennae. One component of male collections consistently gave a strong EAD response, and was absent from collections from female beetles. This putative pheromone was initially characterised by GC-MS and micro-reactions. More than 3000 beetle-days of collection on Porapak resulted in sufficient compound for extensive 1- and 2-D NMR spectroscopic studies, and FTIR. These allowed complete structural characterisation of the pheromone. The only closely related compounds are antibiotics of microbial origin, which were compared with the pheromone by NMR. Currently, efforts to synthesize the pheromone, and test for behavioural activity are in progress.

Mate location & mating behaviour of ***Chrysophtharta agricola*** **(Chapuis) (Coleoptera: Chrysomelidae: Paropsini).**

HF Nahrung
School of Natural Resource Sciences, Queensland University of Technology, GPO Box 2434, Brisbane, Queensland 4001 Australia; h.nahrung@qut.edu.au

The mating system of *Chrysophtharta agricola* comprises prolonged searching scramble competition polyandry, whereby receptive females are evenly dispersed spatially and temporally, and males search competitively for them: 90 % of beetles captured on sticky traps were males. More males were caught on traps baited with sexually receptive conspecific beetles than on traps that contained foliage only. Male mating behaviour comprised long pairing associations with several intromission events, and did not change according to female mated status. Paternity analysis using a polymorphic gene for melanism showed various sperm use over lifetime offspring production. Field data were modelled to estimate that beetles mate 15 – 51 times in a season. Beetles did not select mates based on size, colour, generation or parasitic mite infection.

Sex pheromone of a carpenter moth, *Cossus insularis* **(Staudinger).**

K Nakamuta, X Chen, T Nakashima, F Mochiduki, T Fukumoto
PO Box 16, Tsukuba Norin Kenkyu Danchi-nai, Tsukuba, Ibaraki 305-8687, Japan; nakamuta@ffpri.affrc.go.jp

Cossus insularis (Staudinger) (Cossidae: Lepidoptera) is a woodborer found in Honshu, Kyushu and Tsushima Island of Japan. The larvae excavate their galleries in a group on twigs or trunks of the broad-leaved trees such as willow trees, pear trees, chestnut trees, and cause damage and often mortality of the trees. To utilize sex pheromone for monitoring or controlling the borers, sex pheromone of *C. insularis* was identified. Combined gas chromatography-electroantennographic detection (GC-EAD) analysis of airborne volatiles collected from unmated female moths by a solid-phase microextraction (SPME) showed that two volatile compounds elicited significant electroantennographic responses from the antennae of male moths. These two volatile compounds collected from female moths were identified as (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate by mass spectral and retention index comparisons with synthetic standards. In field bioassays, sticky traps baited with a lure of a 4:1 blend of synthetic (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate captured significantly large number of male moths, while unbaited traps captured no male moths. These results indicate that sex pheromone of *C. insularis* is a mixture of (*E*)-3-tetradecenyl acetate and (*Z*)-3-tetradecenyl acetate.

Plant/plant communication-herbivores & their natural enemies: experiments with spring-sown barley.

V Ninkovic, R Glinwood, J Pettersson
Swedish University of Agricultural Sciences, Department of Entomology, Box 7044, 75007 Uppsala, Sweden; velemir.ninkovic@entom.slu.se

Experiments with a barley crop and weeds have shown that effects of chemical communication between plants can be traced in a tritrophic perspective as follows:*Exposure to allelobiotic substances has a physiological effect on cereal plants, evidenced by significant changes in the pattern of biomass allocation and changes in leaf temperature. *Exposing cereal plants to allelobiotic volatiles from neighbouring plants and root exudates from aggressive weeds decreases the acceptability of the exposed plants for aphids. This happens in interactions between different cultivars of barley (*intra-species*), and between cereals and a number of aggressive weeds (*inter-species*). *Exposure to allelobiosis from weeds causes barley plants to become more attractive to aphid natural enemies, a ladybird *Coccinella septempunctata.* *The results suggest that plant responses to allelobiosis is a preparation for coexistence with other plants and this is a basis for follow up effects in higher trophic levels. The positive effect on searching behaviour of polyphagous predators may increase the ecological success of "listening" plants in a mixed plant stand and, also have negative effects on herbivore plant acceptance.

Artificial substrate bioassay for testing oviposition of the southern green stink bug, *Nezara viridula* (L.) conditioned by soybean plant chemical extracts.

AR Panizzi, M Berhow, RJ Bartelt
Embrapa-Labex-USA, Crop Bio-Protection, USDA/ARS, 1815 North University Street, Peoria, IL 61604, USA; panizzia@ncaur.usda.gov

The southern green stink bug, *Nezara viridula* (L.) (Heteroptera: Pentatomidae) is effectively controlled with egg parasitoids, and egg production is an important component of this strategy. Therefore, a laboratory bioassay was developed for testing its oviposition preference toward chemicals extracted from soybean pods and leaves. An artificial substrate (cheesecloth) was stretched over a wooden ring (embroidery hoops), treated with plant extracts or chromatographic fractions, and then exposed to adult stink bugs to assess oviposition preference. Freeze-ied soybean leaves and pods were extracted with hexane, then with methanol, and finally with water. The organic solvent extracts were fractionated by liquid chromatography, on a C_{18} reverse phase column, on a normal phase silica column, and by thin layer chromatography (TLC) on silica gel. The methanol extract of pods showed the greatest bioassay activity. The most active reverse phase fraction derived from this extract was eluted with 20% methanol in water. After subjecting this fraction to chromatography, the greatest activity occurred in the fraction eluted with 60% methanol in methylene chloride. TLC gave no single fraction with demonstrated activity, but the recombined fractions were again active, indicating that multiple components elicit oviposition. Hairs (long and short) on the female genitalia might be involved in chemical and/or mechanical recognition of oviposition stimulants.

The chemistry of sexual deception in Australian orchids.

R Peakall, FP Schiestl, W Francke
School of Botany & Zoology, Australian National University, ACT, 0200 Australia; rod.peakall@anu.edu.au

Pollination by sexual deception is among the most intriguing of orchid pollination syndromes. Odors are well established as the primary stimuli for sexually attracting the male insect pollinators in these orchids, but we have only begun to discover how many, and which compounds are involved. Using gas chromatography with electroantennographic detection (GC-EAD), GC-mass spectrometry (GC-MS) and GC-IR-spectrometry we have determined that a single active compound, Chiloglottone, produced by both females of the wasp *Neozeloboria cryptoides* and flowers of the orchid *Chiloglottis trapeziformis* is active in antennal neurons of the pollinators, males of *N. cryptoides*. This compound, tested as synthetic copy, proved to be equally attractive to natural extracts of flowers and wasps. We are now determining the chemical identity of sexual attractants in other *Chiloglottis* orchids. GC-EAD and GC-MS analysis indicates only 1 or 2 active compounds are involved and these compounds are related to Chiloglottone. Pollinator specificity and associated reproductive isolation is therefore likely under simple genetic control in these orchids. Thus rapid sympatric speciation is possible. We will present an update of our multifaceted research program that is exploring this hypothesis of sympatric speciation.

Biochemistry & evolution of floral scent.

E Pichersky
Department of Molecular, Cellular and Developmental Biology, University of Michigan, 830 N. University, Ann Arbor, MI 48109-1048, USA; lelx@umich.edu

Floral scents of plants are often complex mixtures of volatiles derived from several metabolic pathways. The number of presently known volatile compounds from flowers is approaching a thousand, and new compounds are constantly being discovered in various plant species. Closely related species have distinct volatile profiles that can be discriminated by specialized insect pollinators, thus limiting gene flow across species boundaries. The ability of related plant species to synthesize different volatiles in their flowers is sometimes due to differential gene expression. However, new enzymes that catalyze the formation of new floral scent components are constantly evolving through the process of gene duplication and divergence, allowing for the majority of floral scent divergence. It has been shown that very small changes in protein sequences can lead to the ability of the changed enzymes to catalyze the transformation of drastically different substrates, leading to the production of new floral scent compounds. Such evolution is facilitated by the presence of large gene families in plant genomes that already encode similar enzymes with slightly different substrate specificities; the large number of such genes makes genes duplications even more likely to occur.

Herbivore-induced plant volatiles identified from interactions at higher trophic levels: persistent effects on plants in the laboratory & field.

TJA Bruce, JL Martin, JA Pickett, BJ Pye, LE Smart, LJ Wadhams
Biological Chemistry Division, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, United Kingdom; john.pickett@bbsrc.ac.uk

In many cases, volatiles produced by plant defensive mechanisms during herbivory act directly to repel insect attack, and may have indirect effects by attracting predators and parasitoids of the pest insect. *cis*-Jasmone occurs as a component of flower volatiles, but can also be produced by damaged vegetative tissues. In an olfactometer bioassay, *cis*-jasmone was repellent to alatae of the grain aphid, *Sitobion avenae* (Homoptera: Aphididae). *cis*-Jasmone is a catabolite of the stress-produced jasmonic acid, which can induce plant defence, but had previously been considered only as a biological sink for the jasmonate pathway. However, bean plants, *Vicia faba*, exposed to *cis*-jasmone vapour were more attractive to the parasitoid *Aphidius ervi*. Moreover, wheat, *Triticum aestivum*, seedlings sprayed with formulated *cis*-jasmone 24 h previously were less susceptible to attack by *S. avenae* than control plants. In field simulator studies, significantly fewer alate *S. avenae* settled on *cis*-jasmone treated plants over a 24 h period. The intrinsic rate of population increase, r_m, of *S. avenae* apterae was reduced on *cis*-jasmone treated seedlings. In a series of small-plot experiments conducted over four years, *cis*-jasmone applications reduced cereal aphid populations infesting wheat in the field.

Polyphagy in *Helicoverpa armigera*: primary host plants, host-associated volatiles & neurosensory stimulation.

C Rajapakse, GH Walter, CJ Moore, C Hull, B Cribb
Department of Zoology and Entomology, School of Life Sciences, The University of Queensland, Brisbane, 4072, Queensland, Australia;
s001370@student.uq.edu.au

Headspace volatiles of a subset of known host plants and non host plants of *Helicoverpa armigera* were screened by the use of Gas Chromatography linked with Electroantennography. Pigeon pea (*Cajanus cajan* L.) is one of the most attractive hosts to *H. armigera* in India, so was included as the primary reference plant to compare the presence and concentrations of electrophysiologically active chemicals across the test plants. Eight active compounds were identified in pigeon pea headspace volatiles in relatively higher concentrations. They include three green leaf volatiles ((E)-2-hexenal, Z-3-hexenylacetate and Z-3-hexenyl-2-methylbutyrate) and five monoterpenes (α-pinene, β-myrcene, Limonene (E) – β-ocimene, and linalool). The other known host plants have a small subset of these chemicals, whereas the non host plants contained even fewer. Green leaf volatiles were prominent in the host plants. The Australian *H. armigera* individuals used in this study did not respond to the group of sesquiterpenes present in pigeon pea headspace, and thus differ from their Indian counterparts. The physiological status and the sex of the moths had no effect on their responses to these chemicals. The study exemplifies how some host plants species are primary targets for searching moths, whereas the other host plants are likely to be incidental targets.

Experimental evidence of semiochemicals modulating the behavior of *Loxosceles intermedia* Mello-Leitão, 1934 (Araneae: Sicariidae).

EN Ramires, FA Marques, JD Fontana, GM Fraguas, LGC Santos, EM Silva
UTP, FACBS, Ciências Biológicas, Project SESA-CPPI-PRONEX-PR-Fundação Araucária-CNPq, RUA Marcelino Champagnat, 505, Curitiba, Paraná, 80710-250, Brazil; eduardo.ramires@utp.br

There is evidence of semiochemicals modulating the behavior of many species of spiders, but few reports regarding the isolation, chemical identification, and synthesis of semiochemicals in these arthropods. Our search is experimentally focused on the occurrence of volatile semiochemicals modulating the behavior *of L. intermedia*, a venomous spider that constitutes a serious public health problem in Curitiba, Brazil (3,334 people bitten in 2002). An olfactometer of rectangular arena was used. The individuals employed as stimuli were put in metallic cages, positioned against air flow. We tested all possible combinations of males and females as stimuli or test individuals. For each stimuli trial different individuals of *L. intermedia* were used. Tests were made on summer and winter 2003, and summer 2004. Only females tested during summer significantly attracted males, indicating a volatile pheromone produced during the summer season. Pheromone glands are not described for spiders, but we suppose the secretory cells are less active during winter. This is the first evidence of semiochemical in the *Loxosceles* genus. Studies involving the extraction and GC-MS identification of the putative semiochemical(s), as well as further experimental observations are being carried out.

Evolution of pheromone biosynthesis in moths.

W Roelofs, B Xue, A Rooney
Dept. Entomology, Cornell University, Geneva, NY 14456, USA wlr1@cornell.edu

In addition to their role in metabolism, acyl-CoA desaturases in moths play a key role in female sex-pheromone biosynthetic pathways. These atypical membrane-bound sex pheromone desaturases have evolved a wide range of regio- and stereospecificities. Recently, it was shown that changes in pheromone blends in moths of the genes *Ostrinia* result from unusual molecular mechanisms that influence the expression and evolution of sex pheromone desaturases. In this talk, an overview of sex pheromone desaturase evolution is presented that covers the phylogeny and evolutionary patterns of sex pheromone genes, the moth sex pheromone molecular clock, and genomics of sex pheromones.

Dynamic irritability in parasitoids.

BD Roitberg
Biological Sciences, Simon Fraser University, 8888 Univ. , Burnby, BC, Canada V5A 1S6;   roitberg@sfu.ca

Parasitoids may encounter other organisms while foraging on host-containing patches. Some of those organisms post direct threats to the foraging wasp. On the other hand, the patch provides resources that that can directly contribute to the parasitoid's reproductive success. Thus, the parasitoids must "decide" how to tradeoff threats versus benefits. Further complicating matters are several parameters that can affect costs and benefits, including: (1) the threatening organism may or may not attack, (2) the patch will diminish in value over time and (3) forager state, in particular, egg load, body mass and energy state. For example, heavier wasps may be less agile or slower in escape than light individuals. Here I consider 2 mutually exclusive decisions, continue foraging vs. abandon the patch as a function of the three aforementioned parameters. In my talk I will develop state-dependent theory and test some predictions from the theory as to conditions under which parasitoids will abandon patches following encounters with threats. I will show both theoretically and experimentally that sensitivity to threats are dynamic i.e. they depend upon parasitoid internal state and perception of danger.

Herbivore-induced volatiles: variability in production & variability in natural enemy response.

MW Sabelis, J Takabayashi, K Shiojiri, T Maeda, M Kant, B Sznajder, M van Wijk
Section Population Biology, Institute For Biodiversity And Ecosystem Dynamics, Universtiy Of Amsterdam, Kruislaan 320, 1098 Sm Amsterdam, The Netherlands; sabelis@science.uva.nl

Ecological interactions between plants and the enemies of their enemies are often mediated by information available as blends of volatile chemical compounds. Because the information is under control of the sender and the receiver cannot check its validity from a distance, the receiver has to base its decisions on previous experiences and this creates opportunity for the sender to cheat. Hence, we expect conflicts of interest between the sender and the receiver. We will present recent evidence for plants that cheat, i.e. produce amounts of chemical information that does not reflect the number of herbivores, so that the predators fail to select plants harbouring the highest densities of their prey. We will also present evidence showing that predatory arthropods can only partly cope with this plant-generated variability by associative learning. Based on theoretical models of the evolution of chemical languages and classic predator-herbivore-plant models extended with an information-perception interphase, we predict that the emergent non-linearities in plant-predator communication have dramatic consequences for the evolutionary and ecological dynamics of tritrophic interactions.

Influence of temperature on mechanosensory host location by vibrational sounding in parasitic wasps.

J Samietz, S Kroder, D Schneider, S Dorn
Swiss Federal Institute Of Technology Zurich (Eth), Applied Entomology, Clausiusstr. 25/Nw, Ch-8092 Zurich, Switzerland; joerg.samietz@ipw.agrl.ethz.ch

Although temperature is one of the most important environmental parameters, there are relatively few studies dealing with its influence on ecological processes between trophic levels, e.g. on host-location mechanisms of parasitoids. Certain parasitic wasps use self-produced vibrations transmitted on plant parts to locate their immobile hosts (lepidopteran pupae) by resonance signals. This mechanosensory mechanism, vibrational sounding, depends both on physical cues of the environment and physical activity of the parasitoid and, therefore, should depend on ambient temperature and the likely adaptation of the insects to their environmental temperature range. We analysed such influences by choice experiments with plant-stem models in the temperate ichneumonid *Pimpla turionellae* and the tropical relative *Xanthopimpla stemmator*. Our results show a substantial effect of temperature on host-location activity and on the success of the process. Outside optimum ranges, the performance of the wasps decreases both at low and high temperatures. The tropical and the temperate species show substantial differences in their temperature range for successful host location and also with respect to their performance at equal temperatures. Using laser Doppler vibrometry in *Pimpla turionellae* we can furthermore show a modification of the self-produced vibrational signals by the ambient temperature with respect to both frequency and intensity.

Hostile behavior to neighbors induced by encounter experience in the Japanese queenless ant, *Pristomyrmex pungens.*

S Sanada-Morimura
Laboratory of Animal Population Ecology, Department of Agriculture, Okayama University, 1-1-1 Naka, Tsushima, Okayama 700-8530, Japan;
sanada@cc.okayama-u.ac.jp

Ant workers cooperate among nestmates within colonies while they perform strong hostile behavior against non-nestmates. It is likely that neighbors are competitors for adjacent resources while strangers are transients from distant colonies. It might be adaptive for a species having the powerful competitors to discriminate neighbors from strangers and selectively attack the former. I hypothesized therefore that the workers can distinguish members of neighboring colonies from those of distant colonies based on some presumable cues in the ant *Pristomyrmex pungens.* To test this hypothesis, I created neighbors and strangers by an experimental method and compared the ant's hostile behavior toward the neighbors and strangers. The ants which had direct encounter experience with the neighbors could distinguish the neighbors from the strangers and showed more strong hostile behavior toward the former. The recognition of the neighbors was maintained for at least ten days after the most recent encounter. Nestmates without the encounter experience showed no hostile behavior toward the neighbors. This finding suggests that information about neighbors (probably colony odor) is not transmitted to nestmates within colonies. Aggressiveness toward neighbors therefore appears to be caused and maintained on the basis of individual memories from direct contact.

Insects associated with forest fires in northern California & Oregon.

NM Schiff
USFS, P.O. Box 227, Stoneville, MS 38776, USA; nschiff@fs.fed.us

Fire has always been a component in the evolution of forest ecosystems affecting among other factors succession, nutrient cycling and species composition. Recent debate about fire suppression has highlighted a need for more information about how fire affects forest species. This study attempts to enumerate a diverse guild of insect species that appear to have coevolved with fire. Insects were hand collected at or shortly after approximately 40 forest fires that occurred in Northern California and Oregon in the latter half of the month of August between 1996 and 2003. Approximately 25 species in 8 families and 4 orders were collected. Factors affecting collection and distribution of insects at forest fires are discussed.

Infrared sensory systems in pyrophilous buprestid beetles.

H Schmitz
Institute for Zoology, University of Bonn, D-53115 Bonn, Germany; h.schmitz@uni-bonn.de

Jewel beetles of the genera *Melanophila* (distributed nearly all over the world except Australia) and *Merimna* (with the only species *atrata*, endemic to Australia) approach forest fires. The reason for this pyrophilous behaviour is that their xylophagous larvae only can develop in burnt wood. Both genera have infrared (IR) receptors to cope with their thermal environment. However, IR receptors are totally different in *Melanophila* beetles and in *Merimna atrata.* In *Merimna* 1 to 3 pairs of IR receptor can be found on the ventrolateral parts of the abdominal sternites. Receptors are innervated by a large multiterminal thermoreceptive neuron and function according to the bolometric principle. In *Melanophila* beetles, two pairs of metathoracic pit organs can be found directly behind the coxae of the middle legs. Each pit organs houses about 70 cuticular sensilla which function according to a photomechanic principle. Physiological and behavioural data suggest that *Melanophila* beetles may use their IR receptor for the detection of remote fires. On the other hand, *Merimna* may use its receptors in the near range to prevent to land on a hot surface. The fundamentally different structure and function strongly suggest that IR receptors have evolved independently in the two pyrophilous buprestid genera.

Fire recognition on the basis of insect olfactory systems.

S Schütz
Institut für Forstzoologie und Waldschutz, Georg-August-Universität Göttingen, Büsgenweg 3, D-37077 Göttingen; stefan.schuetz@forst.uni-goettingen.de

Insect antennae are morphologically and physiologically highly specialised organs for odour perception. Their sensitivity, selectivity, and response time cannot be matched by any technical method of trace analysis. Utilisation of these unique abilities of insects for trace analytical purposes demands a thorough adaptation of technical devices to the special needs of insect antennae. Yet approaches using electroantennogram (EAG) techniques are highly sophisticated, however, detailed examination of sensitivity and cross-reactivity of antennal responses to binary mixtures of odours are needed. By providing these data, practical applications of biosensors on the basis of intact insect antennae as a sensitive odour detecting and recognizing device become more feasible. Besides sex pheromones, insect antennae are able to detect a broad range of odours specific to their habitat. The Black jewel beetle (*Melanophila acuminata*) as well as the Australian pyrophilic beetle *Merimna atrata* shows a very high sensitivity to wood-fire specific volatiles. The results of first field tests of the biosensor will be reported. Practical application and technical development of the biosensor in fire early warning systems will be discussed.

Fire recognition based on new technologies.

A Eberheim, P Schieberle, S Schütz, D Kohl
Institute of Forest Zoology and Forest Protection, Universität of Göttingen, Büsgenweg 3, D-37077 Göttingen; stefan.schuetz@forst.uni-goettingen.de

In Europe, huneds of human beings are killed and huneds of millions € damage to property are inflicted by fires in industrial, domestic or forestry areas every year. In many cases, losses of lives and property could have been prevented by efficient fire recognition and early warning systems. For this reason, development of fire recognition systems is a rapidly growing field integrating techniques as IR/vis- detection, inorganic and organic trace gas detection and aerosol analysis. Driven by results of biological research about fire recognition mechanisms used by animals, technical research and development was focussed to IR detection and organic trace gas detection i.e. "sensors for burnt smell". Especially tin oxide sensor elements showed favourable characteristics. Their high sensitivity and selectivity to hydroxylated and phenolic compounds in combination to low cross-reactivity with water and carbon monoxide mimics highly efficient biological fire detection systems. For sensor evaluation the HRGC/SOMMSA (High resolution gas chromatography/selective odorant measurement by multisensor array) approach has been established.

Pheromone trapping of *Halyomorpha halys* in the eastern USA.

PW Shearer, JR Aldrich, A Khrimian
Rutgers U. Ag. Res. & Ext. Ctr. 121 Northville Rd. Bridgeton, NJ 08302 USA; shearer@aesop.rutgers.edu

The brown marmorated stink bug, *Halyomorpha halys* (Heteroptera: Pentatomidae), is an introduced species in the USA; first being collected in eastern PA in 1996, and subsequently spreading to NJ and MD. We have observed this bug feeding on fruit, vegetables, soybeans, and many ornamental plants. Studies were initiated to evaluate the effectiveness of attracting and capturing *H. halys* in pheromone baited traps. Various purities of synthetic *Plautia stali* (2E,4E,6Z-1:COOMe) and *Thyanta pallidovirens* (2E,4Z,6Z-1:COOMe) (Heteroptera: Pentatomidae) aggregation pheromones were loaded onto rubber septa (2.5 mg/septum) along with a UV inhibitor and anti-oxidant. The first test was started on 12 September 2003. Individual treated septa were placed inside clear football-shaped traps that were hung in fruit trees near known *H. halys* infestations. *Halyomorpha halys* male and female adults and nymphs were captured in traps baited with *P. stali* or *T. pallidovirens* pheromone. A second test consisting of various purities (76, 88, and 94% pure) of *P. stali* aggregation pheromone and 2 types of traps was initiated on 6 October 2003. Football traps with the 76% purity pheromone captured more *H. halys* than traps with the 88 and 94% purity pheromone.

Contextual control of learning in insects.

BH Smith
Department of Entomology, 318 W. 12th Ave., Ohio State University, Columbus, OH 43210; smith.210@osu.edu

Insects are very adept at learning the association of many types of stimuli with biologically important events such as the occurrence of food, a mate, or a predator. There are several behavioral mechanisms associated with this type of learning, and they all in general allow animals to prepare for the occurrence of the event – e.g., flee, fight, or feed. Insects are equally adept at learning, through two or more means, to ignore stimuli that are not associated with important events. This prevents overuse of limited processing capacity associated with attention. With either type of learning, single stimuli are rarely perfectly reliable. The probability of an event (e) given the occurrence of a stimulus (s) - p[e|s] - might be above 0 but well below 1. But several stimuli together as a "context" might provide a more reliable predictor of an event. Associations among stimuli might underlie sensitive contextual control of a response. For example, in the context of S2 p[e|S1] might be much closer to 1 than in the context of S3. Furthermore, the meaning of S1 might be entirely different in S2 and S3. The presentation will review evidence for this type of contextual control of learning in insects.

Carrion mimicry in the dead horse arum.

MC Stensmyr, I Urru, AM Angioy, BS Hansson
Div. Chemical Ecology, SLU, Alnarp, Sweden; Marcus.stensmyr@vv.slu.se

Some plants rely on deception for pollination. These plants typically mimic a favourable insect resource. Attracted insects are subsequently exploited as unrewarded pollinators. Here we describe the multisensory targeting mimicry of the dead horse arum, *Helicodiceros muscivorus*. The arum produces a characteristic odor, most similar to a carcass. Odor collections from the plant and from carrion contain the same active odor components, eliciting identical antennal responses in blowflies. Addition of these odor components to scentless flowers restores their attractiveness to the same level as plants with a natural scent. The arum is furthermore thermogenic, i.e. it produces heat. The arum is capable of producing over 10°C above ambient. Although, heat production is a fairly well known phenomenon, few studies have provided direct experimental evidence as to what function heat plays. We have shown that the heat in the arum primarily serves as a behavioral altering stimulus, enhancing threefold the likelihood that the flies will enter the trap chamber of the plant. Accompanying the olfactory and thermal cues are also visual and tactile cues, reinforcing the overall carrion appearance. The dead horse arum serve as a striking example of how a plant during evolution can acquire the ability to mimic multiple aspects of complex objects.

Pheromone & visual factors contribute to catch of *Synathedon tipuliformis.*

DM Suckling
Hortresearch, Po Box 51, Lincoln, New Zealand; msuckling@hortresesearch.co.nz

Currant clearwing *Synanthedon tipuliformis* (Sessiidae) has been a pioneering and successful target of mating disruption in New Zealand, widely adopted since c. 1990. However, control failures led us to examine pheromone loading and coloured traps. Male attraction to yellow delta traps was equivalent to green delta traps but was greater than to red, black, blue or white traps. Fully yellow delta traps were more attractive than black traps with yellow stripes designed to mimic the insect, and it is suggested that yellow provides a supernormal stimulus (female abdomens have two yellow stripes). However, there was no catch in the absence of the pheromone lure, showing that colour alone was not a sufficient stimulus. Catch increased as a function of pheromone loading and trap colour, but the effect appeared to be additive. However, when plastic funnel traps were used, catch in yellow traps was highly significantly greater than in green plastic traps, indicating greater discrimination between these colours. Curiously, a composite coloured lid-funnel-base of green-yellow-white funnel traps was more attractive than fully yellow-yellow-yellow coloured funnel traps or composite green-yellow-green. These results suggest that the insect has a high degree of visual discrimination between colour shades and surface area. While significant improvements (c. 16-fold) to catch have now been achieved, with an additive combination of trap colour and pheromone loading, more work is needed to decipher the visual discrimination in this species.

Putative identification of the contact sex pheromone of the burnt pine longhorn, *Arhopalus tristis* (Coleoptera: Cerambycidae).

DM Suckling, A Gibb, V Heppelthwaite, LA Manning, AM El-Sayed
PO Box 51, Lincoln, 8152, New Zealand; msuckling@hortresearch.co.nz

The longhorn *Arhopalus tristis* (F) is a pest of pines, particularly those damaged by fire, and is a major export quarantine issue in New Zealand. In our project to develop an attractant to help in monitoring and management of this species, we have investigated the contact sex pheromone. Male burnt pine longhorn initiates copulatory responses to females only after sensing them with their antennae, providing evidence for contact sex pheromone in this species. When applied to a gelatine capsule, hexane wash of female's elytra elicited male copulatory attempts similar to the copulatory response elicited in males by live females. GC-MS analysis of male and female elytra extracts indicated that all of the compounds present in both extracts were saturated and branched hydrocarbons from 25Hy to 33Hy. The GC-MS analysis of the hexane extracts of male and female elytra revealed that the profile of compounds in both extracts was qualitatively similar, but different in the ratio of two peaks. These two peaks were identified as branched 28Hy hydrocarbons and a straight chain 29Hy. Further work is underway to test the activity of these compounds.

Genetic variation in learning ability may mask population-level effects of experience.

B Sznajder, M Egas, MW Sabelis
Kruislaan 320, 1098 SM Amsterdam, The Netherlands; sznajder@science.uva.nl

Variation in learning abilities has long been suspected to have a genetic basis and recently experimental evidence in support of this hypothesis is accumulating. In spite of these developments, in many studies of cognitive abilities such a variation is not controlled for, because populations of mixed or unknown genetic background are tested. We postulate that such an approach may confound the occurrence and/or magnitude of learning effects. We support this postulate with our results on learning in the predatory mite *Phytoseiulus persimilis*. *Phytoseiulus persimilis* responds to volatile chemicals released by plants following infestation by its prey, the two-spotted spider mite. The blend of induced volatiles is herbivore-specific and as such it serves as a signal of prey presence. It has therefore been predicted that learning of volatiles would be highly beneficial for this mite. We show that a collection of *P. persimilis* from natural populations on Sicily exhibits no significant change in responses to the volatiles following the experience. The same tests, however performed on iso-female lines from those populations show variation in learning ability among the lines. These as well as other results on variation in learning abilities raise the question what mechanism maintains such a variation.

Specificity of herbivore-induced volatiles in information transfer in multitrophic interactions.

J Takabayashi, R Ozawa, K Shiojiri
"Center for Ecological Research, Kyoto University, Otsu, 520-2113, Japan; junji@ecology.kyoto-u.ac.jp"

When infested by diamondback moth (DBM) (*Plutella xylostella*) larvae, cruciferous plants emit volatiles that attract a specialist parasitic wasp of DBM larvae, *Cotesia plutellae*. The wasps are not attracted to volatiles emitted by a crucifer plant infested by nonhosts [cabbage butterfly (CB) (*Pieris rapae*) larvae]. We identified specific volatile compounds emitted by cabbage plants with minor DBM larvae infestations, but not emitted by intact cabbage plants. When we compared the attractive properties of each chemical on an intact cabbage plant (treated plant) with that of the solvent alone (control plant), the wasps were equally distributed between the two plants. However, when a mixture of all the chemicals was used instead of each chemical alone, the wasps showed a significant preference towards the treated plants. These data suggest that a specific blend is important in the interaction between cabbage plants, which are infested by DBM larvae, and *C. plutella*. By comparing this tritrophic system with one consisting of cabbage plants, CB larvae, and their parasitoid *Cotesia glomerata*, the specificity of herbivore-induced volatiles in information transfer is investigated.

Cone thermogenesis & volatiles associated with specific pollinators of *Macrozamia* cycads.

I Terry, G Walter, C Moore, P Forster, C Hull
Univ. of Utah, 257 S 1400 E, Salt Lake City, UT 84112 USA; terry@biology.utah.edu

Macrozamia cycads, endemic to Australia, are associated with an unusual and diverse array of insect pollinators compared with other cycads. Some *Macrozamia* species are pollinated by *Tranes* weevils only, others only by thrips (*Cycadothrips)*, and some by both insect types. We show that these cycads' cones have chemical and metabolic traits that are associated strongly with their specific pollinator type. Species pollinated by *Tranes*- only have cones that heat and release volatiles during the early evening, whereas *Cycadothrips*-only cycads have cones that heat and release volatiles during the day. Cones of *Tranes*-pollinated species release volatiles comprising a few monoterpenes, primarily linalool and much lower levels of beta-myrcene, whereas "thrips-only" cycads lack linalool and release numerous monoterpenes, dominated by beta-myrcene emitted at very high rates. Insect movement between male and female cones occurs during the cone heating and volatile emission phase of their specific host. Preliminary evidence suggests that insects are attracted to their host's cone volatiles and they respond neurologically to specific components within the volatile mix.

Cuticular hydrocarbon patterns of termitophiles & their host.

CC Tsai, CS Chen
"Department of Biology, Tunghai University, No. 181, Section 3, Taichung-Kan Road, Taichung, Taiwan 407, chuntsai@mail.thu.edu.tw"

Termitophile can be defined as any animal other than a termite that is normally found in a termite nest. Termitophiles supposed to use "appeasement chemicals" to integrate into the social structure of termite colonies. Since cuticular hydrocarbons are caste- and species-specific, these mixtures may important to termite, possibly used as species recognition cues. Termitophiles were collected from termite nest or around termite galleries in Taiwan. Using gas chromatographic analysis to compare the cuticular hydrocarbons of some termitophiles and their hosts, the chromatograms show some cuticular hydrocarbon components of termites might be similar to those of their termitophiles. Termitophiles might utilize chemical mimicry to integrate into termite society. The similarity of cuticular hydrocarbon component between termitophiles and termite host might indicate the integration degree of termitophiles.

Perspectives for time allocation studies in the future.

JJM van Alphen, C Bernstein
"P.O.Box 9516, NL200RA Leiden, Netherlands; alphen@rulsfb.leidenuniv.nl"

The allocation of foraging time in insects has been a fruitful area blending empirical and theoretical research. About 100 papers with insects or mites as study subjects have appeared since 1990, the same number as for all other organisms (birds, fishes, mammals and gastropods). A survey of this literature and recent developments point to the following promising areas of research.
(A) Recent models on group foraging have not yet seen empirical tests
(B) Individual variation in behaviour has been amply documented. Three explanations have been forwarded to explain this variation: (1) information acquisition and learning, (2) differences in internal state and (3) genetic variation within and between populations. However, the relative importance of these sources of variation has not been investigated.
(C) The recent finding that symbionts, like bacteria and viruses, can change parasitoid behaviour raises the question, of which behaviours might be extended phenotypes of these symbionts, and to what extent conflicts between symbionts and their hosts occur.
(D) Host foraging, the most studied process in patch allocation is one facet of different trade-offs, such as searching for food and searching for hosts. Little is know on how these trade-off affect parasitoid foraging time and how the animals integrate the information of the presence of different resources.
(E) Up to now the study field of patch residence time is restricted to behavioural macroscopic, processes. Insect physiologist should be attracted to the field to unravel processes as the integration of different signals, how the time elapsed is integrated to patch leaving mechanisms, etc.

A maternal chemical cue affecting the behaviour of a parasitoid of aphids on emergence.

H van Emden, S Douloumpaka
Department of Agriculture, The University of Reading, Earley Gate, Reading, RG6 6AR, UK; h.f.vanemden@reading.ac.uk

A fully-defined artificial diet containing no secondary plant compounds produces aphid mummies which give emerging parasitoids no opportunity to learn plant volatiles of the plant on which they were reared. To improve parasitisation of the aphid *Myzus persicae* (Sulzer) by the generalist parasitoid *Aphidius colemani* (Viereck) on the diet, we allowed parasitisation on a host plant leaf for 48 h, after which the aphids were returned to the diet. We now needed to test that this procedure did not provide plant volatile cues to the emerging parasitoids. Unfortunately it did, but only when the plant from which the parent parasitoids had been reared was the same as that on which they had parasitised the aphids. Thus, if parasitisation has occurred on Brussels sprouts, the emerging daughters only preferred the odour of sprouts to cabbage if their parents had been reared on sprouts; if reared on cabbage, there was no olfactory preference for either brassica. The parasitoids clearly leave a maternal cue for their offspring when they oviposit, and we discuss what this might be, where it might be located in the parasitised aphid, how it affects the emerging offspring and why it is left.

Sexual behavior in *Nezara viridula* (L) (Heteroptera: Pentatomidae).

M Virant-Doberlet, A Cokl, M Renou, N Miklas, P Pavlovcic, M Zorovic
National Institute of Biology, P.O.B. 141, SI-1001 Ljubljana, Slovenia; meta.virant@nib.si

The southern green stink bug *Nezara viridula* (L.) (Heteroptera: Pentatomidae) has a complex sexual behavior. As a part of a specific mate recognition system, during courtship male and female exchange chemical and substrate-borne vibrational signals. Sexually mature males release a volatile sex pheromone that is regarded as a long-range attractant and serves to bring bugs to the same plant. When on a plant, both male and female emit several species and sex specific vibrational signals called songs. It seems that volatile chemical signal triggers the emission of the female calling song. Male responds to female calls with his songs and he locates the singing female on a plant using her vibrational signals as a directional cue. Male songs keep female singing for a longer time with a regular repetition rate while the female calling song modulates the emission of the male sex pheromone. Such feed-back modulatory mechanisms probably help to improve the synchronization of sexual activity and could also provide the sensory cues for sexual selection.

Mating behaviour of *Zorion guttigerum* (Westwood) (Coleoptera: Cerambycidae).

Q Wang, LY Chen
Institute of Natural Resources, Massey University, Private Bag 11222, Palmerston North, New Zealand; Q.Wang@Massey.Ac.Nz

Zorion guttigerum *(Westwood) is a diurnal cerambycine beetle endemic to New Zealand. Pair-bonding, mating, and adult feeding occur on flowers while larvae feed on dead tree twigs. Adults live for > 3wks and the male and female arrive at flowers independently, suggesting that long-range sex pheromones may not operate in mate location. Mean pair-bonding period is 22.7± 24.2 (mean ± SD)(ranged from 2.3 to 120.5) min during which time 1.8 ± 1.5 (ranged from 1 to 6) matings occur. Mating lasts an average of 4.7± 2.5 (ranged from 1.2 to 11.7) min. Overall operational sex ratio is male-biased (»1♀:1.5♂) but it becomes very highly male-biased (»1♀:9♂) when pair-bonding and feeding activities decrease to the minimum between 1400 and 1600 h, suggesting that females leave flowers for oviposition. It is probably true that for cerambycid species whose females oviposit alone and mating and oviposition occur on different plants or different parts of plants, the operational sex ratio varies significantly over time on the mating/feeding sites. Duration of pair-bondings also varies over time. Shorter pair-bondings in the morning may suggest a strong sexual selection process. After ca. 2-h selection, both sexes tend to engage in much longer pair-bonding and mate more times before females leave the mating and feeding sites for oviposition in the early afternoon.*

Towards the identification of contact pheromones of the fig longicorn, Agrianome spinicollis *(Macleay).*

AL Ward, CJ Moore
Trawalla, MSF 2058, Pallamallawa 2399 Australia; aneww@stahmann.com.au

Agrianome spinicollis is a cerambycid endemic to the eastern states of Australia and is a serious pest of pecan nut trees. Damage results from larvae feeding within the limbs and trunks of the trees, which ultimately results in the trees' collapse. Observations suggest that contact pheromones on the elytra of female beetles form an important component of the mate recognition system employed by male beetles. Experiments were conducted in which the cuticular hydrocarbons were removed from both male and female beetles. Such solvent-rinsing of females resulted in the loss of attractiveness towards males. The subsequent re-application of the hexane rinse, at concentrations as low as 0.1 female equivalents, was followed by mating attempts by males. Gas chromatographic analysis of the cuticular rinses revealed significant quantitative sex differences in shared components, and possibly qualitative differences. The male extract is dominated by mono-unsaturated hydrocarbons having 25, 27 and 31 carbons. The female extract, in contrast, is dominated by a single alkene, with 26 carbon atoms. As a result of the short range of efficacy of the compounds, these findings are unlikely to have any significant management implications.

Influence of lek size on female visitation in Queensland fruit fly (*Bactrocera tryoni* Froggatt) (Diptera: Tephritidae).

CW Weldon
Fruit Fly Research Centre, School of Biological Sciences A08, University of Sydney, NSW, 2006, Australia; cweldon@bio.usyd.edu.au

The lek mating system of Queensland fruit fly, *Bactrocera tryoni* (Froggatt) (Diptera: Tephritidae), may reduce the ability of this species to colonise new areas. The importance of lek size for female visitation at lek sites and initiation of male pheromone-calling was investigated in large cages using artificial leks. Female visitation at artificial leks was monitored to determine if females visited leks due to passive attraction or showed a preference for larger leks. Female *B. tryoni* display a preference for larger leks rather than being passively attracted to a greater perceived stimulus from large leks. Per capita success of males in attracting females was higher at larger leks than where there was a single male. Calling propensity of male *B. tryoni* was increased by the presence of conspecific males. Overall, female visitation at leks was only weakly associated with male calling, suggesting that lek size and the number of pheromone-calling males is not the only factor important in locating mates in this species.

Integration of multi-sensory information in orientation & navigation behavior.

MA Willis
Department of Biology, Case Western Reserve University, 2080 Adelbert Rd., Cleveland, OH 44106-7080 USA; maw27@po.cwru.edu

The ultimate goal of neuroethology is to describe the neural mechanisms that produce adaptive behaviors in freely moving animals. My lab has been using a virtual reality flight system that closely emulates realistic stimuli that occur during flight, and which produce robust flight behaviors in a tethered moth (*Manduca sexta*) that are similar to those seen in real flight. Concurrently we are able to utilize extracellular multi-unit electrodes to record activity in the region of the ventral nerve cord between the brain and the thoracic ganglia. This system allows us to investigate mechanisms by which *Manduca* responds to visual and olfactory stimuli that it may encounter during actual pheromone-guided flight, and how it might activate and control flight manoeuvres. Initial results reveal ensembles of neurons that show unique activation patterns associated with visual pattern movement associated with flight, and that these patterns are modulated during exposure to pheromone. Similarly, other unique ensembles of neurons are activated differentially when the preparation is in tethered flight or not flying. These experiments are aimed at understanding how multiple streams of information are integrated by the nervous system and how this is meshed with ongoing behavior. Pheromone-modulated orientation mechanisms in walking male cockroaches.

MA Willis
Department of Biology, Case Western Reserve University, 2080 Adelbert Rd., Cleveland, OH 44106-7080 USA; maw27@po.cwru.edu

Perhaps the most remarkable olfactory task achieved by insects is that of locating distant resources using airborne chemical cues. It is currently thought that two primary mechanisms underlie flying insects' ability to perform this behavior: 1) an odor-modulated, visually-mediated orientation to the wind direction and, 2) an odor-activated internal program of turns. The blending of these two mechanisms is thought to generate the upwind zigzagging paths that we observe from insects tracking odors in flight. It is not yet clear whether vision contributes significantly to the odor tracking behavior of walking insects. Recent results suggest that visual information may be very important, but not used in the same manner as flying odor tracking insects. Furthermore, the structure of the walking paths of pheromone tracking cockroaches look remarkably like those observed from flying insects, and thus may be governed by similar mechanisms. Our new results suggest that comparing the odor tracking behavior of walking and flying insects in similar environments may reveal important similarities and differences in how olfactory and other sensory information is used. Supported by: ONR-MURI No. N00014-01-1-0676.

Odor concentration & odor invariance in the olfactory system of the honeybee.

GA Wright
Mathematical Biosciences Institute, 231W. 18th Ave, Columbus, OH 43210; wright.571@osu.edu

Sensory systems have evolved to recognize stimuli over a range of stimulus intensities. A stimulus may be more intense, but it will still retain other qualities that make it classifiable along another dimension. When the qualitative representation of a stimulus remains the same over a specific range of intensity, the stimulus is defined as *invariant* over that range. In olfaction, it is often noted that increasing the intensity of an odorant affects its quality, such that odorants do not remain invariant as a function of their concentration in air. I will discuss how our experiments with honeybees reflect the extent that odorants remain invariant and the implications of failure of invariance for odor coding.

Local resource competition in the solitary parasitoid *Haplogonatopus atratus* (Hymenoptera: Dryinidae).

YY Yamada, Y Nishioka
Insect Ecology Laboratory, Faculty Of Bioresources, Mie University, Kamiha-Cho, Tsu, Mie 514-8507, Japan; yamada-y@bio.mie-u.ac.jp

This is the first study showing local resource competition (LRC) in parasitoids. Females of the parasitoid *Haplogonatopus atratus* are apterous, while males are alate. Individuals of the host, *Laodelphax striatellus* (Hemiptera Delphacidae), are distributed in clumps in paddy fields. These facts suggest the existence of LRC among female offspring of mother parasitoids, and that female parasitoids will produce a lower proportion of male offspring in patches with higher host density. Our laboratory experiments confirmed these predictions, as follows. A female parasitoid was placed in a glass pot with rice seedlings on which different numbers of planthoppers (10, 20, 40, or 80) were feeding. The female was allowed to oviposit freely until she left the seedlings. Sex ratios (male proportions) in emerging adults decreased with increasing host density. Moreover, the average number of eggs laid among parasitized hosts decreased as the host density increased, but hosts with different numbers of eggs laid in the same patch produced similar sex ratios. Host-quality models suggesting that male eggs are more likely to be laid in hosts of low quality (i.e., the parasitized hosts in this case) do not explain the above patterns in the sex ratio.

Identification of semiochemicals for the Asian longhorned beetle, *Anoplophora glabripennis.*

A Zhang
USDA, Agriculture Research Services, Chemicals Affecting Insect Behavior Laboratory, BARC-West, Beltsville, MD 20705, USA; zhanga@ba.ars.usda.gov

A series of long-chain hydrocarbons comprise the cuticular waxes of both sexes of ALB adults. Although for the most part the gas chromatographic profiles are similar for the two sexes, five monounsaturated compounds were consistently more abundant in samples from females than in those from males. These compounds were identified as (*Z*)-9-tricosene, (*Z*)-9-pentacosene, (*Z*)-7-pentacosene, (*Z*)-9-heptacosene, and (*Z*)-7-heptacosene in the approximate ratio of 1:2:2:8:1, respectively. Antennal contact to a micro-centrifuge tube coated with synthetic mixture of the five compounds stimulated copulatory behavior in males. This is the first time that monounsaturated hydrocarbons, (Z)-9-tricosene, (Z)-9-pentacosene, (Z)-7-pentacosene, (Z)-9-heptacosene, and (Z)-7-heptacosene, have been implicated as contact sex recognition pheromone components in the family Cerambycidae. Two male-specific beetle volatiles were found that elicited strong gas chromatographic-electroantennographic detection (GC-EAD) responses from both sexes of adult Asian longhorned beetle (ALB), *Anoplophora glabripennis*. The secretion consisted of a ~1:1 blend of functionalized dialkyl ethers, 4-(*n*-heptyloxy)butanal and 4-(*n*-heptyloxy)butan-1-ol. These compounds are chemically unusual natural products that are previously unknown from insects. Laboratory olfactometer studies showed that a blend of 10 µg of each synthetic compound on a filter paper strip was significantly attractive to ALB adults.

Identification of sex pheromones of *Holcocerus hippophaecolus* (Lepidoptera: Cossidae) & biological activities.

Z Zhong-ning, F Yu-ling, S Jiang-hua, Z Cheng-hua
Institute of Zoology, Chinese Academy of Sciences, Beijing 100080, China; zhangzn@panda.ioz.ac.cn

Holcocerus hippophaecolus Hua (Lepidoptera: Cossidae) is a destructive forest pest widely distributed throughout northern and western region of China. Its primary host-plant is sandthorn (*Hippophae rhamnoides* L.), which is a most widely planted shrub used for preventing from soil erosion and desert control, along the area of loess plateau in China. The fruit of sandthorn could be used for juice and Chinese medicine. Its plantation reached 180 million ha. About half million ha of plantations suffered severely attacking by the pest insect. Seven components were identified from female sex pheromone gland. These components were (*E*)-3-tetradecenyl acetate (E3-14:Ac), (*Z*)-3-tetradecenyl acetate (Z3-14:Ac), (*Z*)-7-tetradecenyl acetate (Z7-14:Ac) and related alcohols: E3-14:OH, Z3-14:OH, Z7-14:OH and (*Z*)-9-tetradecenyl acetate (Z9-14:Ac). Two major ones are as Z7-14:Ac and E3-14:Ac. EAG showed that Z7-14:Ac produced the strongest response and followed by E3-14:Ac in these seven compounds. The field trials showed that the combination of Z7-14:Ac and E3-14:Ac in a ratio of 1:1 could significantly catch much more males than others.

First identification of the sex pheromone of an Australian Lymantriidae, *Teia anartoides:* theromo-labile diverse pheromone blend.

Paper not available at time of production.

Active site of AnyParP, a peptide inducing embryonic diapause of *Bomby mori*

Y An, M Demura, K Suzuki

Department of Agro-Bioscience, Faculty of Agriculture, Iwate University, Morioka, Iwate 020-8550 Japan: anying@iwate-u.ac.jp;

AnyParP (*Antheraea yamamai* paralytic peptide) is a 23-residues peptide with one disulfide bridge. Recent studies showed that synthetic AnyParP not only paralyzed the larvae of both *A. yamamai* and *Bombyx mori*, but also induced embryonic diapause of *B. mori*. To identify the residues important for diapause egg-inducing activity in polyvoltine race (N4), *B. mori*, a series of synthetic mutants of AnyParP were used in bioassay system for comparing with the wild-type AnyParP. Ala replacements of Cys^7 and Cys^{19} (C7.19A), Glu^1-Asn^2 (AA-AnyParP), as well as Phe^3 (F3A) eliminated all activity. The present results indicate that the disulfide bond between Cys^7 and Cys^{19} is essential for maintaining the three-dimensional structure of AnyParP and that the E^1, N^2 and F^3 are very critical for the diapause egg-inducing activity of AnyParP. Our results indicate that these residues in both the core and unstructured domains of AnyParP are required for diapause egg-inducing activity.

Comparision of development of bean bug, *Riptortus clavatus* Thunberg (Hemiptera: Alydidae) and yellow-brown stink bug, *Halyomorpha halys* Stal (Hemiptera: Pentatomidae) at temperature conditions

SD Bae, HJ Kim, JK Park, HJ Cho, ST Park
Yeongnam Agr. Res. Inst., RDA, Milyang 627-130 Republic of Korea; baesdo@rda.go.kr

Development of Bean bug (BB), *Riptortus clavatus* Thunberg and Yellow-brown Stink Bug (YBSB), *Halyomorpha halys* Stal, which are considered as major sucking insect pests on soybean and fruits such as sweet persimmon and apple in Korea, were observed at four temperatures (20, 24, 28 and 32°C). Egg duration was significantly longer in BB (7.0 to 16.7 days) than that in YBSB (3.9 to 12.5 days). At 20, 24 and 28°C, nymphal durations of BB and YBSB were in the range of 23.0 to 37.8 days and 29.9 to 65.0 days, respectively. At 32°C, however, nymphal duration of BB was 18.1 days while all nymphs of YBSB were died within 2nd instar. Pre-oviposition of BB was greatly shorter with 5.4 to 10.8 days than that of YBSB with 9.1 to 43.1 days. Adult female longevity of BB was the longest with 49.0 days at 28°C and the shortest with 12.8 days at 20°C while YBSB was the longest with 75.3 days at 20°C and 28.2 days 28°C, adversely. Accordingly, one generation period of BB and YBSB was 67.3, 79.6, 80.7 and 44.1 days at 20, 24, 28 and 32°C, and was 152.8, 102.4 and 62.6 days at 20, 24 and 28°C, respectively. The threshold temperature was 9.6°C in egg and 9.8°C in nymph of BB while was 13.8°C in egg and 13.3°C in nymph of YBSB.

Summary diapause of *Chrysocharis pubicornis*, a pupal parasitoid of the garden pea leafminer, *Chromatomyia horticola*.

GL Baeza, K Ohno
Laboratory of Applied Entomology, Faculty of Agriculture, University of Miyazaki, Gakuen Kibanadai Nishi 1-1, Miyazaki City, 889-2192 Japan; glbaeza@hotmail.com

The occurrence of summer diapause in the last larval instar of *Chrysocharis pubicornis*, an Eulophid pupal parasitoid of Agromyzid leafminers, was studied in the laboratory. The effects of three constant temperatures (15, 20 and 25°C) and three photoperiods (12, 14 and 16 h) on diapause induction and termination were evaluated in different combinations. Diapause induction was found to be under control of photoperiod and temperature. Larval development showed a short-day type response; the lowest diapause induction rate (0.67%) occurred at 15**°C** and 12L:12D, and gradually increased with photoperiod and temperature, reaching the highest value (74.9%) at 25**°C** and 16L:8D. The critical photoperiod was between 14 and 16h at 25°C. For diapause termination, regardless of photoperiod, the lowest temperature (15°C) caused diapause termination in 90% of individuals, whereas the termination rate at the highest temperature (25°C) was practically 0%; it was only at 20°C when photoperiod exerted effect, with diapause termination nearing 90% at the short photoperiod (12 h) but only 16% at the longest photoperiod (16 h). The adaptation of *C. pubicornis* to the population trend of *C. horticola*, its main host in Japan, as well as the possible implications of summer diapause in a local Agromyzid-leafminer biological control program in greenhouses are discussed.

Can the ligand binding domain of *Xenos peckii* USP/RXR be used as an indicator of strepsipteran phylogenetic affinities?

DC Hayward, JWH Trueman, MF Whiting, EE Ball
Research School of Biological Sciences, Australian National University, P.O. Box 475, Canberra, ACT 2601 Australia; eldon.ball@anu.edu.au

The receptor for the insect molting hormone, ecdysone, is a heterodimer consisting of the Ecdysone Receptor and Ultraspiracle (USP) proteins. The DNA-binding domains of arthropod USPs and their vertebrate homologs, the retinoid X receptors (RXRs) are highly conserved. The ligand binding domain sequences, however, divide into two distinct groups. One group consists of sequences from members of the holometabolous Lepidoptera and Diptera, while the other available arthropod sequences group with vertebrate RXRs. Because the separation between these two groups is so distinct, we wondered whether USP/RXR structure could be used as a tool for clarifying the contentious phylogenetic position of the Order Strepsiptera, which has been placed as sister to either Diptera or Coleoptera. We have cloned and sequenced the USP/RXRs from the Strepsipteran *Xenos peckii* and its host *Polistes fuscatus* and bioinformatic analyses are currently in progress. The results will be reported

Interaction of juvenogens & insect oostatic peptides with developing ovaries of *Neobellieria bullata* (Diptera)

B Bennettová, Z Wimmer, J Hlaváček, R Tykva
Institute of Entomology AS CR, Branišovská 31, CZ-37005 České Budějovice, Czech Republic;
blanka@entu.cas.cz

Juvenogens, fatty acid esters of selected insect juvenile hormone bioanalogues, and insect oostatic peptides (H-YDPAP-OH and H-YDPA-OH) were selected from the screening programme on a model object *Neobellieria bullata* (Diptera) as the most promising ones. They were applied by injections (peptides) or by topical application (juvenogens). At given intervals the flies were dissected and their ovaries were examined for morphological changes and hatchability of eggs in the uterus, respectively. Under described regime of applications the development of the first egg was not morphologically affected. Hatchability of eggs in uterus slightly decreased, ranging from 60 to 80 percent compared to controls. The second gonotrophic cycle was characterized by remarkable changes in the follicular epithelium of about 60% of oocytes. Monolayered cylinical follicular epithelium with nuclei in the centre is altered the following way: first the nucleoli became prominent and subsequently multiplied, nuclei show slight difference in their size. Some bizarre nuclei with great number of nucleoli start to appear; nucleoli often merge together. The nucleocytoplasmatic ratio grows for the benefit of nucleus. Groups of giant cells appear. The epithelium proliferates towards the inner part of egg chamber. In some sections the follicular epithelium forms pseudopapillar projections, stratification is severely disturbed and extensive invagination to the centre of the egg chamber appears.

Life cycle of *Hydroscapha natans* & the development of gonads

J Büning

Developmental Biology Unit, Zoological Institute, University of Erlangen-Nuremberg, Staudtstr.5, D-91058 Erlangen, Germany; jbuening@biologie.uni-erlangen.de

Hydroscapha natans belongs to the myxophagan beetles (Coleoptera, Myxophaga), which is one of the "ancient" suborders of beetles. *H. natans* live in shallow water habitats and feed on algae. I have bread this species successfully in the laboratory for several years. After copulation females lay eggs over a period of one to two month. Two eggs can be layed daily. Embryogenesis: 5d, the primary larva (L1): 3d, L2: 3d, L3: 4d, L4: 11d, pupal phase: 2,5d. Live span of adults is about half a year. The gonads are formed during larval stages. In males the testes are composed of three testioles each. The polarized testioles house anteriorly stem cells, cystoblasts and mitotically dividing cysts. The zone of meiotic divisions and finally the zone of spermiohistogenesis follow. In females, three telotrophic meroistic ovarioles build each ovary. The morphology is similar to the telotrophic ovaries found as yet only in Neuropteroidea (Megaloptera, Sialidae and Rahphidioptera). During larval phases, ovarioles develop small germ line cysts in their anterior compartments. Later, membranes of central cyst cells dissolve and a membrane free central syncytium remains surrounded by a monolayer of germ cells, the tapetum cells. Only the posterior tapetum cells can develop subsequently into oocytes.

Cadmium effects on vitellogenesis in two strains of *Oncopeltus fasciatus* (Heteroptera: Lygaeidae)

A Cervera, AC Maymó, N López-Soler, R Martínez-Pardo, M D Garcerá
Departamento de Biología Funcional y Antropología Física, Universitat de València, Moliner 50, 46100 Burjassot, Valencia, Spain;
amelia.cervera@uv.es

Cadmium may act as an endocrine disruptor in fishes, and also can inhibit vitellogenin (Vg) synthesis in the large milkweed bug *O. fasciatus*. Vitellogenin (VgA and VgB) levels in hemolymph of 3 and 5-day old insect females exposed to 50 mg Cd/litre in inking water were determined by SDS-PAGE. Two different strains were studied: OS, a laboratory-reared strain, and OC, a strain that had been subjected to Cd selection for more than 40 generations, and supported 50 mg Cd/litre at the moment of the experiment. Vitellogenin levels in OC females were significantly higher than those in OS females (88% for VgA and 44% for VgB at day 3, 16% for VgA and 22% for VgB at day 5). When OC and OS females were exposed to 50 mg Cd/litre, Vg concentrations were decreased in both strains. However, Vg levels in OC exposed females were still similar to those of control OS females. Likewise, OC females chronically exposed to 50 mg Cd/litre from eclosion to adulthood had reduced levels of hemolymph Vg when compared to control OS insects, but Vg concentrations were higher that those of OS insects exposed to 50 mg Cd/litre for 2-5 days. OC females also accumulated 20% more Cd than OS females. These results suggest that enhanced Vg levels may play a role in Cd resistance in the OC strain.

The expression of circadian rhythm in electroantennogram (EAG) of the German cockroach, *Blattella germanica* (L.)

TH Chang, EC Yang, HJ Lee
Department of Entomology, National Taiwan University, Taipei 106, Taiwan; tt8745@yahoo.com.tw

Male German cockroaches (*Blattella germanica*) express circadian rhythmicity in locomotion and its peak activity occurs at night. We found circadian rhythm of neuron activity expressed in olfactory response by measuring electroantennograms (EAGs). By using ethyl acetate as the stimulus, the amplitude of EAG response kept fluctuating in subjective day and night under constant darkness. Although female German cockroaches do not express locomotion circadian rhythm, the EAG responses of female expressed robustly. The peak of response was at the beginning of subjective night. Dilution-responses curves of EAG indicated that the amplitude of 10-fold different dilutions showed only 3 times of change in sensitivity. The results indicated that both sexes expressed EAG circadian rhythm and masking effect on female's locomotion did not hinder the EAG response.

Clock controlled proteins from the vas deferens of *Spodoptera littoralis*

J Kotwica, E Joachimiak, MA Ciuk, J Sikora, B Cymborowski, JM Giebultowicz, P Bebas
Warsaw University, Miecznikowa 1, 02-096 Warsaw, Poland; piotrbe@biol.uw.edu.pl

The circadian oscillator located in the male reproductive tract of *Spodoptera littoralis* controls sperm release from the testis into the upper vas deferens (UVD). The daily cycle of sperm release is precisely regulated; sperm leave the testis at dusk, and remain in the UVD for several hours. The retention of sperm in the UVD is associated with secretion of glycosylated proteins from the UVD epithelium. The goal of this study was characterization of these rhythmically secreted glycoproteins. Protein extracts from the UVD wall, luminal fluid and sperm were analyzed using 2D-electrophoresis. Two acidic 105kD and 40kD glycoproteins were detected in the UVD lumen prior to sperm release while two other proteins of 50kD and 75kD were detected during sperm release. Differences were also observed in the glycoprotein composition between pre-release sperm from the testis and sperm in the UVD lumen. Taken together these data suggest that rhythmic sperm release is associated with glycosylation of existing sperm proteins and attachment of new glycoproteins to the spermatozoa in the UVD. Using lectins to characterize protein glycosylation in UVD tissues and sperm, it was shown that the glycan chains of these proteins are chiefly carbohydrates with terminal mannose and glucose residues. Supported: KBN2P04C04426.

Egg maturation & bacteriocyte inclusion in immature & adult *Bemisia gigantea* Martin (Hemiptera: Aleyrodidae)

MT Coombs, HS Costa, RC Rosell, P De Barro
CSIRO Entomology, Long Pocket Laboratories, Indooroopilly Queensland, 4068 Australia; marc.coombs@csiro.au

In this study we investigated patterns of egg production and inclusion of bacterial endosymbionts in the whitefly *Bemisia gigantea*, a species native to lowland tropical rainforests of North Queensland, Australia. Development of the female reproduction system of *B. gigantea* becomes evident in fourth instar nymphs, with extensive accumulation of mature (chorionated) eggs occurring 1-2 days prior to adult eclosion. Evidence from light and electron microscopy indicates that bacteriocytes (specialised cells containing bacterial endosymbionts) appear scattered through the abdominal region in close association with the developing eggs. In fourth instar nymphs, bacteriocytes enter developing eggs basally through the pedicel, and after oviposition move distally from the pedicel as the embryo matures. In addition, developing ova without bacteriocytes were evident in 3-day-old females, indicating that oogenesis and bacteriocyte inclusion is an on going process.

Adenosine deaminases

E Dolezelova, M Zurovec
Institute of Entomology, Branisovska 31, Ceske Budejovice, 37005, Czech Republic; pavlova@entu.cas.cz

We present a comparison of insects and human adenosine deaminases, their phylogenetic relationship, expression patterns and possible roles in organisms based on lost of function mutations. Adenosine deaminases are involved in the enzymatic conversion of nucleosides adenosine and 2`-deoxyadenosine into inosine and 2`-deoxyinosine, respectively. Recent discoveries and completion of genome sequencing of several model organisms revealed that two subfamilies of adenosine deaminases with common enzymatic domain but different N- terminal regions could be distinguished among metazoa. The first group contains „bona-fide" adenosine deaminases, while the second group is comprised of ADGF-like adenosine deaminases. Most species examined, including human and *D. melanogaster* contain genes belonging to both subfamilies. Vertebrate and invertebrate adenosine deaminases are subject to complex developmental and tissue-specific regulation. Despite the fact that mammals and insects prefer different subfamily members as "principal" adenosine deaminases, an interesting parallel exists in both groups in respect of the requirement of highest adenosine deaminase activity – in guts and lymphoid organs/blood cells.

Protein expression in the reproductive organs of male German cockroach (*Blattella germanica*)

YL Fu, YY Yang, HJ Lee
Department of Entomology, National Taiwan University, Taipei 106, Taiwan; lisafu@ms29.url.com.tw

Male accessory reproductive glands (ARGs) contain factors that are transferred with sperm during mating to the female. One such factor (sex peptide of Drosophila) inhibits female's receptivity to additional mating. Here, we analyzed ARGs protein content and pattern for males of the German cockroach (*Blattella germanica*). Lower protein mass were found in young males (<3day-day-old) when compared to older ones (3~10-day-old) by SDS-PAGE. This study shows the expression of genes in ARG was different with age, but the protein content of testis remained the same after adult emergence. In addition, western blot analysis and whole-mount immunohistochemistry were used to investigate sex peptide-like immunoreactivity in the reproductive organs of the male. Unexpectedly, the sex peptide-like substance was only found in the testis of *B. germanica*. The significance of this finding is currently under investigation.

Local adaptation & diapause traits of two noctuid moths, *Helicoverpa armigera* **&** *H. assulta* **(Lepidoptera: Noctuidae)**

K Shimizu, K Fujisaki
Laboratory of Insect Ecology, Graduate School of Agriculture, Kyoto University, Kyoto 606-8502 Japan; fujisaki@adm.kais.kyoto-u.ac.jp

In recent years, two noctuid pests are becoming more and more hazardous in agroecosystems in Japan. One is the cotton bollworm, *Helicoverpa armigera*, which is rather described as a newcomer species from the south, while the other, the oriental tobacco budworm, *H. assulta*, has been observed for decades in Japan. When focused on their local adaptations, the ability to overwinter is absolutely vital, although it still remains uncertain how the ability contributes in the field or how it differs among species. Preceding researches reported no geographical cline in photoperiodical reaction of local populations of *H. armigera* in Japan. Even less attention has been paid for *H. assulta*. On the way of our research, it turned out that diapause reaction to a constant photoperiod was not a reliable standard to clarify interspecific or interpopulation variation in diapause tendencies of these noctuid moths. It should be desirable that standard methods are more reflective of natural conditions such as decreasing temperature or shortening photoperiod through the development period. Reconsideration of diapause traits of these species revealed detailed differences that stem from the specific climate and their distinctive biology, which will lead to deeper understanding of their local adaptation.

Insect hormones, theirs analogues & antagonists in development & reproduction of *Spodoptera littoralis* (Boisd)

AI Gelbic

"Institute Of Entomology As Cr, Branisovská 31, 370 05 Ceske Budejovice, Czech Republic; gelbic@ENTU.CAS.CZ"

Effects of methoprene, 20-hydroxyecdysone, metyrapone RH-2485 and RH-5992 on the development and maturation of male germinal cells in *Spodoptera littoralis* were studied. Spermatogenesis begins early in the postembryonic development. In the first to third larval instars formation of spermatogonia occurs. Meiotic division starts in 4th instar and in the last larval instar all developmental stages of spermatozoa can be found. The first bundle of mature spermatozoa occurs in prepupae. In 5 day-old-pupae more than 90 % of the spermatozoa are mature. Application of juvenoids or ecdysterone caused some disorders in the development spermatozoa. After application of different concentration of methoprene on the different developmental stages reduction of the reproductive ability of males was observed. This reduction is caused by numerous disorders in development of spermatozoa. Numerous pycnosis appear in spermatogonia, inhibition of spermatocytes and their gradual disintegration and disorders of spermateliosis take place. On the other hand application of 20-hydroxyecdysone pathological changes were not found and the spermateliosis was earlier with comparison with control animals. After application of metyrapone or RH compounds the pathological changes were not found and experimental animals were fully fertile. All tested compounds caused dose dependent changes in the development – prolongation of larval intermoult periods, formation of different larval pupal intermediates.

Heat-shock-responsive genes are not involved in the expression of diapause in two dipteran species, *Drosophila triauraria* & *Lucilia sericata*

SG Goto, SI Tachibana, H Numata
GRAD SCH SCI, Osaka City University, Osaka, 558-8585, Japan; shingoto@sci.osaka-cu.ac.jp

Although the molecular regulation of diapause remains largely unknown, there is an accumulation of data suggesting the involvement of heat-shock proteins (Hsps) in the expression of diapause or dormancy. However, we previously reported that Drosophila *triauraria* Bock & Wheeler (osophilidae) does not express *Hsp70* transcripts at normal temperatures, regardless of the diapause state. Here we investigated the transcriptional regulation of heat-shock-responsive genes, *Hsp23*, *Hsp26*, *Hsp83* and *Hsrw* in diapause adults of *D. triauraria* and *Hsp23*, *Hsp70* and *Hsp83* in diapause larvae of *Lucilia sericata* (Meigen) (Calliphoridae). The present study revealed that these genes are not regulated as a function of diapause, suggesting that they are not involved in the expression of diapause in both species. It is noteworthy that in *L. sericata Hsp83* expression was clearly up-regulated when diapause was terminated by temperature- and/or long-day-exposures. The results suggest that expression of *Hsp83* is a part of the process promoting normal development.

Electron-tomography of the adult retinal cells in *Drosophila melanogaster.*

JY Mun, KE Lee, IS Kim, T Arii, K Hama, M Muller, SS Han
136-701, 5-Ga, Anam-dong, Sungbuk-Gu, Seoul, Korea, sshan@korea.ac.kr

Studies about the structure of *Drosophila melanogaster*'s photoreceptor cell using electron microscopy were carried in detail by Waddington (1962), Farquhar and Palade (1963), and Perry (1968). But, these results can have limitations in functional research because of two-dimensional structure. High voltage electron microscopy (HVEM) has been a natural outgrowth of the desire to obtain 3-dimensional information due to problems related to interpretations of 3-dimensional images from 2-dimensional electron microscophs are numerous. The fine-structure preservation of cells or tissues can be achieved by using fast freezing followed by freeze-substitution techniques. It is estimated that samples prepared by high pressure freezing are fixed in 20-50 mess, as compared to the seconds and/or minutes by chemical fixations. In this study, the adult retina of *Drosophila melanogaster* was investigated employing HVEM, fixation by high pressure freezing followed freeze-substitution, thick serial sections, and electron tomogram. The thickness of section was 200 nm and HVEM images were obtained from about 500 serial sections. From all these images the distribution of microtubules, mitochondria, and nuclei was reconstructed as three-dimensional structure using IMOD program. The current data provide us more precise cellular information and better understanding on the animal vision mechanism in new dimension.

Synchronization of bursting rhythms in a population of neurosecretory cells in the silkmoth

T Ichikawa

Kyushu University, Fukuoka 812-8581, Japan; tichiscb@mbox.nc.kyushu-u.ac.jp

The brain of the silkmoth *Bombyx mori* has four pairs of neurosecretory cells producing an insulin-related peptide, bombyxin. Individual bombyxin producing cells in a pupa had an intrinsic, ultradian bursting rhythm and collective burst patterns showed a complex dynamics including spontaneous synchronization and desynchronization of different combinations of cells. Statistical cross correlation analyses of the burst rhythms revealed that one cell usually relate more closely to a few particular cells with a similar periodicity. Close investigation of phase differences between individual bursts of the related cell pairs revealed that an in-phase synchronous state was usually maintained for many cycles, while an anti-phase state was transient and lasted only one or two cycles, thereby suggesting that an in-phase state is significantly stable. On the other hand, in a particular pupa whose brain-retrocerebral neurohemal complex was completely isolated from remaining nervous systems to sever the connections with a heartbeat reversal mechanism, an anti-phase relationship was also observed between several cell pairs. The result suggests that a periodic signal from the heartbeat reversal mechanism plays a significant role in the phase synchronization dynamics of the coupled oscillator system. I propose a dynamic model for the system.

Annexin IX participates in the determination of timing of PCD

Y Kaneko, S Tuzuki, M Iwami, S Sakurai
Kanazawa University, Kakumamachi, Kanazawa, Ishikawa, 920-1192, Japan; kaneko@stu.kanazawa-u.ac.jp

"Anterior silk gland (ASG) of the silkworm, *Bombyx mori*, undergoes programmed cell death (PCD) during pupal metamorphosis, and the PCD is triggered by 20-hydroxyecdysone (20E). To identify the 20E-inducible genes that are involved in the PCD, we performed subtraction PCR using the ASGs incubated with or without 20E *in vitro*. We obtained seven novel genes, one of which was annexin IX. Annexins are Ca^{2+} and phospholipids binding proteins conserved throughout animals, but they have not been studied in detail. In the cultured ASGs, 20E dose-dependently up-regulated the annexin IX gene. By contrast, developmental profile of its expression in the fifth instar showed that annexin IX mRNA level was high when the ecdysteroid titer was low, and decreased with an increase in the titer. The expression was mostly ceased when the ASGs began the PCD sequence in response to ecdysteroid. The expression profile of annexin IX was different between tissues depending on whether they undergo PCD or not. In addition, tissues destined to die initiated the PCD sequence after annexin IX was down-regulated. These results suggest that annexin IX participates in the determination of timing of PCD by delaying or suppressing the execution of PCD.
"

What triggers diapause in the blue-banded bee?

K Hogendoorn, M Keller, CL Gross, M Sedgley
The University of Adelaide, School of Agriculture and Wine, Adelaide SA 5001, Australia; mike.keller@adelaide.edu.au

A breeding program for blue-banded bees (*Amegilla cingulata*) is currently under development. This will allow the use of these bees as pollinators in greenhouses in Australia, in particular for tomato pollination. Tomato growers wish to use *Amegilla* year round, which makes it is necessary to prevent the brood from entering diapause. We report on an investigation of what triggers diapause. Blue-banded bees have a short generation time and several generations are produced during spring and summer. Adults die in autumn and winter, and the brood hibernates as large larvae in their dark cells. This suggests that the onset of diapause is triggered either directly by the effect of lowered autumn temperature on brood development, or indirectly by the effect of light and/or temperature on the reproducing mother, who then hormonally triggers diapause in her offspring. We investigate what triggers diapause in two ways: A) Correlatively by:- Reviewing capture dates from collections at different locations and latitudes- Documenting bee activity at different locations and latitudesB) Experimentally by presenting females and brood with:- Elevated temperatures- Artificially increased day lengthThe results of this ongoing research will be reported.

Drought responsive genes in the sleeping chironomid, *Polypedilum vanderplanki*

T Kikawada, M Watanabe, A Fujita, M Fujita, K Snigorska, T Okuda
National Institute of Agrobiological Sciences, Ohwashi 1-2, Tsukuba, 305-8634 Japan; kikawada@affrc.go.jp

Organisms have evolved various mechanisms for adaptation to adverse environmental conditions. The sleeping chironomid, *Polypedilum vanderplanki,*is the largest multicellular animal known to tolerate almost complete dehydration without ill effect. The anhydrobiotic (cryptobiotic) larvae could survive at extreme temperatures from -270°C to +106°C (Hinton, 1968). We have demonstrated that rapid accumulation of trehalose coincided with loss of water form the larvae, also that cerebral regulation was not involved in the process of anhydrobiosis like plants or unicellular organisms. To address molecular events during desiccation going into anhydrobiosis in this insect, we cloned several genes concerning trehalose metabolism, water transport and so on, by RT-PCR using degenerated primers and screening EST database of *P. vanderplanki*, and subsequently carried out Northern blot analysis to measure amounts of expressions of these genes during desiccation. Consequently, we obtained five drought responsive genes at least. We will discuss how these drought responsive genes orchestrate anhydrobiosis in *P. vanderplanki*.

Effect of temperature on development & reproduction of the emma cricket, *Teleogryllus emma* (Orthoptera : Gryllidae)

NJ Kim, SJ Hong, KY Seol, SH Kim
Department of Agricultural Biology, NIAST, RDA, 61 Seodun-dong, Gwonsun-gu, Suwon, PO Box 441-853, Republic of Korea; vastnj@rda.go.kr

To establish the indoor-rearing system of the emma cricket, *Teleogryllus emma*, the effects of temperature on development and reproduction of the emma cricket have been studied. The influence of temperature on developmental periods of emma cricket was investigated under the eight temperatures of 15, 18, 21, 25, 27, 29, 31 and 35°C, the humidity of 60±5%R.H., and the 16L·8D photo regimen. The developmental periods of *T. emma* nymphs had a range of 124.8 days to 44.4 days at the temperature of 21 and 35°C, respectively. At 15 and 18°C, however, all tested individuals died before emergence. The highest emergence rate was 86.7% at 27°C, but there were no statistically significant differences among the temperatures. The adult weight increased with increasing temperatures although the weight at 35°C was decreased. In addition, the influence of temperature on reproduction of emma cricket was investigated under three temperatures 22, 25 and 28°C, the humidity of 60±5%R.H., and the 16L·8D photo regimen. The longevity of female/male adults were 65.8/79.2, 68.5/67.8, 46.8/57.4 days at the temperature 22, 25 and 28°C, respectively. The pre-oviposition and oviposition periods were 32.5 and 26.9 days at 22°C, 22.9 and 34.1 days at 25°C and 22.1 and 21.8 days at 28°C. The highest average fecundity per female was 737.3 at 25°C. As a result, the optimum of temperature for the development and reproduction of *T. emma* were 27~31°C and 25°C, respectively.

Oosorption in the stink bug, *Plautia crossota stali*: vitellogenin dynamics & the site of protein degradation.

T Kotaki
National Institute of Agrobiological Sciences, Tsukuba, Ibaraki 305-8634, Japan; kotaki@affrc.go.jp

Oosorption is a phenomenon in which oocytes in the ovary are resorbed in response to internal and/or environmental factors. To understand its underlying physiological mechanism, the fate of vitellogenin and proteinase activity during oosorption in the stink bug, *Plautia crossota stali* were followed. The ovaries undergoing normal vitellogenesis rapidly accumulated vitellogenin as well as other proteins after adult emergence. Western blotting using an anti-vitellogenin antiserum showed that vitellogenin consists of several peptide fragments and is modified to form vitellin. When oosorption was induced by starvation, vitellogenin and protein contents in the ovaries began to decrease in 1 or 2 days. Western blotting of haemolymph samples from starving females failed to detect either ovary or oosorption-specific protein fragments. The results suggest that during oosorption vitellogenin/vitellin in the oocytes is rapidly degraded and released into the haemolymph as amino acids or small peptides that can no longer be recognized by the antiserum. Film *in situ* zymography revealed a high level of proteinase activity was not found in the degenerating oocytes but in the follicle cell layer in the ovaries.

Juvenile hormone induction of glutathione S-Transferase activity in the larval fat body of the common cutworm, *Spodoptera litura* (Lepidoptera: Noctuidae)

KH Lu, MC Wu
Department of Entomology, National Chung-Hsing University, 250 Kuo-Kuang Road, Taichung, Taiwan 402 khlu@agon.nchu.edu.tw

The effect of juvenile hormone (JH) on the activity of glutatione S-transferase (GST) in the fat body of larval common cutwrom, ***Spodoptera litura*****, has been investigated. The activity of fat body GST in the newly ecdysed (day-0) 6th instar female larvae dramatically increased within 12 h by treating a single topical application of 100 µg pyriproxyfen (a juvenile hormone analog, JHA) in comparison with the untreated larvae, and a similar result was obtained in the treatment with JH III as well. In contrast, both 1- and 2-day-old larval fat bodies did not show significant increase on the GST activity in response to the JHA treatment. Furthermore, both amanitin and cycloheximide suppressed the JH-induction of the GST activity, suggesting that it was affected on the gene transcription level. In this study, we first time demonstrated that the GST activity in an insect fat body can be elevated on the gene expression by JH.**

BDNF promotes development of AL neurons of *Bombyx mori in vitro*

BH Lee, JH Kim, DK Sung, MY Kim, CO Choi, HY Song, KK Kim
School of Life Sciences and Biotechnology, Korea University, Seoul 136-701, Korea; bhlee@korea.ac.kr

This study was conducted to investigate the effects of BDNF on neurite growth and survival rate of antennal lobe (AL) neurons in primary culture, and production and secretion of BDNF in brain and retrocerebral complex of the silk moth, *Bombyx mori*. BDNF induced a significant neurite extension of some projection neurons in antennal lobe (AL) and also stimulated to significantly outgrow primary branches of principal neurites of interneurons. In primary culture with BDNF, 20-HE and 5-HT, AL neurons showed higher survival rate by BDNF and especially the highest by a combination of BDNF and 5-HT. Results from western blots, ELISA assay and immunolabelings suggested that BDNF is synthesized by median and lateral neurosecretory cells with molecular weight of 38 kDa, then transported to corpora allata, and finally perhaps secreted into hemolymph for its action.

Pattern of neuronal apoptosis in insect brain induced by 20-hydroxyecdysone

BH Lee, KM Kim, KK Kim, CO Choi, MY Kim, HY Song
School of Life Sciences and Biotechnology, Korea University, Seoul 136-701, Korea; bhlee@korea.ac.kr

This study was conducted to investigate a pattern of apoptotic neurons in brains of the silk moth *Bombyx mori* during metamorphosis and also determine whether 20-hydroxyecdysone (20E) induces brain neuron apoptosis *in vivo* and *in vitro*. Postembryonic brains were treated by TUNEL assay to detect apoptotic neurons. The 20E was injected into 3rd instar larva and then isolated brains were treated by TUNEL assay. To demonstrate whether apoptosis of cultured neurons are induced by 20E *in vitro*, dissociated pupal brain neurons were cultured with **2**0E and then treated by TUNEL assay. Apoptotic neurons were first found in brain of 1st instar larva. Brain neuronal apoptosis increased during 2nd and 3rd instar larval periods. Brains of late 4th instar larvae showed the most increased number of apoptotic neurons of all postembryonic periods and brains of late 5th instar larvae also exhibited a number of apoptotic neurons. Apoptotic brain neurons reduced in number in early wandering stage, but number of apoptotic brain neurons strikingly increased again in late wandering stages. Early pupae showed a gradual decreasing slope of apoptotic neurons, but in mid stage, pupae exhibited a new peak of apoptotic neurons. Injection of 20E into larva or pupa and culture of brain neurons with 20E resulted in increase of apoptotic neurons, suggesting that 20-HE might induce neuronal apoptosis in developing brains.

The neuropeptide, [His^7]-corazonin induces phase-related morphological changes in the desert locust, *Schistocerca gregaria*.

K Maeno, T Gotoh, S Tanaka

Laboratory of insect life cycles and physiology, DIAS, IAI, Tsukuba, Ibaraki, 305-8634 Japan and Laboratory of Applied Entomology and Zoology, Faculty of Agriculture, Ibaraki University, Ami, Ibaraki, 300-0393 Japan; otokomaeno@yahoo.co.jp

A neuropeptide, [His^7]-corazonin, was isolated as the dark-color inducing neurohormone in locusts, *Locusta migratoria* and *Schistocerca gregaria*. In *L. migratoria,* it also induces morphometric changes related to phase polyphenism when injected into isolated-reared (solitary) nymphs. The present study aimed to examine the role of [His^7]-corazonin in the control of phase-related morphogenesis in *S. gregaria.* Gregarious (crowed-reared) adults have smaller F/C (F = hind femur length / C = head width) and larger E/F (E = forewing length /F = hind femur length) ratios than the solitary counterparts. Injection of [His^7]-corazonin (1 nmol) into solitary nymphs at the 2nd and 3rd instars caused a significant shift in F/C and E/F ratios toward the value typical for gregarious adults in both. In this case, it is important to analyze the results for locusts with 5 and 6 nymphal instars separately. A single injection of the peptide (2 nmol) into solitary nymphs at different instars indicated that the earlier the injection the larger the 'gregarizing' effects of the peptide. A similar effect was found on the number of antennal olfactory (basiconic type A and coeloconic) sensilla. These results suggest that [His^7]-corazonin plays an important role in the control of phase polyphenism in locusts.

Endocrine mechanisms on the termination of larval diapause in the bamboo borer (*Omphisa fuscidentalis* Hampson)

M Manaboon, T Singtripop, S Sakurai
Department of Biology, Faculty of Science, Chiang Mai University, Chiang Mai, Thailand, 50200; m_manaboon@hotmail.com

During the diapause of the bamboo borer larvae, the ecdysteroid titer is very low and prothoracic glands (PG) exhibit low secretory activity. An application of JH analogue (JHA) induced pupation with an activation of the PG. To elucidate the hormonal mechanisms of the PG stimulation by JHA, we first examined the minimum JHA-stimulation to activate the PG. JHA-treated PG were transplanted to non-treated (recipient) larvae on successive day after JHA treatment, and the recipients were observed. Results showed that one-day stimulation was enough to induce pupation. The PG's activity of the recipients increased transiently 16 days after the transplantation after which hemolymph ecdysteroid increased gradually. In order to study the EcR mRNA expression, Omphisa EcR was cloned. The amplified region of Omphisa EcR was 973 base pair with high homology of the nucleotide of Junonia EcR (81.1%) and Manduca EcR (80.9%). Quantitative PCR was analysed to compare the EcR mRNA levels between JHA-treated PG and non-treated PG. The results showed that the expression of Omphisa EcR mRNA in JHA-treated PG was higher than in non-treated PG. From these results, it is suggested that JHA is tightly involved in the termination of the larval diapause in the bamboo borer by increasing the ecdysteroid titer and EcR mRNA expression in the prothoracic glands.

Postembryonic development of the wing imaginal discs in the female of the wingless-legged bagworm moth *Bacotia sakabei* (Lepidoptera: Psychidae)

S Niitsu
Department of Natural History, Graduate School of Science, Tokyo Metropolitan University, Minami-Ohsawa 1-1, Hachioji-shi, Tokyo 192-0397, Japan;
niitsu-shuhei@c.metro-u.ac.jp

Wing reduction in female moths exists in several grades of the Psychidae; thus, studies on the wing degeneration process can help us understand the evolution of this family. In the Bagworm moth, *Bacotia sakabei*, the female adult has atrophied wings. However, the female pupa has vestigial wings. Using light and electron microscopy, I examined the processes of wing development during the last larval-instar stage and wing degeneration during the pupal stage in this species. Female wing imaginal discs proliferated during the last larval-instar stage. In the prepupal stages, however, wing imaginal discs degenerated due to programmed cell death (PCD). In the pupal stage, phagocytotic hemocytes floated within the bilayer of the wing epithelial cells in the female. This is also considered an apoptotic event, or PCD. Tracheae, which insert adult wing veins in the late prepupal stage, were undeveloped in the pupal wings. In the present study, I found that female-specific wing degeneration in *B. sakabei,* caused by programmed cell death, occurred two times, i.e. in the larval and pupal stages. Such a process of wing degeneration is probably unique to the bagworm moth of the family Psychidae.

Investigations on the fat body role in the dynamics of sunn pest populations

C Popov, M Rotarescu, M Guran
915200 Fundulea-Calarasi, ICDA Fundulea, Romania; fundulea@ricic.ro

In the sunn pest damaging area from Romania, three Eurygaster *species with different proportion, are present:* E. integriceps *(95 %),* E. maura *(3 %) and* E. austriaca *(2 %). The main factor which determines the population proportion is the fertility (*E. integriceps, *64 egg/female;* E. maura, *42;* E. austriaca, *29). This depends by the fat body value, very different between species. Detailed analyses on* E. integriceps *were performed. The accumulation of reserve matter and the fat body level present a great ununiformity, both individually and from one zone to another or from one generation to another, being the consequence of a complex of factors from which the climatic and agrotechnical ones are the most important. The fat body presents a significant role into life-cycle of this species, constituting one of the most important factors of perpetuation and numerical blasting with invasion role. The fat body level influences the mortality during diapause, the sterility and fertility, strongly influencing the bug population multiplication. The fat body is consumed in a proportion of 25% for maturation during diapause and 50% for oviposition. The multiplication index ranges between 0 and 56.47 depending on the fat body level.*

Factors in mating signal transduction in the ring-legged earwig.

SM Rankin, MA Innocenti, CA Eicher, D Furst
Department of Biology, Allegheny College, Meadville, PA 16335 USA; srankin@allegheny.edu

Mating is critical for the expression of oviposition and maternal care in earwigs; additionally, mating diminishes mating receptivity, and promotes a decline in juvenile hormone synthesis at the end of the gonadotrophic cycle. Severance of the ventral nerve cord of newly emerged, virgin females similarly promoted egg deposition and ensuing maternal care, diminished mating receptivity and elicited a timely decline in juvenile hormone biosynthesis. Mating of intact females to males castrated on day 1 of adult life resulted in reduced clutch sizes, but did not abolish fertilization; indeed, castrated males could produce viable offspring after 6 matings. Such castrated males had smaller seminal vesicles than did intact males, presumably attributable to sperm depletion. Mating of intact females to adult males that were castrated as larvae did not abolish oviposition; however, clutch sizes were reduced, and no eggs developed, indicating (not surprisingly) lack of fertilization. These results are consistent with the notion that ventral nerve cord severance mimicked mating. Following mating, the ventral nerve cord likely is a conduit to release the brain from inhibiting ovipositional and maternal behaviors. The presence of sperm in the spermatheca is not necessary for release of this inhibition, but may modulate clutch size.

Structure & function of sperm storage organs in **female** *Archisepsis diversiformis* **(Diptera: Sepsidae)**

L Rodríguez Sevilla
Escuela de Biología, Universidad de Costa Rica, 2060, San Peo, San José, Costa Rica, Central America; leonorars@racsa.co.cr

Female *Archisepsis diversiformis* has two spherical spermathecae, one larger than the other, and one ventral receptacle. The spermathecae are sclerotized, porous capsules surrounded by possibly glandular cells; part of the spermathecae capsule projects internally at the opening. The ventral receptacle has two non-sclerotized capsules and an expandable pedicel, all surrounded by muscle fibers. The pedicel, lined internally by spicules, has a chitinous plate and a circle or arch with spines. The spermathecae are for long-term storage of sperm, while the ventral receptacle is for short-term storage during fertilization. The spermathecae are filled 2-4 hours after a female's first mating. The sperm probably coil around the internal projection of the spermatheca, resulting in a organized, circular distribution of sperm. The small spermatheca is apparently the first to release sperm during oviposition, when the sperm are probably transferred to the ventral receptacle and stored temporarily in the two capsules. During the first 20 minutes of a second mating, the amount of sperm in the small spermatheca increases, while the amount of the large one decrease. Perhaps the large spermatheca re-fills the small one before the sperm of the second male are stored.

Early polytrophic meroistic oogenesis in the scorpion fly (Panorpa: Mecoptera)

R Rübsam, J Büning
Developmental Biology Unit, Zoological Institute, University of Erlangen-Nuremberg, Staudtstr.5, 91058 Erlangen, Germany; rruebsam@biologie.uni-erlangen.de

Scorpion flies (Genus *Panorpa*) have polytrophic meroistic ovaries. In *Panorpa*, an ovarian follicle consists of an oocyte, three sibling nurse cells and a monolayer of somatic follicle cells which encases the germ cell cluster. Germ cell clusters are formed in the germarium. A cystoblast runs through two successive rounds of synchronous mitoses followed by incomplete cytokineses. Thus, the four resulting cystocytes remain interconnected by three permanent ring canals. Using immunocytochemical assays we were able to detect significant differences between early oogenesis in *Panorpa* and the polytrophic model insect *Drosophila*. *Panorpa* germaria miss a distinct stem cell nice of the *Drosophila* type. The anterior compartment of the *Panorpa* germarium is occupied by a population of mitotically active, completely dividing germ cells, which represent the precursors of the cystoblasts. Neither by anti α-spectrin nor by phalloidin labelling we were able to identify spectrosomes in these cells. Dividing cystocytes accumulate α-spectrin and f-actin in their ring canals, not in a continuous polyfusome. In anti α-spectrin-labelled specimen a polyfusome becomes first visible after completion of cluster divisions. Subsequently the polyfusome is replaced by a polarised microtubule cytoskeleton. Ongoing ultrastructural studies will shed further light on the cellular processes underlying early oogenesis in *Panorpa*.

Gene & functional analyses of enzymes for juvenile hormone degradation

T Shiotsuki, A-J Tan, T Kanda, T Tamura
1-2 Owashi, Tsukuba, Ibaraki 305-8634, Japan; shiotsuk@affrc.go.jp

Juvenile hormone (JH) esterase and JH epoxide hydrolase (JHEH) are known to regulate JH concentration in lepidopteran insects. First, cDNAs coding the JH esterase and JHEH of silkworm, *Bombyx mori* were cloned and sequenced, and mRNA expression was investigated by quantitative PCR. At mid-ultimate larval stage, almost all organs investigated were detected, whereas expressions were varied in organs at mid-penultimate larval stage. According to the results of developmental changes in mRNA expression and enzymatic activity of those enzymes, JH in larval body is cleared totally from mid-ultimate instar by hemolymph JH esterase and JH titer in each organs are regulated by cellular JH esterase and JHEH before the stage. Both JHEH and JH esterase have played also important role in embryos, and the rate of hatching fell by injection of dsRNA of JHEH into freshly laid egg in dose-dependent manner. Development of the individuals which injected with dsRNA of JHEH was abnormal when the embryo was observing after 5 day of the injection. It is speculated that the JHEH at embryonic stage controls JH concentration for every organs individually like at larval stages before last molting, and that high concentration of JH at certain organ(s) interferes normal embryonic growth.

Correlation of oxygen consumption rate, cytochrome C oxidase activity & CO I gene expression in larval diapause of the bamboo borer (*Omphisa fuscidentalis* Hampson)

T Singtripop, M Saengsakda, N Tatun, S Sakurai
Department of Biology, Faculty of Science, Chiangmai Univ., Chiangmai 50200, Thailand;
scboi020@chiangmai.cmu.ac.th

Bamboo borer is a larva of the moth, Omphisa fuscidentalis *Hampson (Lepidoptera, Pyralidae). Previous study shows that juvenile hormone analogue (JHA, S-methoprene) induces pupation of the diapause larvae with increasing the ecdysteroid titer through the prothoracic gland activation. At the time of diapause termination, metabolic rate of the diapause larvae may increase due to an activation of cellular respiration by ecdysteroid. Accordingly we studied the changes in oxygen consumption rate with the correlation to cytochrome C oxidase activity and CO I gene activation. Results indicated that oxygen consumption rate showed a supradian rhythm, at about 12 hrs. cycles at 25°C during diapause. During the 6-month larval diapause from October to March, oxygen consumption rate was significantly higher in March than in October to January ($P<0.05$). When 1 mg JHA was topically applied to diapause larvae, rate of oxygen consumption increased 7 days after the application. The rate decreased slightly in G0, increased in G1-G2 and then reached a maximum at pupation. Next we studied how the cytochrome C oxidase activity changes after application of JHA. Cytochrome C oxidase activity increased gradually after 1 day of JHA application and reached the maximum level at pupation ($P<0.05$). These indicating that termination of diapause, either it occurs naturally or artificially induced by JHA, associates with increasing of oxygen consumption rate and cytochrome C oxidase activity. JHA may elicit a high metabolic activity that is correlated with the increasing of cytochrome C oxidase activity and oxygen consumption rate in the larval-pupal transformation. A partial sequence of cytochrome C oxidase subunit I (CO-I) was used to examine the CO-I mRNA expression in the diapause larvae mid gut following the JHA application. Results of semi-quantitative PCR showed that CO-I mRNA increased gradually from day 4 of JHA application to the pupation. These results suggests that JHA is tightly involved in the termination of the larval diapause in the bamboo borer by increasing the ecdysteroid titer, which causes an increase in oxygen consumption through the activation of CO-I gene and cytochrome C oxidase activity.*

Localization of allatostatin & FMRFamide in brain & retrocerebral complex of the termite *Reticulitermes flavipes* & the effect of allatostatin on juvenile hormone synthesis

B Stay, KJ Yagi, KK Chan, R Kwok, RR Setter,TG Myles, SS Tobe
Dept. of Biological Sciences, University of Iowa, Iowa City, IA 52242 USA; barbara-stay@uiowa.edu

A family of allatostatins with the C-terminus Phe-Gly-Leu amide was discovered in a cockroach by the inhibition of juvenile hormone (JH) synthesis by the corpora allata (CA). These peptides occur throughout the nervous system in many groups of insects and also have many other functions. The effect on CA has, to date, been shown only for cockroaches and crickets in which axons from lateral neurosecretory cells of the protocerebrum arborize extensively in the CA. Some of these cells show allatostatin colocalized with FMRFamide in the cockroach *Diplptera punctata.* Because termites and cockroaches are closely related we have investigated the localization of cockroach-like allatostatin and FMRFamide-like peptides in different casts of the termite *Reticulitermes flavipes.* Both medial and lateral neurosecretory cells of the protocerebrum are immunopositive for cockroach-like-allatostatin and a few of these cells show colocalization of FMRFamide-like immunoreactivity. Extensive arborization of allatostatin immunoreactive axons occurs in the CA of secondary reproductives but less is found in the CA of workers and nymphs. *D. punctata* allatostatins inhibit JH synthesis by CA of secondary reproductives in a dose dependant way. Thus Phe-Gly-Leu amide allatostatins affect JH synthesis in this termite species and very likely in other termite species as well..

Regulation of prothoracic gland ecdysteroidogenic activity leading to pupal metamorphosis.

MK Takaki, S Sakurai
Kakumamachi, Kanazawa-shi, Ishikawa-ken, 9201164, Japan; takaki@stu.kanazawa-u.ac.jp

Insect metamorphosis is under the controlled of ecdysteroid secreted from the prothoracic glands (PGs). PGs are activated by prothoracicotropic hormone (PTTH) and under the feedback regulation. Comparison of the gland activities in the third, fourth and fifth instars showed that PGs in early fifth (final) instar is unique: they neither exhibit ecdysteroid secretion nor respond to PTTH. We supposed that this 'silent' period was the first signal leading to the pupal metamorphosis. We examined a possible involvement of feedback control in the silence by examining the PGs activity after injection of 20-hydroxyecdysone (20E). 20E inhibited PG activity in the late fourth instar stronger than that in early fourth instar. When 1μg of 20E was injected in early fourth instar, we discovered the activity never appeared again. By contrast, the PGs of larvae whose brain-corpora allata complex had been removed were once inhibited by 20E but recovered the secretory activity. Combined data suggest that the sensibility of the PGs to 20E increases through the penultimate instar, and JH suppresses the recovery from the feedback inhibition. We also determined the developmental profiles of EcR and USP in order to identify the factor(s) involved in the changes of the sensibility to 20E.

Effects of photoperiod & temperature on diapause development in the nymph of the scutellerid bug, *Poecilocoris lewisi*

SI Tanaka, C Imai, H Numata
Osaka Environmental Technology and Research Co., Ltd., Osaka, 558-0013, Japan; shinchan@yo.rim.or.jp

Poecilocoris lewisi (Heteroptera: Scutelleridae) enters diapause in the 5th (final) nymphal instar under short-day conditions. The critical daylength inducing this nymphal diapause is 14.5 h at 25°C, and this photoperiodism causes a partially bivoltine life cycle in central Japan. When diapause nymphs were transferred to longer daylengths, they terminated diapause and emerged as adults. Diapause was terminated after a long period even under the same conditions that induced the diapause. Low temperature treatment of 10°C had only a little effect on the diapause termination. Transfers of diapause nymphs from natural conditions to the laboratory conditions revealed that the diapause development proceeds gradually but not constantly from autumn to spring. As a result, the nymphal diapause was maintained until late February under natural conditions. The diapause development, however, had been completed in late December under natural photoperiod at constant 25°C. We suggest that in nature the diapause development proceeds constantly during the temperature is relatively high, and after the temperature becomes low, the rate of diapause development decreases. The effect of temperature on diapause development is regarded as a mechanism to keep both the first and the second generations in diapause until early spring.

Effects of 20-Hydroxyecdysone & juvenile hormone analogue on the development of wing imaginal disks of the bamboo borer, *Omphisa fuscidentalis* Hampson

K Tanmuangpak, T Singtripop
Department of Biology, Faculty of Science, Chiang Mai University 50200, Thailand;
kittizipzip@hotmail.com

Larvae of the bamboo borer, *Omphisa fuscidentalis* are in diapause for nine months, from September until the following June. To examine the growth and differentiation of wing imaginal disks, size measurement and protein assay of disk were determined during September to April. Results showed that both fore wings and hind wings size of diapausing larvae increased gradually from October to April. Pupal induction of diapause larvae by different concentrations of 20-hydroxyecdysone(20E) and JHA application caused the wing imaginal disk growth and differentiation in dose-dependent manner. Previous studies show that topical application of JHA induces pupation by increasing of ecdysteroid titer through the prothoracic glands activation. The expression of OfEcR-B1 in the wing disks was measured by semi-quantitative PCR after JHA application. Results showed that OfEcR-B1 mRNA expression in the wing imaginal disks increased from day 5 to day 10 of JHA application and rapidly decreased at pupation. These results suggest that JHA terminated the larval diapause of the bamboo borer by increasing the ecdysteroid titer which induced the EcR-mRNA expression and the development of wing imaginal disks.

An involvement of juvenile hormone analogue & ecdysone receptors on changes of trehalase activity of the bamboo borer, *Omphisa fuscidentalis* *Hampson.*

N Tatun, Y Kaneko, T Singtripop, S Sakurai Department of Biology, Faculty of Science, Chiang Mai University, Chiang Mai 50200,Thailand; nujiratatun@hotmail.com

During larval diapause from September to May trehalose concentration in hemolymph remains between 40-50mM and decreases to an almost undetectable level after pupation. Since trehalose metabolism, depend on trehalase locating on surface of midgut, trehalase activity in midgut homogenates was measured through the larval diapause period and pupal stage. The midgut homogenate exhibited low trehalase activity from December to April, showed a 4-folds increase in May and remained high at pupal stage in July. After JHA application, trehalase activity increase gradually attained the maximal level at pupal stage. Injection of 20-hydroxyecdysone (20E) caused an increase of trehalase activity in vitro and in vivo. To examine an involvement of 20E and JHA on the change of trehalase activity during larval diapause, two isoforms of ecdysone receptor from the bamboo borer,*Omphisa fuscidentalis* (OfEcR) were identified and examined their expression level in the midgut during diapause period and after JHA application. The expression of both isoforms in midgut was studied by RT-PCR. After JHA treatment, the expression level of EcR-A and EcR-B1 correlated with the time of increasing titer of hemolymph ecdysteroid. Suggest that JHA stimulated an increasing of hemolymph ecdysteroid, then ecdysteroid induced the transcription of EcR gene and trehalase activity.

Developmental profiles of two storage proteins from the bamboo borer, *Omphisa fuscidentalis.*

J Tungjitwitayakul, O Kamsroi, T Singtripop, S Sakurai
Department of Biology, Faculty of Science, Chiang Mai University, Thailand; t_jatuporn@hotmail.com

Storage protein 1 (SP1) and storage protein 2 (SP2) are major components of haemolymph proteins of diapausing larvae of the bamboo borer, *Omphisa fuscidentalis*. They were purified from the larval haemolymph by ammonium sulfate precipitation, followed by three difference chromatographies using Q-sepharose, superose 6 and Mono Q columns. Each purified protein exhibited a single band on SDS-PAGE. The molecular sizes of SP1 and SP2 were estimated to be 75 and 72 kDa, respectively. Gel chromatographical analysis indicated that the molecular sizes of SP1 and SP2 in native conditions were 423 and 403 kDa, respectively, showing that these storage proteins were hexamers. Storage proteins in lepidopterans are usually synthesized by fat body and secreted into haemolymph in feeding period and reabsorbed into the fat body during prepupal period. We therefore examined the developmental profiles of SP1 and SP2 concentrations in male and female pupae by Western blot using rabbit polyclonal antibodies. The results showed that SP1 and SP2 concentration in haemolymph dramatically decreased while gradually increased in fat body during pupation. The study indicates that SP1 and SP2 are incorporated into fat body at the time of diapause break., like other storage proteins. Partial amino acid sequence of those proteins indicated that SP1 is highly homologous to arylphorin and SP2 to hexamerin.

Induction of cryptobiosis excised-fat body of the sleeping chironomid, *Polypedilum vanderplanki*

M Watanabe, T Kikawada, A Fujita, F Yukuhiro, T Okuda
NIAS, Ohwashi 1-2, Tsukuba, Ibaraki 305-8634, Japan; masahiko@affrc.go.jp

A rain pool dweller, *Polypedilum vanderplanki*, can stand complete dehydration. This species is known as the only insect able to enter cryptobiosis. The larvae accumulated a large amount of trehalose during dehydration. We have demonstrated that induction of cryptobiosis occurred without the cerebral regulation in this chironomid. To confirm whether individual tissues can prepare for entering cryptobiosis by themselves, excised tissues were dehydrated *in vitro* with various kinds of media. Excised-fat body desiccated gradually for 2 days *in vitro* with BmHem (heat-treated hemolymph of *Bombyx mori* larvae) accumulated a large amount of trehalose and recovered even after extended dry preservation for 3 months. Excised-alimentary canal in contrast produced little trehalose *in vitro* during dehydration with the same medium and failed to recover after rehydration. Excised-fat body quickly desiccated within a day with BmHem contained only a small amount of trehalose and failed to recover. Based on these results in *P.vanderplanki*, we discuss the significant roles of trehalose to protect tissues and cells of the cryptobiotes during complete desiccation.

Termination of reproductive diapause in adults of the rice bug, *Leptocorisa chinensis*

T Watanabe
National Agricultural Research Center, Tsukuba, 305-8666 Japan; tomonari.watanabe@affrc.go.jp

The rice bug, *Leptocorisa chinensis*, is one of the major insect pests of rice in the south to the central Japan. Field studies have revealed that *L. chinensis* spend two generations a year in Tsukuba (36°01'N, 140°06'E). Overwintering adults appear on gramineous weeds in late June to early July and two successive generations occur during mid July to late September. Adults of the second generation enter reproductive diapause after mid September. To specify the timing of diapause termination, second generation adults were collected late in October and kept in cages under outdoor conditions. These insects were transferred monthly from the cage to laboratory conditions in January to June, and reared as single male and female pairs under a long-day (16L8D, LD) or a short-day (12L12D, SD) condition at 25°C. SD maintained reproductive diapause and LD gradually shortened the pre-oviposition period in females transferred from cages between January and late May. Females transferred from cages in mid June showed a short pre-oviposition period under both LD and SD. The results show that the long day length is necessary for the diapause termination in *L. chinensis*.

Effects of locomotive phase on reproduction in the German cockroach (*Blattella germanica*) & the double-striped cockroach (*B. bisignata*)

HH Wu, HJ Lee
Department of Entomology, National Taiwan University, Taipei 106, Taiwan; hsin@nhps.tp.edu.tw

The German cockroach (*Blattella germanica*) and the double-stripped cockroach (*B. bisignata*) are sibling species, but their habitats are dramatically different. The former is a cosmopolitan, household species, whereas the latter is a complete feral species and distributed only in Southeast Asia. It has been demonstrated that the mate-finding locomotion of both species showed circadian rhythmicity. Apparently, the circadian clock is involved in the reproductive behaviors. Since the mate-finding locomotion represents the calling behavior, which is the first step of the mating sequence, the courtship and copulation are the following steps leading to a successful mating. The contribution of circadian timing on the success of each mating sequence is investigated in detail.

Thermoperiodic restoration of *Drosophila* circadian rhythms in constant light

T Yoshii, Y Heshiki, A Matsumoto, T Tanimura, K Tomioka
Department of Biology, Faculty of Science, Okayama University, Okayama 700-8530, Japan; dns15403@cc.okayama-u.ac.jp

Although circadian locomotor rhythms of the fruit fly *Drosophila melanogaster* disappear in constant light (LL) under constant temperature, the rhythm is restored by exposing to temperature cycles. We examined molecular and cellular basis of this thermoperiodic restoration of the rhythm. Several transient cycles were required to establish steady state entrainment, suggesting that the rhythm is driven by an endogenous circadian clock. PER and TIM exhibited rhythmic expression in their abundance under temperature cycles, both increasing in cryophase and decreasing in thermophase. Arrhythmic mutant flies, *per*^{01} and *tim*^{01}, also showed rhythmic locomotor activity under temperature cycles in LL, but the rhythm was quite different from that of wild-type flies. *disco*^{2} mutant flies that lack lateral neurons (LNs), putative clock neurons, also show abnormal rhythmicity similar to that of *per*^{01} and *tim*^{01} flies. These results suggest that rhythmic expression of *per* and *tim* is involved in the restoration of the locomotor rhythm by temperature cycles and that LNs play an important role in this rhythm restoration.

Interaction of Juvenogens and Insect Oostatic Peptides with Developing Ovaries of *Neobellieria bullata* (Diptera)

B. Bennettová, Z. Wimmer, J. Hlaváček, R. Tykva
Institute of Entomology AS CR, Branišovská 31, CZ-37005 České Budějovice, Czech Republic; e-mail: blanka@entu.cas.cz

Juvenogens, fatty acid esters of selected insect juvenile hormone bioanalogues, and insect oostatic peptides (H-YDPAP-OH and H-YDPA-OH) were selected from the screening programme on a model object *Neobellieria bullata* (Diptera) as the most promising ones. They were applied by injections (peptides) or by topical application (juvenogens). At given intervals the flies were dissected and their ovaries were examined for morphological changes and hatchability of eggs in the uterus, respectively. Under described regime of applications the development of the first egg was not morphologically affected. Hatchability of eggs in uterus slightly decreased, ranging from 60 to 80 percent compared to controls. The second gonotrophic cycle was characterized by remarkable changes in the follicular epithelium of about 60% of oocytes. Monolayered cylindrical follicular epithelium with nuclei in the centre is altered the following way: first the nucleoli became prominent and subsequently multiplied, nuclei show slight difference in their size. Some bizarre nuclei with great number of nucleoli start to appear; nucleoli often merge together. The nucleocytoplasmatic ratio grows for the benefit of nucleus. Groups of giant cells appear. The epithelium proliferates towards the inner part of egg chamber. In some sections the follicular epithelium forms pseudopapillar projections, stratification is severely disturbed and extensive invagination to the centre of the egg chamber appears.

Making many, few, or no eggs: The structural and molecular basis of oogenesis in polyphenic social bees

K. Hartfelder, E. D. Tanaka, K. R. Guidugli, A. M. Nascimento and Z. L.P. Simões
"Depto. Biologia, Faculdade de Filosofia, Ciências e Letras de Ribeirão Preto, Universidade de São Paulo, Depto. Biologia Celular, Molecular e Bioagentes Patogênicos, Faculdade de Medicina de Ribeirão Preto, Universidade de São Paulo, Av.. Bandeirantes 3900, 14040-901 Ribeirão Preto, SP, Brazil, email: khartfel@rge.fmrp.usp.br"

Plasticity in reproduction is a hallmark of social insects. To understand the underlying mechanisms we investigated the structural organization of queen and worker ovarioles of two highly eusocial bees. In the honey bee, we observed clusters of potential stem cells in the terminal filament. Mitotic activity was confirmed by BrdU incorporation, and their germ line nature is currently being checked by *vasa* expression. Microfilaments and microtubule organization analyzed by immunofluorescence microscopy revealed progressive oogenesis in the germaria even in workers kept in the presence of the queen. The process of vitellogenesis was probed by Northern Blot and RT-PCR analysis of vitellogenin expression in the fat body and in the ovaries, and its regulatory circuitry was investigated by RNA interference followed by juvenile hormone titer analysis. These studies revealed a negative feedback relationship between vitellogenin expression and the hormone titer in worker bees, adding an important facet to the mechanisms underlying reproduction and division of labor. In the stingless bee, the ovarioles of newly ecloded queens and workers contained one follicle undergoing previtellogenic growth, thus deviating considerably from the picture observed in the honey bee. The observed levels of plasticity can be related to life history strategies in these bees.

Thermoperiodic restoration of *Drosophila* circadian rhythms in constant light

T Yoshii, Y Heshiki, A Matsumoto, T Tanimura, K Tomioka
Department of Biology, Faculty of Science, Okayama University, Okayama 700-8530, Japan, dns15403@cc.okayama-u.ac.jp

Although circadian locomotor rhythms of the fruit fly *Drosophila melanogaster* disappear in constant light (LL) under constant temperature, the rhythm is restored by exposing to temperature cycles. We examined molecular and cellular basis of this thermoperiodic restoration of the rhythm. Several transient cycles were required to establish steady state entrainment, suggesting that the rhythm is driven by an endogenous circadian clock. PER and TIM exhibited rhythmic expression in their abundance under temperature cycles, both increasing in cryophase and decreasing in thermophase. Arrhythmic mutant flies, *per*^{01} and *tim*^{01}, also showed rhythmic locomotor activity under temperature cycles in LL, but the rhythm was quite different from that of wild-type flies. *disco*^{2} mutant flies that lack lateral neurons (LNs), putative clock neurons, also show abnormal rhythmicity similar to that of *per*^{01} and *tim*^{01} flies. These results suggest that rhythmic expression of *per* and *tim* is involved in the restoration of the locomotor rhythm by temperature cycles and that LNs play an important role in this rhythm restoration.

Synaptogenesis in the giant fibre system of *Drosophila*

RJ Dawber-Coen, LA Goulding, JA Davies, JP Bacon
School of Life Sciences, Sussex University, Brighton BN1 9QG, UK; j.p.bacon@sussex.ac.uk

Electrical synapses, which allow direct signal transmission are, in effect, gap junctions. In invertebrates, innexins are the major structural components of gap-junction channels (Phelan et al 98, Nature 391: 181-184). The *shaking-B* locus encodes three members of this family: ShakB(neural), ShakB(N+16) and ShakB(lethal). Here, we show that electrical synapse formation between the Giant Fibre (GF) and its major synaptic target, the tergotrochanteral motor neuron (TTMn), requires expression of different innexins on each side of the synapse. The mutation *shaking-B*^{2}, which removes both ShakB(neural) and ShakB(N+16) function, disrupts dye coupling between the GF and TTMn (Phelan et al 96, J Neurosci 16: 1101-1113), although the two neurons still come into cell-cell contact in this mutant (Blagburn et al 99, J Comp Neurol 404: 449-458). Expression of ShakB(N+16) in the GF and TTMn is sufficient to restore dye coupling in the mutant. However, expression of ShakB(neural), identical to ShakB(N+16) but for the absence of the first 16 amino acids, fails to afford rescue. Expression of a dsRNA construct against ShakB(lethal) in the TTMn abolishes dye coupling between the GF and TTMn. Thus, expression of ShakB(N+16) in the GF and ShakB(lethal) in the TTMn are required for electrical synapse formation between these neurons.

A heavy load of sperm; male investment in reproduction of *Yponomeuta* moths.

AC Bakker, P Roessingh, S Menken
UvA, IBED, Evolutionary Biology, Kruislaan 320, 1098 SM Amsterdam, The Netherlands; abakker@science.uva.nl

Females are choosy, as is generally believed, because of their large investment in reproduction compared to males. However, male investment can be considerable. Males in two closely related moth species, *Y. padellus* and *Y. cagnagellus*, lose on average respectively 13.5% and 17.2% of their body weight during spermatophore transfer to the female. Therefore, they invest substantially into reproduction. It has been suggested that male investment should be positively correlated with sperm competition. This is currently investigated. *Y. cagnagellus* mates more often than *Y. padellus*, probably increasing the level of sperm competition. Therefore, *Y. cagnagellus* should invest more than *Y. padellus.* Indeed, we found that this species transfers a significantly larger percent of its bodyweight to the female. If higher sperm competition leads to maximization of sperm numbers, we expect that spermatophores of *Y. cagnagellus* to contain relatively more sperm than spermatophores of *Y. padellus.* Furthermore, it has been suggested that some male lepidopteran species can tailor their ejaculate according to sperm competition risks i.e. spermatophore weight and number of sperm transferred to the female can vary according to female mating status and body size. We will therefore investigate sperm transfer for first and second matings in the two *Yponomeuta* species.

Boundary between two cell types coordinates follicular morphogenesis

EJ Ward, JE Dorman, RL French, KE James, CA Berg
Dept. of Genome Sciences, Univ. of Washington, Box 357730, Seattle, WA 98195-7730 USA; berg@gs.washington.edu

Oogenesis in the fruit fly *Drosophila melanogaster* is an excellent model system for studying how cell-cell interactions regulate cell shapes and movements during development. In the ovary, follicle cells surround the oocyte in a single-layer sheet; signaling from the oocyte induces a subset of follicle cells to change their shape and position and form two tubes. These cells secrete eggshell proteins into the tube lumens to produce the dorso-lateral eggshell appendages, which facilitate respiration in the developing embryo. Interactions between cells coordinate this morphogenetic process. Two cell types make each tube: cells expressing the transcription factor Broad form the roof and sides of each tube, while cells expressing the *rhomboid-lacZ* reporter gene make the floor. A combination of signals involving EGF-receptor and BMP2/4 pathways specifies these cell types. The Notch pathway participates in the process that defines a border between the Broad- and *rho-lacZ*–expressing domains. The roof- and floor-forming cells express different cell-fate and adhesion markers, exhibit distinct behaviors, never intermingle, and coordinate their movements, even in patterning and morphogenesis mutants. We hypothesize that a boundary exists between these two cell types and that signaling across the boundary coordinates the cell shape-changes and rearrangements that form the tube.

The rhythmic component of photoperiodic time measurement: cause or consequence?

WE Bradshaw, CM Holzapfel
CEEB, 5289 University of Oregon, Eugene, OR 97403-5289, USA; Bradshaw@darkwing.uoregon.edu

Organisms at temperate latitudes encounter seasonal environments that vary with geography and modify their seasonal programming of development and diapause accordingly. The mosquito, *Wyeomyia smithii*, ranges from the Gulf of Mexico to northern Canada where it occupies only the water-filled leaves of a single species of pitcher plant. This constancy of habitat makes it ideal for studying the relationship between photoperiodism that regulates seasonal activities and the circadian clock that regulates daily activities. In *W. smithii*, the critical photoperiod mediating the switch from continuous development to diapause tracks latitude and altitude more closely (R^2>90%) than any other known ecogeographic trait. Concomitantly, the rhythmic response to the Nanda-Hamner protocol, historically used to infer a circadian basis for photoperiodism, declines with increasing latitude and altitude (R^2 = 70%). Critical photoperiod and the rhythmic response to Nanda-Hamner are genetically correlated within populations, but not between populations. Hence, photoperiodic response is capable of evolving independently of the circadian clock, even within a single species. The relationship between photoperiodism and circadian rhythmicity may be correlational but is not causal. Elucidating the mechanics of photoperiodisn will involve the genetics of photoperiodism itself, rather than considering it simply as an adjunct to the circadian clock.

Stem cells, germ cell cluster formation and fusomes in insect gonads

J Büning, R Rübsam
Developmental Biology Unit, Zoological Institute, University of Erlangen-Nuremberg, Staudtstr.5, D-91058 Erlangen, Germany; jbuening@biologie.uni-erlangen.de

Throughout the animal kingdom germ cells differentiate into oocytes and sperms. Oocytes are immobile and have to grow into giant cells, thereby providing all the resources needed for early embryogenesis. Sperms are mobile and a huge number is needed to ensure fertilization. As a consequence, sperms minimize their volume. This division of labor between gametes is achieved by sex-linked differentiation of germ cells. Both, the male and the female pathway start with a multiplication strategy. In the beginning, a few germ cells succeed in becoming stem cells which undergo differential mitoses. In doing so, cystoblasts are generated from which syncytial germ cell clusters arise by a number of synchronized mitoses coupled with incomplete cytokinesis. In most insects studies so far, this cluster formation is accompanied with a special germ cell organell, the fusome. The fusome is build and maintained during the cluster multiplication steps. These intrinsic steps of germ cell differentiation are coupled with extrinsic germ cell - somatic cell interactions. Variations of stem cell activity, as well as the variations during germ cell cluster development, both in combination with extrinsic factors, are sufficient to generate the differences leading to the panoistic, polytrophic and telotrophic organization of insect ovarioles.

How similar are daily and seasonal biological clocks?

HV Danks
Biological Survey of Canada (Terrestrial Arthropods), Canadian Museum of Nature, P.O. Box 3443, Station D, Ottawa, Ontario K1P 6P4, Canada; hdanks@mus-nature.ca

Daily and seasonal timing systems in insects have usually been supposed to share similar mechanisms, because both rely in large measure on information from the daily light-dark cycle: daily clocks can ensure that activity coincides with the appropriate time of day, and seasonal time is indicated most reliably by daylength. However, several lines of evidence suggest that the systems are different. For example, receptor features, photosensitive pigments, clocks, and the effectors that mediate responses to information derived from the clock may have different daily, seasonal and general functions and properties, and several different systems are known. Therefore, it is unlikely that there is any single master clock for insect timing, despite the long-standing belief that such a thing exists. The absence of a single clock would be consistent with the fact that temporal responses serve a very wide range of purposes, meeting many different ecological needs on different time frames.

Wigglesworth Memorial Lecture. From insect ovaries to sheep red blood cells: a tale of two hormones

KG Davey
Department of Biology, York University, 4700 Keele Street, Toronto On Canada M3j 1P3; davey@yorku.ca

Insect juvenile hormone is widely acknowledged to act at least two levels in the cell. In exercising its metamorphic control, it is held to interact in some way with the genome. Certain other effects, such as those controlling the volume and shape changes of follicle cells during yolk uptake, are the result of JH interacting with a membrane receptor. The vertebrate hormone thyroxine exerts many of its effects via a well described nuclear receptor complex, but also has some more immediate effects through a yet to be fully characterised membrane receptor. Although the two hormones are very different in structure, they are, in their membrane effects, mimics of one another: some thyroid hormones act on the follicle cells as mimics of JH, and JH mimics the membrane effects of thyroxine on mammalian red blood cells. The evidence suggests that the connecting link may be a sensitivity of the membrane receptors to CO_2. The implications of these discoveries for the origin and evolution of receptors will be explored.

Genes involved in flesh fly diapause: lessons from microarrays

DL Denlinger, JP Rinehart
Department of Entomology, Ohio State University, 318 W. 12th Avenue, Columbus, OH USA 43210-1242; denlinger.1@osu.edu

One of the challenges of working with a non-genetic organism is the lack of available mutants and genomic databases for molecular analysis. This challenge is especially acute for work on insect diapause because none of the genetically-known organisms have a well defined diapause. Until such databases become available for species that have a diapause, an alternative is to use cross-species hybridization. In our case, flesh flies (*Sarcophaga crassipalpis*) and *Drosophila melanogaster* appear to be sufficiently close phylogenetically to allow us to captilalize on microarray chips available for *D. melanogaster.* This approach has enabled us to identify numerous genes that are uniquely up- or down-regulated during early, mid-, and late-diapause in *S. crassipalpis.* The most abundantly expressed genes associated with diapause are those encoding stress proteins and structural proteins associated with the cytoskeleton. Genes of potential regulatory importance include those that encode regulatory proteins, including transcription factors, and signal transduction proteins involved in the *shaggy, notch* and *wingless* pathways.

Comparative studies on germ cell formation in crustaceans and insects: patterns of epigenesis and preformation with respect to arthropod phylogeny

CG Extavour
Laboratory for Development and Evolution, Department of Zoology, University of Cambridge, Downing Street, Cambridge CB2 3EJ, England; cgme2@hermes.cam.ac.uk

The diversity in the temporal and spatial origin of arthropod germ cells is extreme. Studies on model organisms indicate that germ cells may be specified through the asymmetric localisation of germ line determinants (germ plasm), or by non-autonomous signals from neighbouring cells to germ cell precursors. In *Drosophila melanogaster*, germ plasm components are synthesised during oogenesis by nurse cells and transported to the oocyte, where they are then asymmetrically localised to the region of ooplasm that will form germ cells. However, this dipteran model cannot be applicable to all hexapods, since in many species of primitive insects, oogenesis functions without nurse cells; indeed, most of the basal insect orders for which data are available do not appear to have early segregated germ cells. Since recent arthropod phylogenies suggest that crustaceans and insects are sister groups, examination of both basal insects and crustacean taxa can help to determine what kinds of germ cell specification mechanisms might have been ancestral to insects. I have used a molecular marker to study germ cell development in the amphipod crustacean *Parhyale hawaiensis*, and have determined the capacity of individual early cleavage blastomeres to form germ cells by blastomere isolation and culture. My experiments provide experimental evidence that germ cell determinants are present in only one cell at the two-cell stage in *P. hawaiensis*. These results will be discussed within the context of the existing literature on crustacean and hexapod germ cell specification.

Sperm storage dynamics: when molecular techniques and morphological studies meet

AH Fritz
Biological Sciences, EIU, 600 Lincoln Ave., Charleston, IL, USA, 61920; cfahf@eiu.edu

The tephritid fruit fly, *Anastrepha suspensa*, has a complex reproductive system which includes four sperm storage organs and offers many potential opportunities for selection on female-controlled sperm storage and use. Thus, this species provides a good model system for examining sperm partitioning patterns from multiple matings. Microsatellite primers and sperm amplification techniques were developed to examine sperm partitioning from multiple ejaculates in wild populations of this species to determine potential effects on paternity outcomes.

Sperm competitive ability in stalk-eyed flies is influenced by meiotic drive and seminal fluid

CL Fry, GS Wilkinson
Dept. of Biology, Building 144, University of Maryland, College Park, MD 20742 USA; cfry@wam.umd.edu

Sperm competition is common in many insect species; however, the mechanisms underlying differences in sperm precedence are not well understood. In the stalk-eyed fly, *Cyrtodiopsis whitei* (Diptera, Diopsidae), sperm precedence is influenced by the presence of sex chromosome meiotic drive. When drive-carrying males compete with non-driving males for fertilizations within a female, the number of progeny sired by drive males is significantly fewer than predicted by sperm mixing alone. Thus, drive males apparently suffer not only a reduction in the number of viable sperm produced, but also a reduction in sperm competitive ability. By interrupting copulations before sperm, but after seminal fluid, was transferred, we found that seminal fluid from another male influences the number of progeny sired by a drive-carrying male when both males mate with the same female. Sperm viability staining revealed that sperm from drive males are incapacitated by seminal fluid from other males within the female reproductive tract. These results suggest that multiple mating by females enables seminal fluid products to interact differentially with sperm and may reduce the transmission advantage of the drive chromosome.

Significance of prolonged copulation in reproductive success of *Dysdercus koenigii*

KK Gupta
"Department of Zoology, Deshbandhu College (University of Delhi), Kalkaji, New Delhi 110019, India; kamal_suyash@yahoo.com"

The adults of *Dysdercus koenigii* remain in continuous copula up to 72 hr. The adaptive significance of prolonged copulation in the reproductive bioactivities of *Dysdercus* was investigated by a series of interrupted mating experiments. The adults were allowed to mate for a specified duration. The studies indicated that insemination in the female takes place during the first day of mating. The female, if mated for a longer time interval acquired additional sperm and male accessory gland secretions which modify the reproductive behavior of the female. Duration of mating had a profound effect on onset of oviposition and total number of eggs and egg batches laid by the female in its life span. Duration of mating was correlated to fertility of the female. Therefore, a female if mated for 24hr laid lesser number of fertile eggs. The fertility was significantly decreased in the egg batches laid during later part of life. The mated female exhibited a rhythm in ovipositional behavior. For instance, the female mated for shorter time intervals exhibited a change in magnitude of egg laying and ovipositional rhythm. Duration of mating was found a crucial factor in governing oviposition behavior. Further, the rate of oocyte growth was dependent on duration of mating as evidenced by a shorter inter-oviposition period in case of females mated for longer duration.

Endocrine regulation of a diapause-associated increase in fat storage in flesh flies.

DA Hahn, JP Rinehart, DL Denlinger
Dept. of Entomology, Ohio State University, Columbus, OH 43210; hahn.144@osu.edu

The flesh fly, Sarcophaga crassipalpis, spends the winter as a diapausing pupa. To support metabolism during this long period of dormancy, diapause-destined larvae accumulate significantly greater lipid stores than direct developing larvae. We have shown that diapause destined larvae accumulate their greater lipid stores by an overall increase in anabolic growth that yields individuals that are both larger and fatter. We have also shown that diapause-destined larvae feed for significantly longer to support this increase in body size and lipid stores. Because insulin signaling is important for regulating growth and metabolism in both vertebrates and invertebrates, we cloned a probe for the Sarcophaga insulin receptor homologue and used it to quantify receptor expression in diapause and direct developing individuals during larval feeding, wandering, and pupal development. We discuss our findings with regard to the role of insulin signaling in generating increased growth and lipid storage in diapause-destined flesh fly larvae.

Ecdysone receptor function and structure

GN Hannan, LD Graham, A Pawlak, L Noyce, R Eaton, D Tohidi-Esfahani, G Lovrecz, L Lu, J Carmichael, VC Epa, P Pilling, MC Lawrence, RJ Hill
CSIRO Molecular Science, Po Box 184, North Ryde, NSW 1670, Australia; ron.hill@csiro.au

We have cloned and characterised full-length cDNAs encoding both EcR and USP subunits for ecdysone receptors from the cotton bollworm *Helicoverpa armigera* (Lepidoptera), the Australian sheep blowfly *Lucilia cuprina* (Diptera) and three members of the Hemiptera, the peach aphid *Myzus persicae,* the silverleaf whitefly *Bemesia tabaci* and the green vegetable bug *Nezara viridula*. The cDNAs have been placed into expression vectors and transfected in to CHO and CV1 mammalian cells along with reporter genes functionally linked to ecdysteroid responsive promoters. The ability of the receptors to activate reporter genes in response to insect ecdysteroids, phytoecdysteroids and a commercial synthetic compound has been studied. The responses of our cloned ecdysone receptors to different ligands will be discussed. Full-length receptor encoding cDNAs have been expressed in an *in vitro* transcription and translation system to examine the protein products of their open reading frames. Regions from within both EcR and USP subunits of our cloned receptors have also been subcloned for expression in a baculovirus system. Studies of the properties of the expressed protein segments, including competition ligand binding *in vitro*, are in progress. The three-dimensional structure of the *B. tabaci* ecdysone receptor heterodimeric ligand-binding domain has been determined by X-ray diffraction.

Diapause and circadian clock gene expression in the linden bug, *Pyrrhocoris apterus*

D Dolezel, I Sauman, M Hodkova
Institute Of Entomology, Academy Of Sciences, Branisovska 31, C. Budejovice, 370 05, Czech Republic; magda@entu.cas.cz

Although photoperiodism is undoubtedly one of the most important functions of the circadian system, the role of circadian clock genes remains unclear. Molecular cloning of the pivotal clock gene homologs *period* and *Clock* from the European linden bug, *Pyrrhocoris apterus*, enabled us to test their possible role in the bug photoperiodic timing system. We compared the expression of *period* and *Clock* genes in the head of animals kept under diapause promoting short days (SD) and diapause preventing long days (LD), using RNase protection assay. There was only a weak diurnal rhythm in both *period* and *Clock* mRNA under LD and no detectable rhythm under SD. Under SD, however, the level of *period* mRNA was about 10-fold, and that of *Clock* mRNA about 2-fold higher than under LD. In a mutant, that does not undergo diapause, even under SD, levels of both transcripts were low in both photoperiods. The block to diapause photo-responsiveness was not associated with defects in the circadian timing, but levels of *period* and *Clock* mRNAs were related to the properties of activity rhythms. The differential regulation of the levels of two clock gene transcripts in a photoperiodic mutant strongly indicates a link between photoperiod, the magnitude of clock gene expression, and developmental outputs.

Accessory nuclei as a vehicle for transporting snRNPs in hymenopteran oocytes

MK Jaglarz, SM Biliński
Institute of Zoology, Jagiellonian University, R. Ingardena 6, 30-060 Krakow, Poland; jagla@zuk.iz.uj.edu.pl

In some insects, oocytes contain characteristic organelles termed accessory nuclei, which originate by budding off the oocyte nucleus and are surrounded by an envelope identical to the nuclear envelope. In the common wasp, *Vespula germanica*, within accessory nuclei dense inclusions, immersed in translucent ground substance, occur. Ultrastructural analysis revealed that these inclusions form gradually during oogenesis and consist of a spherical homogenous body with an attached hemispherical granular structure. EM immunogold labelling and in situ hybridization experiments demonstrated that the mature inclusions contain small nuclear RNAs and proteins: Sm, coilin and SMN, factors involved in pre-mRNA splicing. In the investigated species, in early previtellogenic oocytes, the accessory nuclei surround the oocyte nucleus but as oogenesis progresses, they migrate to the cortical ooplasm and remain there until early embryonic development. Together, these results suggest that the accessory nuclei may be involved in transporting and localizing small nuclear ribonucleoproteins (snRNPs) to the oocyte periphery.

Fertilization chamber and ventral receptacle: diversity in form and function of a homologous structure in the female reproductive tract of higher flies

M Kotrba
Muenchhausenstr 21, 81247 Munich, Germany; marion.kotrba@zsm.mwn.de

In addition to 1-4 spermathecae, which are always connected to the dorsal vagina wall, a further sperm receptacle, the ventral receptacle (VR), occurs in most acalyptrate flies. The VR is positioned in the ventral vagina wall directly opposite to the spermathecal ducts. It functions as a temporary reservoir of sperm. In several instances the VR was found to be the fertilization site. Moreover, in some taxa it has completely taken over the function of sperm storage from the spermathecae. Conformity of position and function support the homology of the VR with the fertilization chamber, known to occur in several calyptrate flies. However, the VR is generally much more elaborate, varying from one-chambered to tubular or multi-chambered, from membranous to strongly sclerotized, from an inconspicuous pouch to a large and sometimes bizarre vessel. Because the VR holds a key position for fertilization, its diversity in shape and size must have implications for the possibilities of sperm competition and female sperm selection. New results about the morphology of the VR in various families will be presented along with hypotheses for its evolution from a simple fertilization chamber to the various elaborate shapes and sizes.

Development of the telotrophic meroistic ovary of the bug *Dysdercus intermedius*

JM Kugler, R Rübsam, J Trauner, J Büning
University of Erlangen-Nuremberg, Developmental Biology Unit, Staudtstr. 5, 91058 Erlangen, Germany; jmkugler@biologie.uni-erlangen.de

Bug ovaries are of the telotrophic meroistic type. Nurse cells are restricted to the apical tropharium and are in syncytial connection with the oocytes via cytoplasmic projections. It is unknown whether the syncytium is established by cell divisions with incomplete cytokinesis as observed in polytrophic meroistic species and lower hemipterans or by cellular fusion. We analysed the development of the ovary of *Dysdercus intermedius* throughout the five larval instars. Up to the third instar, non-dividing germ cells form a tight sphere in the ovariole anlage. In the center of the sphere phosphotyrosine containing proteins and f-actin accumulate and form the so-called PY-structure. With the molt to the fourth instar germ cells begin to divide asynchronously. Simultaneously, the PY-structure expands throughout the germarium. In the fifth instar the PY-structure retracts to an apical position, where it is maintained even in adult ovarioles. Germ cells that loose contact to the PY-structure cease proliferation. The basalmost of these cells enter meiosis to become oocytes and those located more apically endopolyploidise to function as nurse cells. Throughout larval development neither ring canals nor fusomes were observed. Taken together, these findings support the idea that the germ cell syncytium develops through cellular fusion.

Effect of *Toxoneuron nigriceps* polydnavirus gene expression in *Drosophila* germ-line

C Malva, S Gigliotti, P Varricchio, P Falabella, MR Grimaldi, F Graziani, F Pennacchio
Institute of Genetics and Biophysics, CNR, 80121 Napoli, Italy; malva@iigb.na.cnr.it

Several parasitic wasps, when ovipositing in host insects inject proteins and a polydnavirus (PDV) that disrupt their immune reaction, development and physiology. Polydnavirus DNA is integrated as provirus in the parasitoid genome, excise and replicate in the calyx epithelium of the ovary to produce viral particles containing circular DNA molecules of different sizes. We focused on the *Toxoneuron nigriceps* (Viereck) (Hymenoptera, Braconidae), parasitoid of the larval moth *Heliothis virescens*, and its associated TnBV polydnavirus. We found that TnBV genome contains three genes (TnBVank1-3), coding for proteins with ankyrin repeats and showing 30% similarity with the *Drosophila* Cactus and other IkB proteins from different organisms. The viral proteins are small, 146 to 194 aa and, unlike other IkB proteins, do not contain the *N*-terminal conserved IKK target motif. We produced *Drosophila* transgenic lines carrying TnBVank1 and, using the Gal4/UAS system, we expressed the gene in the germ line and in somatic follicle cells. We observed that expression of the TnBVank1 viral gene in the germ-line induced a female sterility phenotype, while expression in follicle cells seemed to have no effect. Thus, with these experiments we could have disclosed a new function of Ikb-like proteins during *Drosophila* oogenesis, to be further characterised.

Functions of multiple sperm-stores in females of the damselfly *Ischnura senegalensis*

M Nakahara, Y Tsubaki
Department of Ecosystem Studies, The University of Tokyo, and Biodiversity Conservation Research Group, National Institute for Environmental Studies, Tsukuba, 305-8506 Japan; nakahara.miri@nies.go.jp

Many insect females have multiple sperm-stores: i.e., bursa-copulatrix and spermatheca(e). The function of this multiplicity has been controversial. Arms' race theory suggests that multiple stores have evolved in females to avoid sperm competition. While cryptic female choice (sperm selection) theory suggests that multiple stores have evolved because of easiness for females to influence on paternity. We propose a new type of sperm selection mechanism within female sperm stores, which was suggested by sperm count conducted on the damselfly *Ischnura senegalensis*. Virgin females were allowed to copulate with a virgin male and then kept individually. Females were dissected on varying days after copulation. Bursa-copulatrix and spermatheca were taken out from the female and the number of sperm was counted under a microscope. We found that the number of sperm in bursa-copulatrix decreased with time, but the number of sperm in spermatheca did not, suggesting that the sperm mortality is higher in bursa-copulatrix. This result suggests that females discriminate against sperm in bursa-copulatrix, from which sperm may be displaced if she happens to recopulate later. Female sperm-storage organs may also function as spaces for the sperm discrimination (selection) as well as for the avoidance of sperm competition.

Regulation of juvenile hormone synthesis in mosquito: physiological, biochemical and molecular studies

FG Noriega, Y Li, S Hernandez-Martinez
Department of Biological Sciences, Florida International University, Miami, FL; USA.

We aim to understand the regulation of juvenile hormone (JH) synthesis in mosquitoes, and how nutritional signals affect the activity of the neuroendocrine system. JH III synthesis is low immediately after adult emergence, increases in sugar-fed females and decreases after blood-feeding. Aedes-allatotropin makes CA in newly emerged females capable for JH biosynthesis. *Anopheles gambiae* PISCF-amide-allatostatin (allatostatin-C-type) is very effective inhibiting JH synthesis. By raising larvae under different nutritional diets two different adult phenotypes (large and small females) were generated. Teneral reserves (protein, lipids and glycogen) were significantly lower in small females. JH synthesis was significantly reduced in females emerged with low teneral reserves and stimulated by sugar feeding; only when nutrients are appropriate the CA becomes capable of synthesizing enough JH to activate reproductive maturation. Libraries were made from corpora allata-corpora cardiaca complexes from *Aedes aegypti* and *Anopheles albimanus.* More than 1850 clones have been sequenced. Enzymes involved in JH synthesis and other important regulatory molecules have been identified among these clones. Supported by NIH RO1 to FGN.

Phase response of the circannual rhythm in the varied carpet beetle, *Anthrenus verbasci*

H Numata, Y Miyazaki, T Nisimura
Graduate School of Science, Osaka City University, Osaka, 558-8585, Japan; numata@sci.osaka-cu.ac.jp

Anthrenus verbasci (L.) (Coleoptera: Dermestidae) shows a circannual rhythm in pupation. This rhythm continues under constant light-dark cycles and shows temperature compensation to some extent. Switching larvae to a different daylength accelerates or delays pupation, thus indicating that a change in photoperiod functions as a zeitgeber in this system. Phase response curves have been obtained for circadian rhythms in various organisms to characterize the oscillators involved in these rhythms. In the present study, we examined the phase response of the circannual rhythm in *A. verbasci*. Larvae were kept under short-day conditions (LD 12:12) at 20 ºC, and exposed to long-day conditions (LD 16:8) for 4 weeks at various phases. The exposure to long-day conditions produced a phase-delay or a phase-advance in the pupation rhythm, depending on the phase at which larvae were exposed to long-day conditions. Thus, a phase response curve for the circannual rhythm was obtained. The curve resembled that for the circadian eclosion rhythm in *Drosophila pseudoobscura*, and was classified into Winfree's Type 0. Therefore, there is a common feature in phase responses between the circadian oscillator and the oscillator involved in the circannual rhythm.

Cryptobiosis of the sleeping chironomid, *Polypedilum vanderplanki*: a unique mechanism to cope with an unpredictable drought

T Okuda, M Watanabe, T Kikawada, N Minakawa, A Fujita and F Yukuhiro
National Institute of Agrobiological Sciences, Ohwashi 1-2, Tsukuba, 305-8634 Japan; oku@affrc.go.jp

Diapause is a period of arrested development in many insects to survive adverse environmental conditions. Astronomical information, mainly the change in daylength is employed to predict future environmental changes. The sleeping chironomid, *Polypedilum vanderplanki*, is a dweller in temporal pools in semi-arid regions in Africa. The small and shallow pools are easily ied up even no rain for a few days, and larvae in the drying pools are also desiccated completely but can revive after rehydration by the next rain. Such a developmental arrest with zero-metabolism is called "cryptobiosis" or "anhydrobiosis". It is of interest to know how *P. vanderplanki* larvae deal with an unpredictable drought. We found that trehalose plays an important role for successful induction and maintenance of cryptobiosis. We also demonstrated that rapid accumulation of trehalose coincided with loss of water from the larvae without cerebral regulation. This paper will summarize physiological and molecular mechanism inducing cryptobiosis in the sleeping chironomid, *P. vanderplanki.*

Molecular analysis of cross-talk between juvenile hormone and 20-hydroxyecdysone

SR Palli, D. R. Kethidi
Department of Entomology, University of Kentucky, Lexington KY 40546 USA; rpalli@uky.edu.

We discovered that the expression of juvenile hormone esterase gene from *Choristoneura fumiferana* (Cfjhe) is induced by JH I and the JH I induction is suppressed by 20-hydroxyecdysone (20E). Cloning and analysis of the promoter region of Cfjhe gene identified a 30 bp region that supports both JH and 20E response observed for the Cfjhe gene. This 30 bp sequence contains a direct repeat element with a 4-nucleotide spacer and is designated as JH response element (JHRE). A reporter gene placed under the control of JHRE is induced by JH in a dose- and time-dependent manner in CF-203, L57, HvE1s and Aa23 cells, and 20E in the presence of EcR was able to suppress JH induction. Nuclear proteins isolated from all four cell lines bound to JHRE. Protein kinase C-mediated phosphorylation decreased the binding of nuclear proteins to JHRE. JH or calf intestinal alkaline phosphatase-mediated dephosphorylation increased the binding of nuclear proteins to JHRE. The results from these studies suggest that the JH action and its cross-talk with 20E involve multiple signal transduction mechanisms.

Comparisons of neural development in insects and crustaceans

NH Patel
UC Berkeley/HHMI, 3060 VLSB # 3140, Berkeley, CA, USA, 94720-3140; nipam@uclink.berkeley.edu

Several lines of evidence have been used to homologize specific neurons and neural precursor cells between insect species and between insects and crustaceans. Our lab has recently characterized the expression pattern of Pax3/7 ("pairberry") family members between multiple arthropod species, and I will present data obtained from these studies that furthers our understanding of the evolutionary relationship of neural patterning and development in insects, and between insects and crustaceans. I will also present recent data on how the Notch/Delta signalling system, so widely used for neuroblast formation in insects, is also used for other early patterning functions.

The evolution of germline development and axial patterning

NH Patel
UC Berkeley/HHMI, 3060 VLSB # 3140, Berkeley, CA, USA, 94720-3140; nipam@uclink.berkeley.edu

While germline development and early axial patterning are well understood in the model insect, *Drosophila melanogaster*, it is clear that many interesting evolutionary differences between species exist in these processes. I will review my lab's progress in understanding the nature of these evolutionary changes, how they might have occurred, and their consequences on subsequent development. I will focus on studies of axial patterning involving maternal factors in the grasshopper, Schistocerca americana, the amphipod, Parhyale hawaiensis, and the fruit fly, *Drosophila* melanogaster. I will also present data on the similarities and differences in the behaviour of germ cells between insects, and their sister taxa, the crustaceans.

Signal transduction in the corpora allata of adult *Heliothis virescens*

A Rachinksy, SB Ramaswamy, A Srinivasan
Department of Entomology, Kansas State University, Manhattan, KS 66506; sonny@ksu.edu

The concerted action of juvenile hormone and allatotropin (AT) is necessary for egg development in *Heliothis virescens*, which is mediated by second messengers in the corpora allata (CA). The Ca^{2+} ionophore, A23187, stimulated JH production, as did *Manduca sexta* allatotropin (Mas-AT). Thapsigargin, which increases intracellular Ca^{2+}, significantly stimulated CA activity. The membrane-permeable Ca^{2+} chelator, BAPTA/AM antagonized effects of thapsigargin and Mas-AT, suggesting that Mas-AT likely affects CA activity by increasing intracellular Ca^{2+}. The inhibitor of IP_3-induced Ca^{2+} release from intracellular stores, 2-APB, had no effect on *H. virescens*. 2-APB also failed to affect Mas-AT activity, indicating that 2-APB may not act as an efficient Ca^{2+} release blocker. Modification of intracellular Ca^{2+} concentration clearly affects CA activity, however, CA are insensitive to changes in extracellular Ca^{2+}, suggesting efficient Ca^{2+} homeostasis. The diacylglycerol (DAG)-kinase inhibitor R59022 no effect on CA activity, but it potentiated effects of Mas-AT. This indicates that DAG might serve as a second messenger. PDBu, the phorbolester activator of protein kinase C (PKC), did not affect CA activity when applied alone or in combination with Mas-AT. In most animal there are several, tissue-specific, PKC isoforms present, which show different sensitivities towards inhibitory or stimulatory ugs, thus, requiring further experiments.

Juvenile hormone, broad, and adult development of the *Drosophila* abdomen

LM Riddiford, X-F Zhou, and H-Y Cui
Department of Biology, University of Washington, Seattle, WA 98195-1800, USA; lmr@u.washington.edu

In its developmental role, juvenile hormone (JH) acts to direct ecdysone action during the molt so that it does not cause the switch in programs that is necessary for metamorphosis. Broad is an ecdysone –induced transcription factor that is necessary for pupal development. Both its appearance and disappearance in polymorphic epidermis is prevented by JH, but not in imaginal discs. When misexpressed during either the larval or the adult molt of *Drosophila* at the beginning of new cuticle formation, Broad causes the production of a pupal cuticle by activating pupal cuticle genes and suppressing either larval or adult cuticle genes. Studies with the upstream promoter of an adult cuticle gene Acp65a show that Broad-Z1 can suppress expression by the 236 bp minimal promoter. The effect of mutations within the putative BR-Z1 binding site is under study. We have found several mutants with P-element insertions in the regulatory region of CG14709, a putative ABC transporter, that in response to JH show the prolonged expression of BR in the abdominal imaginal cells but form normal adult abdomens. The role of this gene in the JH pathway is presently under study. Supported by NIH.

Summary diapause of redlegged earth mite, *Halotydeus destructor* (Acari: Penthaleidae) in Australia

TJ Ridsdill-Smith, CC Pavri
CSIRO Entomology, Private Bag 5, PO Wembley, Western Australia, 6913; james.ridsdill-smith@csiro.au

In winter dominant rainfall regions of southern Australia, redlegged earth mite, an introduced pest from South Africa, feeds on plants during the cool moist winter months. The hot dry summer is spent as a diapausing egg inside the cadaver of the adult female mite. Diapause is broken by exposure to high temperature in summer and the eggs hatch the following autumn, triggered by combined moisture and cold temperature requirements. The induction of diapause in spring was measured over several years at different sites, by dissecting mites weekly to record the proportion of diapause eggs present. Induction of diapause was found to be triggered by day-length and climatic factors and was relatively constant between years at any one site, but varied across southern Australia by up to six weeks. This was modelled as a single date for any given location which predicted the onset of diapause. The predictions were tested at different locations by dissecting mites weekly at locations across Southern Australia to record proportion of diapause eggs. At 88% of the 75 sites, diapause occurred within seven days of the predicted date.

The role of spermatophores as mating plugs that cause unsuccessful matings (pseudocopulations) in *Archisepsis diversiformis* (Diptera: Sepsidae)

L Rodríguez Sevilla
Escuela de Biología, Universidad de Costa Rica, 2060, San Peo, San José, Costa Rica, Central America; leonorars@racsa.co.cr

Copulations of non-virgin female *Archisepsis diversiformis* reared in captivity were of two types: successful (average duration 28,9 min., spermatophore transferred and inserted into the spermathecal duct) and unsuccessful (average duration 1.3 min., no spermatophore transferred). Only about half of the matings were successful, and females only mated when their eggs were relatively immature. Successful matings occurred after egglaying and in absence of a spermatophore in the vagina from a previous mating. Pseudocopulations, in contrast, occurred before egglaying, with an old spermatophore present in the vagina. Three hypotheses are suggested: 1- Spermatophores may function as nourishment for the female, her eggs or the sperm, because they are usually degraded, rather than discarded intact. 2- Female retention of the spermatophore may function as a mating plug, preventing insemination when she is not ready to mate and saving energy she would otherwise have to spend trying to physically reject or discourage undesired males. 3- The male leaves the spermatophore as a mating plug to prevent future males from copulating successfully. It is not clear whether females are capable of discarding fresh, intact spermatophores.

Comparative aspects of dorsoventral axis formation in *Tribolium* **and** *Drosophila*

S Roth, P Kalscheuer, A Basal, M. van der Zee, O. Stockhammer, C. Mikulski
IfE, Gyrhofstr. 17, 50923 Cologne, Germany; siegfried.roth@uni-koeln.de

The pupal RNAi technique has allowed a detailed functional comparison of maternal and zygotic dorsoventral patterning genes from *Drosophila* and *Tribolium*. As in *Drosophila* the dorsoventral axis of *Tribolium* embryos relies on a maternal signaling cascade, which requires a Toll-like receptor and a Dorsal-like NF-kB transcription factor. The loss-of-function of *Toll* or *dorsal* lead to apolar, completely dorsalized phenotypes, which are strikingly similar to the corresponding *Drosophila* mutant phenotypes. In contrast, the major zygotic patterning system responsible for the subdivision of the ectoderm in insects and vertebrates, the *decapentaplegic/short gastrulation* system (BMP/chordin in vertebrates) has a more fundamental role in *Tribolium* than in *Drosophila*. A knockdown of *short gastrulation* in *Tribolium* leads to strongly dorsalized embryos. In *Drosophila* the Toll-Dorsal system apparently has overtaken some functions which were fulfilled by the *decapentaplegic /short gastrulation* system in more ancestral insects. Thus, the relative importance of the two patterning systems has changed in evolution.

Follicle cell differentiation in bgcn mutant *Drosophila* ovaries

R Rübsam, R Cordes, J Büning
Developmental Biology Unit, Zoological Institute, University of Erlangen-Nuremberg, Staudtstr.5, 91058 Erlangen, Germany; rruebsam@biologie.uni-erlangen.de

Mutations in the *Drosophila benign gonial cell neoplasm (bgcn)* gene affect germ cell differentiation and proliferation in both sexes. For normal gametogenesis to occur, *bgcn* function was shown to be essential in the germ line. Loss of *bgcn* function arrests ovarian germ cells at an early developmental stage that combines characters of stem cells, cystoblasts and early cystocytes. The development of somatic follicle cells, however, proved to be independent from germ cell differentiation to a large extent. Follicle cells always adopted epithelial polarity. By using cell-type specific reporter gene - and enhancer trap - lines and various antibodies we were able to identify a number of correctly specified follicle cell types in *bgcn* mutant ovaries. Among them were polar follicle cells, stalk cells and centripetal follicle cells. Even more surprising, the majority of follicle cells in mutant ovaries underwent terminal differentiation, i.e. they stopped their mitotic activity, became polyploid and finally secreted a multilayered eggshell with ultrastructural properties comparable to those of wild type eggs. Thus, follicle cells in *bgcn* mutant ovaries reveal an intrinsic developmental program that appears to be largely uncorrelated to germ cell differentiation.

Genomic and non-genomic action of ecdysteroid: both are required for completion of programmed cell death in the anterior silk gland

M El-Mogy, M Iga, T Sekimoto, M Iwami, S Sakurai
Division of Life Sciences, School of Natural Science and Technology, Kanazawa University, Kanazawa 920-1192, Japan; ssakurai@kenroku.kanazawa-u.ac.jp

Programmed cell death (PCD) of the anterior silk glands (ASG) of the silkworm, *Bombyx mori*, is triggered by 20-hydroxyecdysone (20E) with exhibiting serial responses in order, i.e., blebbing, cell shrinkage, nuclear condensation, DNA fragmentation and nuclear fragmentation. The blebbing and cell shrinkage are under the control of genomic action of 20E. Among early genes, EcR B1, E75A, BHR3 and BR-C are up-regulated, while EcR-A and E75B are not. In addition to the genomic action, nuclear fragmentation and DNA fragmentation are controlled by a non-genomic action of 20E through its membrane receptor. The partially purified putative membrane receptor exhibits a high affinity to ponasterone A. A PKC inhibitor and a caspase 3 inhibitor equally suppressed the nuclear fragmentation as well as DNA fragmentation, and nether calcium ionophore nor phorbol ester mimicked the 20E action, indicating that the down-stream of the putative membrane receptor includes Ca^{2+}-independent protein kinase C and caspase 3. Combined results indicate that 20E acts through two distinctly different pathways, and the PCD is accomplished by an integration of the genomic and non-genomic actions.

Roles of pigment-dispersing factor immunoreactive neurons in circadian rhythms and photoperiodism in the blow fly, *Protophormia terraenovae*

S Shiga, Y Hamanaka, H Numata
Graduate School of Science, Osaka City University, Osaka, 558-8585, Japan; shigask@sci.osaka-cu.ac.jp

Adult females of the blow fly, *Protophormia terraenovae* show clear circadian activity rhythms and photoperiodism controlling reproductive diapause. The present study examined roles of pigment-dispersing factor-immunoreactive (PDF-ir) neurons in circadian activity rhythms and photoperiodism by electron microscopy and ablation experiments. Electron microscopy has revealed that at a region of the dorso-lateral protocerebrum PDF-ir fibers form output synapses with neurons in the pars lateralis (PL), which are necessary for diapause induction. PDF immunoreactivity was detected exclusively in large dense-core vesicles but not in synaptic vesicles. Ablation of a region at the anterior base of the medulla in the optic lobe abolished circadian rhythmicity under constant darkness in about 30 % of flies. There are 4 small and 4 large PDF-ir cells at the anterior base of the medulla. The more small PDF-ir cells were removed, the more flies showed arrhythmicity. The same operation invalidated photoperiodism. Diapause incidence was low both under long-day and short-day conditions irrespective of the number of PDF-ir cells remained. In the present study synaptic inputs from PDF-ir neurons to PL neurons were demonstrated. It is suggested that the small-type PDF-ir neurons are indispensable to circadian activity rhythms, and regions by PDF-ir cells play important roles in photoperiodism.

Involvement of *timeless* gene in photoperiodic induction of diapause in drosophilid fly, *Chymomyza costata*

K Shimada, V Kostal, J Pavelka
Inst Low Temperature Sci, Hokkaido Univ, Sapporo 060-0819, Japan, Inst Entomology ASCR, CZ-370 05 Ceske Budejovice, Czech Republic;
kshimada@pop.lowtem.hokudai.ac.jp

In drosophilid fly, *Chymomyza costata*, photoperiodic response and circadian rhythmicity seem to be controlled by common elements. Non-photoperiodic-diapause (npd) mutants which have lost photoperiodic response for diapause induction show arrhythmic behaviour. We cloned *period* and *timeless* genes from wild-type and npd strains. Abundance of mRNA of both clock genes in adult heads of wild-type was low in daylight and high at night with circadian variation. In npd mutants, transcription of *period* was arrhythmic and *timeless* was suppressed. Genetic linkage analysis demonstrated that *period* was not directly related with critical daylength in photoperiodism but deficient allele of *timeless* was strictly linked with loss of photoperiodic response. These results indicate that *timeless*, important oscillator of circadian clock, is involved in photoperiodic time measurement system. Larvae of this fly enter diapause when they grow under subcritical short daylengths. Cell-growth and differentiation for imaginal development are interrupted at 3rd-instar under short days. *timeless* possibly plays important function in photoperiodic control of cell proliferation.

Agonistic female responses to insemination: cryptic choice or self defence?

MT Siva-Jothy, K Reinhard, R Naylor.
Dept. of Animal & Plant Sciences, University of Sheffield, Sheffield S10 2TN, UK; m.siva-jothy@sheffield.ac.uk

Bed-bugs are unique amongst dioecious organisms in that they show traumatic insemination. When the male stabs the female with his intromittent organ sperm and seminal fluids are introduced into the female's haemocoel, but so are opportunistic bacteria. Several authors have suggested that the resultant immune response functions to select sperm in a manner that enhances female fitness. We present the results from experimental studies that examine the consequences of this mode of insemination and the function of the female's physiological response to it, given that microbes are also transmitted during insemination. Our results provide an insight into how selection via sexual conflict shapes the evolution of secondary sexual traits.

Egg start: from stem cell to cyst to oocyte

AC Spradling, E deCotto, T Kai, R Cox, B Ohlstein, M Buszczak
HHMI/Embryology, Carnegie Institution of Washington, 115 W. University Pkwy. Baltimore, MD, 21210, USA; spradling@ciwemb.edu

Germline stem cells (GSCs) reside at the tip of the *Drosophila* ovariole in a niche that serves as a model for understanding how stem cells are regulated by BMP, Hedgehog and other signals. After GSC division, one daughter remains in contact with cap cells, a major niche component, while the other moves away and under the control of the *bag-of-marbles (bam*) gene divides synchronously to form a cyst of interconnected cells containing an asymmetric actin cytoskeleton (fusome). Forming cysts interact with somatic inner sheath cells, and later with the pre-follicle cell daughters of distally located somatic stem cells (SSCs). During the cyst stage we find that selected organelles and specific macromolecules are actively transported into the future oocyte to form the Balbiani body. We also find that a subpopulation of inner sheath cells is part of a previously undescribed stem cell lineage, and we name these cells "escort cells." Escort cells accompany germ cells as they leave the niche until they are replaced by pre-follicle cells. During much of this time, germ cell cysts retain the capacity to de-differentiate into GSCs if placed in an appropriate environment such as the larval gonad. We have studied the regulation of escort stem cells, their role in the growth and differentiation of germ cells, and their interactions with GSCs and SSCs. These studies have been facilitated by a "gene trap" screen, using P and PiggyBac elements, that fuses proteins encoded throughout the genome with GFP in living flies.

The transition from vitellogenesis to choriogenesis during silkmoth oogenesis.

L Swevers, N Salia, T Georgomanolis, M Glushek, K Ito, K Iatrou.
Institute of Biology, National Centre for Scientific Research "Demokritos", Athens, Greece; swevers@bio.demokritos.gr.

In the silkmoth, *Bombyx mori*, follicle development occurs asynchronously and follicles of unique developmental stages are arranged as single rows in the developing ovarioles. Because the developmental periods of vitellogenesis and choriogenesis are very extended, isolation of follicles at many distinct developmental stages during these periods is feasible. This feature makes silkmoth oogenesis an attractive system for studies on the long-term developmental program that governs the terminal differentiation of ovarian follicles. An overview of the regulatory factors that are involved in the regulation of the transition from vitellogenesis to choriogenesis in the silkmoth will be presented. This transition is signaled by the decline of active ecdysteroids in the circulation and the induction of a regulatory cascade initiated by the orphan nuclear receptor BmFTZ-F1. Current research is focused on the regulatory roles of two key transcription factors that have postulated to be involved in the control of initiation of choriogenesis, BmGATAb and the orphan nuclear receptor BmE75C. Through the use of the yeast two-hybrid system, proteins interacting with these factors have been isolated. Their possible role in the transduction cascades controlled by the two transcription factors under investigation will be presented.

Male coercion, cryptic female choice, or both? A case study from spotted cucumber beetles

DW Tallamy
University of Delaware, essor and Chair, Department of Entomology and Wildlife Ecology 250 Townsend Hall, Newark, DE 19717 USA; dtallamy@UDel.Edu

Debate continues over the degree to which males and females control the paternity of their offspring. Reproduction in *Diabrotica undecimpunctata howardi*, the spotted cucumber beetle (Coleoptera; Chrysomelidae), demonstrates how male coercion and female choice can operate simultaneously. Females control access to their bursas by constricting vaginal musculature. Males use copulatory courtship and cuticular odors to "coax" females into relaxing their vaginal muscles to permit complete penetration. When females do not cooperate, some males attempt to overpower females or exhaust them in order to force sperm through their vaginal tract. Sperm obtained in this way remains in the bursa and is not moved by the female into the spermatheca. But when an attractive male subsequently deposits a complete spermatophore into the bursa, sperm from the rejected male is transported to the spermatheca along with the sperm of the accepted male. Coercive tactics can be so successful that up to 56 % of the offspring are sired by rejected males.

Role of [His^7]-Corazonin in the control of phase polyphenism in locusts

S Tanaka
Lab. of Insect Life-Cycles & Physiology, Division of Insect and Animal Sciences, IAI, Tsukuba, 305-8634 Japan; stanaka@affrc.go.jp

A neuropeptide, [His^7]-corazonin, present in the brain and corpora cardiaca of locusts is known to induce dark colors in locusts and grasshoppers. The present paper reviews the highlights of our locust project on the function of this neuropeptide in the control of phase-related characters. [His^7]-corazonin was first isolated from the American grasshopper *Schistocerca americana* without known function by J.A. Veenstra (1991), and recently we demonstrated that it induces black patterns in the nymphs of this species. Solitary adult locusts are characterized by large F/C (hind femur length / head width) and small E/F (forewing length / hind femur length) ratios compared with gregarious adults. Injection of [His^7]-corazonin into solitary (isolated-reared) nymphs caused a shift in these ratios towards the values typical for gregarious adults in the migratory locust *Locusta migratoria*. Gregarious adults are known to have fewer coeloconic sensilla (chemoreceptors) on the 8th antennal segment than solitary adults. Injection of [His^7]-corazonin was found to mimic the effect of crowding on development of this sensillum. Similar effects on morphometrics and antennal sensilla were also observed in the desert locust *S. gregaria*. These results suggest that [His^7]-corazonin plays an important role in the control of phase polyphenism in locusts.

Ecdysteroid titers and expression of ecdysteroid receptor during vitellogenesis in the soft tick, *Ornithodoros moubata* (Acari: Argasidae)

K Ogihara, Y Nakajima, D Taylor
Institute of Agriculture & Forestry, University of Tsukuba, Tsukuba, Ibaraki, Japan; demartaylor@yahoo.com

A blood meal is essential for tick reproduction and results in the transmission of various pathogens. Therefore understanding the reproductive processes are essential for tick control. Our research indicates the involvement of two factors, one a peptide and the other likely a steroid, in the regulation of vitellogenesis. Here we present data indicating a role for ecdysteroids, as the second factor, in the regulation of vitellogenesis of *O. moubata.* Injections and topical treatment with high concentrations of ecdysteroids stimulated an increase in vitellogenin and egg laying. Vg synthesis occurs in both engorged mated and virgin females, but is not activated in virgin females sufficiently for eggs to mature. Engorged mated females show three ecdysteroid peaks (previtellogenic, oocyte maturational, and preovipositional phases) in the hemolymph and four peaks (previtellogenic, oocyte maturational, preovipositional and ovipositional phases) in the whole body extracts. Virgin females have no ecdysteroid peaks and do not lay eggs. The ecdysteroid receptor of *O. moubata* has been identified and receptor expression appears to coincide with vitellogenin up-regulation, egg maturation and oviposition. These results suggest ecdysteroids induce vitellogenin synthesis, egg maturation and oviposition in *O. moubata*.

Generation of cell diversity in the developing CNS of *Drosophila*

GM Technau
Institute for Genetics, University of Mainz, Saarstrasse 21, D-55122 Mainz, Germany; technau@uni-mainz.de

Development of the central nervous system (CNS) involves the transformation of a two-dimensional sheath of uniform ectodermal cells (the neuroectoderm) into a three-dimensional structure in which particular numbers of various neuronal and glial cell types become arranged in a reproducible pattern and establish specific connections. *Drosophila* is a suitable model organism to study the mechanisms that lead to pattern and cell diversity in the CNS. One of the first steps during neurogenesis in the *Drosophila* embryo is the delamination from the neuroectoderm of a stereotype population of neural stem cells, called neuroblasts (NBs). Each NB acquires a unique identity, which is reflected by the time and position of its delamination from the neuroectoderm, the combination of genes it expresses, and by the production of a specific cell lineage. Specification of a unique NB fate largely depends on positional information in the neuroectoderm. In the developing ventral nerve cord NBs arising from corresponding segmental positions generally give rise to very similar lineages. However, some of these serially homologous NB lineages express distinct segment-specific characteristics. Segmental diversification of NBs is much more pronounced in the developing brain. Aspects of the specification and development of NB-lineages in the embryonic ventral nerve cord and processes of early patterning in the brain will be presented.

Photoperiodic modulation of circadian rhythms in crickets

K Tomioka, S Yasumura, T Sakamoto
Department of Biology, Faculty of Science, Okayama University, Okayama 700-8530, Japan; tomioka@cc.okayama-u.ac.jp

"The mechanism of photoperiodic time-measurement remains to be clarified, although hypothetical models have been proposed. Most of the models that incorporate circadian clocks assume that parameters of the clock are rather stable irrespective of given photoperiods. We analyzed photoperiodic modulation of circadian locomotor rhythms in crickets, *Teleogryllus emma* and *Modicogryllus siamensis*, of which post-embryonic development is known to be regulated by photoperiods. Short-days accelerate it and long-days decelerate in *T. emma*, although reversed effects are observed in *M. siamensis*. The circadian waveform of their locomotor rhythms was highly dependent on the photoperiod during the post-embryonic development. In *T. emma*, the length of subjective night was longer when exposed to longer nights. In *M. siamensis*, adults always showed nocturnal rhythms, while nymphs were diurnal in long-day conditions but nocturnal in short-day conditions. Results of experiments using *Gryllus bimaculatus* suggest that the photoperiodic modulation occurs at the circadian clock and coupling of the clock is important for the maintenance of the modulated waveform. The possible involvement of the photoperiodic modulation of circadian system in the photoperiodic time-measurement mechanism will be discussed.
"

Towards functional analysis of oogenesis in *Tribolium castaneum*

J Trauner, M Klingler, J Büning
Developmental Biology Unit, Zoological Institute, University of Erlangen-Nuremberg, Staudtstrasse 5, 91058 Erlangen, Germany; jtrauner@biologie.uni-erlangen.de

Tribolium castaneum has ovaries of the telotrophic meroistic type, i.e. the nurse cells are not included into the follicle, but remain in the anteriormost compartment of the ovariole, the tropharium. In contrast to *Drosophila*, germline cells are mitotically inactive in adult *Tribolium* beetles - cluster formation takes place during larval and pupal stages only. To date, little is known about the mechanisms underlying the differentiation process of germ cells into oocytes and nurse cells in this species. By morphological criteria, several pro-oocytes, located posteriorly in the tropharium, can be clearly distinguished from nurse cells. The pro-oocytes enter the vitellarium one by one and differentiate into oocytes. Every oocyte remains connected to the nurse cells via the so-called nutritive cord, a long protrusion formed by the anterior pole of the oocyte. Using RNA interference, we have initiated loss-of-function studies on *Tribolium* oogenesis. Females injected with *gbb* (*glass bottom boat*, a Bmp-orthologue) double-stranded RNA are completely sterile, and oocyte development is arrested at a premature stage. Analysis of injected females indicate that *gbb* is also involved in the organogenesis of the ovary.

Use of in vivo imaging of neurons to study hormone action on the insect CNS

JW Truman
Department of Biology, University of Washington, Box 351800, Seattle WA 98195, USA; jwt@u.washington.edu

During insect metamorphosis most larval tissues degenerate and adult organs are formed from the diploid cells sequestered in the imaginal discs and imaginal nests. The CNS is more complicated than other tissues, however, because many of the larval neurons persist through metamorphosis and undergo cellular remodeling, allowing them to perform new functions in the adult. Ecdysone and juvenile hormone are the two metamorphic regulators of cellular remodeling. They regulate the expression of intrinsic programs for pruning and regrowth of denitic and axonal arbors in a given neuron but they also are responsible for extrinsic cues produced in the cell's immediate environment which interact with the cell's intrinsic programs. Our goal has been to determine the intrinsic and extrinsic factors that regulate cellular remodeling. The talk will focus on the use of in vivo imaging of remodeling neurons as a tool for examining how ecdysone and juvenile hormone regulate this process. Mutants, RNA interference and dominant negative receptors have been used to disrupt hormone response in either individual neurons or their cellular environment. These experiments indicate that remodeling involves a complex choreography of interactions between a neuron and the cells that it contacts.

Neuronal lineages and the development and evolution of the insect CNS

JW Truman, DW Williams
Department of Biology, University of Washington, Box 351800, Seattle WA 98195, USA; jwt@u.washington.edu

The neurons in the segmental ganglia of insects arise from a stereotyped number of stem cells called the neuroblasts (NBs). In basal insect groups the NBs produce all of their progeny neurons during embryogenesis, but in insects that have complete metamorphosis many of the NBs split their neurogenesis into embryonic and postembryonic phases, to generate neurons for the larval and adult nervous systems, respectively. Although the early born neurons coming from each NB have been identified, the bulk of the neurons produced by each stem cell remain unknown. With this in mind, we undertook an extensive clonal analysis in *Drosophila* in which we determined the initial projection patterns for the late born neurons in all of the thoracic lineages. The late-born cells are remarkably homogeneous in their projection patterns and suggest functional restrictions amongst the lineages. For example some neuroblasts make interneurons that project only to presumptive leg neuropils whereas others project to presumptive flight neuropils. Since the arrays of NBs have stayed remarkably stable through the evolution of the insects, this description may provide the foundation for a better understanding of the evolution and diversification of the insect CNS.

Regulation of matrix metalloproteinases during metamorphosis of the lepidopteran *Galleria mellonella*

M Wedde, A Vilcinskas
Institute of Biochemistry and Biology, University of Potsdam, Lennestr. 7a, 14471 Potsdam, Germany; vilcinsk@rz.uni-potsdam.de

Reorganization of the extra cellular matrix during tissue differentiation and metamorphosis is predominantly mediated by matrix metalloproteinases (MMP´s) which are regulated by tissue inhibitors of metalloproteinases (TIMP´s). More than 27 MMP and 4 TIMP´s homologues member of these families have been reported from vertebrates[1]. Recently, the first MMP and TIMP homologues have been reported from *Drosophila* [2,3] . Here we report our recent progress in identification of MMP´s in the lepidopteran *Galleria mellonella* and we provide evidence for the regulation of this endogenous metalloproteinases by a novel insect metalloproteinases inhibitor (IMPI) which represents the first non-TIMP-like metalloproteinaseinhibitor identified in animals[4]. Cloning and expression of the IMPI as well as analysis of the signalling pathway mediating its induction led to the discovery of a feedback loop regulation mechanism in *G. mellonella* that controls endogenous MMP´s mediating remodelling of the extra cellular matrix during metamorphosis.

Molecular cloning and recombinant expression of antimicrobial peptides from house fly, *Musca domestica*

JX Wang, XF Zhao, LC Wang, L Li, XJ Du
School of Life Sciences, Shandong University, Jinan 250100, China; jxwang@sdu.edu.cn

Two antimicrobial peptide genes, the cecropin and defensin, were cloned by from the houseflies, *Musca domestics.* The full length of the cecropin cDNA was 403 bp and the open reading frame of the cDNA encoded a 63 amino acid procecropin. A potential signal sequence of twenty-three amino acids was identified, ending with the residues QSEA. A single cleavage reaction at Ala-23 therefore would generate the mature forty-amino acid *Md*-Cec peptide. The N-terminal portion of the molecule is highly basic, while the C-terminal domain is predominantly hydrophobic. The sequence identity with other cecropin was between 80% and 97%. The open reading frame of the defensin encoded a 92-amino acid peptide, which contained an NH_2-terminal signal sequence (1~22) followed by a propeptide and the mature peptide (53~92). The sequence identity with other insect defensin is between 51% and 73%. The mature peptide, with a predicted molecular weight of 4.0 kDa, and pI of 8.69, has 1 negative charged amino acid and 4 positive ones. The cecropin and defensin were expressed in *E. coli* and yeast and the recombinant peptides in yeast had the activity against several Gram negative and positive bacteria. The recombinant cecropin and defensin were confirmed by amino acid sequencing.

Bridging the gap between molecular and cellular functions of axon guidance molecules

PM Whitington, K Bates, K-L Harris, L Parsons
Dept. Anatomy And Cell Biology, University Of Melbourne, Vic 3010, Australia; p.whitington@unimelb.edu.au

Over the last decade, many molecules that play key roles in axon guidance have been identified. However there remains a substantial gap between our understanding of the biochemical functions of such molecules and how their effects are translated into specific guidance decisions. To tackle this problem, we have chosen the sensory nervous system of the *Drosophila* embryo as our model. The identities of the growing axons, their cellular guidance cues and key axon choice points are known in detail in this system and *Drosophila* offers an arsenal of powerful molecular/genetic tools. Using the candidate gene approach, we have identified roles for a number of known axon guidance molecules in sensory axon guidance. These include Slit and its receptors, the Robo family, Semaphorins and their receptors, the Plexins and the cell adhesion molecule Neuroglian. Our results have shed new light on the cellular mechanisms by which these proteins mediate axon guidance. We now seek to determine how the growth cones of the sensory neurons integrate these multiple guidance signals at particular axon choice points.

Molecular cloning and expression patterns of the molt-regulating transcription factor, Hhr3 from *Helicoverpa armigera*

XF Zhao, JX Wang, XL Xu, ZM Li, CJ Kang
School of Life Sciences, Shandong University, Jinan 250100, China; xfzhao@sdu.edu.cn

A 1668 bp cDNA encoding a molt-regulating transcription factor, hormone receptor 3 (HHR3) was cloned from *H. armigera,* which deduced a protein with 556 amino acids. The isoelectric point of this protein was pI 6.52 and the molecular mass was 62 kDa. A DNA-binding region signature of nuclear hormone receptor was found from No. 107 to 133 amino acids. A possible transmembrane helice from outside to inside was found from No. 72 to 90 amino acids. Five bands of HHR3 were detected from the larvae by northern blotting. Among of them, band 1 and 2 were the dominant populations. The expression patterns of HHR3 *in vivo* were variable upon developmental stages and tissues. Results suggested that bands of 1 4 of HHR3 was only shortly expressed during molting which suggested that they were involved in the regulation of molting cascade, whereas, band 0 was observed in both molting and feeding larvae. Band 1 and 2 of HHR3 could be inducted from epidermis by RH-2485. The cDNA of HHR3 was expressed in *E. col.* A reconstructed HHR3-NPV was prepared and the efficacy to pest insect was studied. The work was supported by grants: 3008002, 30330070 and 2001AA214031-1-2.

A possible pathway for diapause termination in *Helicoverpa armigera*

WH Xu
School of Life Science, University of Science and Technology of China, Hefei 230027, China; whxu@ustc.edu.cn

Diapause hormone (DH) is a 24 amino acid peptide amide which induces embryonic diapause in *Bombyx mori*. A DH-like neuropeptide, which is 62.5% identical with *B. mori* DH was found in the PBAN cDNA from the suboesophageal ganglion (SG) of the bollworm, *Helicoverpa armigera* (Har). Using quantitative RT-PCR and ELISA, we observed that expression of the Har-DH-PBAN mRNA in the SG and the DH-like immunoreactivity in hemolymph of nondiapause-type pupae was significantly higher than in diapause-type pupae. Injection of the amidated Har-DH into diapausing pupae effectively promoted development at all stages of diapause. Immunocytochemical results indicated that the level of DH gene expression and axonal release are related to the diapause decision. Ecdysteroidogenesis in prothoracic glands (PGs) was stimulated by synthetic DH *in vivo* and *in vitro*, and labeled DH bound to a receptor on the PG, thus suggesting that DH breaks diapause by activating the PG to synthesize ecdysone. Furthermore, the response of DH in terminating diapause was temperature-dependent. Decerebration experiments showed that the brain can control pupal development through the regulation of DH, and DH can terminate diapause and promote development without the brain. This result suggests a possible mechanism of response for the DH signal in *H. armigera*.

Effects of circadian phases on sperm competition in *Drosophila melanogaster*

YY Yang, HJ Lee
Postal address: Dept. Entomology, National Taiwan University, Taipei 106, Taiwan; nasuta@mail2000.com.tw

Females in almost all animal groups copulate with multiple males. In addition, female insects have spermatheca to store sperm. Hence, sperm competition is an important component of fitness in males. Many insects show daily rhythms in their mating. The mating activity of *Drosophila* is controlled not only by an endogenous clock, but also by light itself. It has been suggested that circadian clock is important for sperm release in *Drosophila melanogaster*. In this study, sperm precedence was studied by employing various mutant strains and a wild type strain. These strains were entrained in two different LD conditions (anti-phased for 10hrs). The preliminary data showed the circadian phase did not affect the outcomes of sperm competition. The underlying mechanisms were also investigated.

Gene expression during diapause initiation of the Colorado potato beetle, *Leptinotarsa decemlineata*

GD Yocum
RRVARC, ARS-USDA, 1605 Albrecht Blvd, Fargo, ND, USA, 58105; yocumg@fargo.ars.usda.gov

Duration of diapause can be influenced by environmental factors prior to the initiation of true diapause. To clarify the molecular mechanism(s) regulating diapause initiation and how the duration of diapause is determined, early diapausing beetles are being screened for diapause regulated genes. To date, six genes have been isolated and their expression investigated in prediapause and early diapausing beetles. Diapause-associated transcripts 1 & 2 (DAT-1 & 2) are expressed beginning on day 3 after adult emergence in short day adults. DAT-3, HSP70A and a small heat shock protein are expressed at the initiation of diapause. An unidentified nondiapause upregulated transcript is expressed in day 1 nondiapausing adult female beetles. Genomic structures of several of these genes have been determined in order to identify possible promoter sites and to identify possible noncoding RNAs within the introns. Six possible promoter sites have been identified within 700 bp upstream of the TATA box of DAT-3. A possible ncRNA associated with these diapause regulated genes has also been isolated, indicating another layer of complexity in the regulation of diapause.

Development, evolution and function of a highly conserved insect stretch receptor

Paper not available at time of production

Extremely female-biased sex ratios in a parasitoid wasp, *Melittobia australica* (Eulophidae), in relation to emergence pattern and lethal male combat

J Abe, Y Kamimura, M Shimada
"Department of Systems Sciences (Biology), University of Tokyo, Meguro, Tokyo 153-8902, Japan, abej@dolphin.c.u-tokyo.ac.jp"

The parasitoid wasp *Melittobia australica* mates on their hosts. Sex ratio is predicted to follow local mate competition (LMC) theory. Notwithstanding that LMC models predict the sex ratio will increase from female-biased toward a 1:1 ratio with increasing numbers of foundresses, the observed female-biased sex ratios (about 2% males) hardly increased in response to an increased number of foundresses. In this paper, we report sex ratios of two foundresses who sequentially parasitized the same host. We distinguished them individually using microsatellite DNA marker. The offspring sex ratios of both were extremely female-biased (first foundress, 1.1%; second foundress, 2.7%). Emergence period of offspring produced by the two foundresses were widely overlapped each other and their sons intermittently emerged during a prolonged period at constantly low late. In addition, an arena combat experiment showed later emerging males were killed by former ones even when they were brothers. These results suggest that each foundress should produce small number of male eggs at some intervals in order to prevent from producing wasting males that were to be killed by lethal male-male combat. This combat may be one of factors that explain the extremely female-biased sex ratio even with increasing foundresses in this species.

Reversal of the left/right-asymmetry in male genitala: a non-rare modification in Asian sericine chafers (Coleoptera: Scarabaeidae: Sericini)

D Ahrens
"Deutsches Entomologisches Institut (DEI) im ZALF, Eberswalder Str. 84, D-15374 Müncheberg, Germany, ahrens.dirk_col@gmx.de; dahrens@zalf.de"

The examination of genital morphology is widely accepted as a principal diagnostic feature for species' identification in most insect groups. During an extensive amount of examinations of aedeagi among sericine beetles (Coleoptera: Scarabaeidae) it was noticed that the reversal of left/right-asymmetry in male ectodermal genitalia, a phenomenon rarely reported from insects in literature, seems to cumulate within this group. Among several hundreds of species with tens of thousands of specimens examined, so far from Asia only, seven species showed a left/right asymmetry reversal. The modified structures were parameres and phallobasis, only, showing the mirror imagine from the original state. The portion of reversal reported range from 0.003 to 0.5 percent of the studied male individuals. Since in the modified specimens, neither the asymmetric mandibles nor the asymmetric sutural junction of elytra were affected by any modification of normal left/right asymmetry, it should be supposed that the reversal is gained during abdominal segmentation.

Self regulation of the sun collector efficiency of *Archeoprepona menander* (Charaxinae – Lepidoptera)

S Berthier
Laboratoire d'Optique des Solides; berthier@ccr.jussieu.fr

In butterflies favouring direct absorption of solar energy through their wings, The absorption by the black areas situated at the wing bases provide the body with the most part of the exogenous energy. Absorption is very high over the whole solar spectrum (a ~ 0.98). This absorption ids due to both the dendritic structure of the scales and the melanin pigments. In the infrared range, the absorptivity reveals two strong peaks at 3µm and 6µm, then remains more or less constant at a relatively high value (~0.4) up to 50 µm. This situation contains the outline for a remarkable self regulation phenomenon of the radiative balance, allowing the stabilization of temperature in the survival area of the butterfly. The first absorption peak, centered on 3 mm, i.e. between the solar radiance and the thermal emission spectra, is not involved in the radiative balance at these temperatures. However, the second one on the edge of the emission spectrum, plays a key role as a thermal regulator. Its marginal situation is such that according to the wing temperature, it overlaps or not the emission spectrum, modifying the collector efficiency, and thus its temperature.

Characterisation of a Type IV secretion system identified from the insect endosymbiont *Wolbachia pipientis.*

J Brownlie, B Cass, S O'Neill
University of Queensland, St Lucia, QLD, 4073, Australia. j.brownlie@uq.edu.au

Wolbachia is a reproductive parasite of as many as 70% of all known insect species, and imposes a range of effects upon the host including parthenogenesis, cytoplasmic incompatibility and selective male killing. Little is known about the molecular events that impose these effects. Using the recently completed genome sequence of *Wolbachia pipientis*, 12 ORFs were identified, on the basis of sequence homology and synteny, as putative Type IV secretion system genes. Type IV secretion systems are known to facilitate the export of bacterial effector molecules, protein or DNA, into a host environment to establish a favourable environment in which the bacterium may reside. Such systems are utilised by plant biotechnologists for the genetic transformation of plants using *Agrobacterium* and are responsible for the secretion of toxins from a range of medically important pathogens. We are interested to know if the putative *Wolbachia* Type IV secretion system is responsible for delivering effector molecules into host insect environment and thereby inducing the observed host effects. We provide here evidence that these ORFs are expressed in *Wolbachia* and discuss what *Wolbachia* proteins interact with components of the putative secretion system identified from our initial yeast-two hybrid experiments.

Number of sexual alleles in two Amazonian *Melipona* bee population

GA Carvalho, DC Freire, CG Nunes-Silva, AC da Silva
Av. André Araújo 2936, Petrópolis, CEP69083-0001, Manaus, AM,Brazil. gislene@inpa.gov.br

Sex determination in stingless bees (Hymenoptera, Meliponini) involves the multi-allelic gene *xo* or *csd* (Complementary Sex Determine) locus. Diploid females are heterozygous for the sex locus, whereas males are haploid and arise from unfertilized eggs. To count and monitor the number of *xo* alleles is a practical method to detect inbreeding and the consequence of arising diploid males, in a limited population. This work was carried out on a meliponary located in Manacapuru, State of Amazonas, Brazil, were we monitored 33 *Melipona seminigra* and 202 *Melipona compressipes* colonies in a period of two years. In order to verify the female and male segregation we follow the methodology used by Carvalho (2001) obtaining the first brood cells disc from a young fertilized queen. The results show 16 alleles in both species indicating that the introduction of new fisogastric queens and the proximity to the native nests located in the near forest fragments serves to keep the sexual alleles variability and guarantees the colonies survival and artificial multiplications, and according to the proposle by Carvalho *et al.* (1995), it does help *Melipona* beekeepers maintain the variability of their colonies.

The evolution of new sex chromosomes of *Drosophila albomicans*

T-P Chang, H Chang
Department of Entomology, National Taiwan University, 106, Taipei timasius@mail2000.com.tw

The neo-X(3), neo-Y(3) arms of *Drosophila albomicans* and the 3rd autosome of *D. nasuta* are homologous. The former two are newly formed sex chromosome arms through fusion during speciation of *D. albomicans* about 500,000 years ago, and the last one remains to be an autosome in its sibling species *D. nasuta*. For the lack of recombination in male *Drosophila*, the neo-Y(3) is expected to accumulate deleterious mutations and degenerate. On the contrary, the neo-X(3) suffers higher selection force when presents in a male. Comparing homologous sequences from these chromosomes can be informative. Based on some pilot studies I did in the previous year, I've found the best way to approach this aim. A cDNA library of *D. nasuta* and the male genomic library of *D. albomicans* will be constructed. About 50 cDNA clones will be mapped by *in situ* hybridization on the salivary gland polytene chromosomes. A few important clones located on this particular part of the genome will be chosen. The corresponding genomic clones will be sequenced, and proper primers will be designed accordingly. By properly designed mating procedure, flies with homologous chromosome can be generated, and used for PCR-sequencing. Then, homologous sequences from the three groups of chromosomes will be obtained for comparison. Theoretical hypotheses about evolution rate, polymorphism, *etc.* will be proposed and tested.

Rapid cold hardening tactics in Antarctic arthropods

P Convey, MR Worland
British Antarctic Survey, NERC, High Cross, Madingley Road, Cambridge CB3 0ET, UK

Collembola and Acari form the large majority of Antarctic terrestrial arthropods. They are predominantly freeze avoiding and survive low winter temperatures by supercooling. In the summer, animals which are active and feeding run the risk of low levels of cold tolerance. Seasonally, most species are known to stop feeding and cold-harden prior to winter. However, a particular problem exists in summer habitats which are chronically close to 0ºC, as surface temperatures can approach the freezing boundary rapidly, leaving feeding animals vulnerable to freezing, while not providing sufficient cue to allow the activation of seasonal hardening tactics. Species such as the common Antarctic springtail, *Cryptopygus antarcticus*, have developed the ability to rapidly enhance cold-hardening over a period of hours, leading to a reduction in freezing point from c. -5 to below -25°C. This strategy allows individuals to take maximum advantage of any short warm spells for feeding and activity, thereby contributing to the remarkable abundance seen in some Antarctic terrestrial habitats, and the speed of response of the species to local climate change. We present data quantifying the rate of the cold hardening response and the environmental factors which initiate it, and provide an initial comparison with the tactics used by other polar species from habitats with different thermal characteristics.

Diversity and chromosome distribution of retroposons in *Anopheles gambiae*

AL Collinson, MR Pancholi, JL Crainey, CA Malcolm
School of Biological Sciences, Queen Mary, University of London, Mile End Road, London E1 4NS, UK; a.l.collinson@qmul.ac.uk

Mosquitoes are the first species group to demonstrate high diversity of retroposons. A detailed analysis of retroposons in the *Anopheles gambiae* genome identified 9 distinct clades. CR1 was the most diverse clade with 36 distinct families. In contrast RTE contained only two, but very large, families. Further analysis examined chromosomal distribution of the different types of elements to determine if insertion sites were a factor in determining inter-family or inter-clade differences. For example, the rDNA specific insertions observed with R1 elements, or co-amplification with tandem arrays of repetitive DNA observed with Juan elements. The distribution of all retroposons was shown to be non-random, but no specific inter-family or inter-clade trends were observed. High densities of retroposons were found in the sub-telomeric and gene poor regions of the chromosomes. Detailed analysis of retroposon dense and poor regions is in progress. Also, the retroposon distribution is being compared to other repetitive DNA distributions. For example, chromosome maps of all microsatellites have been constructed using “MSFind”, a program written to identify the start and end positions of all microsatellite repeats >10 bp.

Retroposon diversity and chromosome distribution in insects

AL Collinson, MR Pancholi, JL Crainey, CA Malcolm
School of Biological Sciences, Queen Mary, University of London, Mile End Road, London E1 4NS, UK; a.l.collinson@qmul.ac.uk

Mosquitoes are the first species group to demonstrate high diversity of retroposons. A detailed analysis of retroposons in the *Anopheles gambiae* genome identified 9 distinct clades. CR1 was the most diverse clade with 36 distinct families. In contrast RTE contained only two, but very large, families. Aspects of polymorphism in the grasshopper *Orphulella punctata* (DeGeer) in Jamaica

JE Dixon
"Department of Life Sciences, Faculty of Pure and Applied Sciences, University of the West Indies, Mona, Jamaica; jud_dixon@yahoo.com"

Polymorphism describes a population with two or more forms of a species existing at the same time, yet the rarest occurs at a greater frequency than that which can be maintained only by recurrent mutation. The geneticist, E. B. Ford, was among the first to describe polymorphism in the 1940s. Colour pattern polymorphism is common in acridid grasshoppers and has been studied in several temperate species. In the Jamaican grasshopper, *Orphulella punctata* (DeGeer), it is seen as a green-brown variation overlaid with patterns. A detailed classification of this polymorphic system revealed three colour morphs and ten patterns occurring in various combinations. Sampling in different rainfall zones showed a significantly higher frequency of green forms in wetter areas. Green and green-brown females are also significantly larger than brown females. Colour therefore, either plays a role in fitness, or has coevolved with size. Breeding experiments to analyse the genome structure, especially gene linkages, are in progress. Analysis of randomly polymorphic DNA is also being done to discover the relatedness of these forms, and give insight into their evolution. The aim is to understand the main factors keeping polymorphism stable within the disturbed habitats in which this species live.

Wing shape differences between migrant and resident monarch butterflies, *Danaus plexippus* (L), in Cuba

C Dockx
University of Leiden. Institute of Biology. P.O.Box 9516. 2300 RA Leiden. The Netherlands; cristinadockx@yahoo.com

The majority of migrant monarchs from eastern United States and southeast Canada migrate to Mexico, however, some of them migrate to Cuba and possibly to other areas of the Caribbean. Cuban migrants hatch in the southwest of Canada and eastern United States, and then engage in a southern trip of 4000 km to this Caribbean island. In Cuba, these migrants encounter the resident monarchs, which do not migrate and instead move between plant patches looking for nectar, mating partners, and host plants. Resident monarchs fly short distances and close to the vegetation, in contrast, migrant monarchs fly very long distances at high elevations. I explored whether flight behavioral differences between migrant and resident monarch in Cuba are associated with differences wing shape. To test if migrant and resident monarchs differ in wing shape, monarchs were collected for four years in Cuba. Fourier analyses was used to quantify wing shape differences between these two populations, as well as wing angular measurements. Results show that migrant and resident females differ in their wing shape. Female migrant monarchs have more elongated wings to reduce turbulence and drag during their long migration south and to enhance gliding. Cuban migrant monarchs are not an homogenous group in terms of their wing shape, either.

Sexual dimorphism and sexual selection in a highly dimorphic orb-weaving spider

MW Foellmer, DJ Fairbairn
Department of Biology, University of California, Riverside, CA, 92521-0427, USA, daphne.fairbairn@ucr.edu

Spiders (Araneae) are the only free-living terrestrial taxon where extreme female-biased sexual size dimorphism is common. Current hypotheses for the adaptive significance small size ("dwarfism") in male spiders predict a small male advantage during mate search or during mating with cannibalistic females, or assume that sexual selection for large size due to interference competition is weak. Here, we examine selection on adult males of the highly dimorphic orb-weaving spider *Argiope aurantia*, using a multivariate approach to distinguish selection targeting different body components. Our results show that selection tends to favour longer legs during mate search. This is consistent with the pattern of sexual dimorphism in shape, and also results in net selection for larger males. Large male size is also favoured during interference competition over access to moulting females, the most common mating situation for males. Males that mate with mature, post-moult females face an 80% chance of a cannibalistic attack, but this does not result in selection on male body size. Thus, we find no support for any of the current small-male advantage hypotheses. In spite of extreme female-biased size dimorphism, net selection on adult male *A. aurantia* tends to favour larger rather than smaller males.

Life cycle synchronization of *Chrysolina aurichalcea* (Mannerheim) (Coleoptera: Chrysomelidae) to host phenology of *Artemisia princes*, with special reference to temperature and photoperiodic responses of egg diapause.

S Fujiyama, UK Aryal
Department of Biology, Faculty of Science, Shinshu University, Matsumoto 8621 Japan; sfujiya@gipac.shinshu-u.ac.jp

C. aurichalcea has a univoltine life cycle with commonly two diapause periods of egg and adult. It is a very common insect and is widely distributed in the Japanese islands. Eggs hatch early spring and adults emerge in early summer. Adults enter summer diapause and the breeding season begins early autumn. Eggs laid in autumn enter winter diapause. Egg hatching is synchronized to the sprout emergence of host plant, *Artemisia princes*. The emergence begins at rather cold temperature near to 0-5**°C** prior to those of other weeds. The phenology of host plant varies drastically among geographic populations, i.e. evergreen in warmer area but deciduous in winter at cooler area. We examined the effects of temperature and photoperiod on the egg period. The intensity of egg diapause collected at same date among different altitudes increased with the decrease of winter temperature. The diapause intensity of the egg from transient zone was influenced by both temperature and photoperiod of not only eggs period but also their adults. Furthermore the effect seemed to vary with the different of their maternal age. The significance of such variations to seasonal adaptations under different climatic conditions and different host plant phonologies will be discussed.

Egg guarding and second oviposition as a plastic response to egg predation in a crab spider

K Futami, S Akimoto
Department of Ecology and Systematics, Graduate School of Agriculture, Hokkaido University, Sapporo, Hokkaido, 060-8589, Japan;
futami@res.agr.hokudai.ac.jp

Females of a crab spider, *Lysiteles coronatus* guard their egg sac against other arthropods without taking food in folded leaves. This study determined the evolutionary factors of egg guarding and second oviposition by *L. coronatus* females. Egg survival was significantly lower when the mother was experimentally removed than when the mother was allowed to continue egg guarding. Predation by other arthropods is attributed to the major source of egg mortality that has led to the evolution of maternal egg guarding. Females lost about 30.2% of their weight for about a 40-day period of egg sac guarding, and they had degenerated ovaries at the termination of egg care. Such high cost of egg care would have prevented *L. coronatus* females from subsequent oviposition. However, when females were separated from their eggs and given sufficient food, they produced a second egg mass. The ability of second oviposition peaked at the midpoint of egg-guarding period and then reduced. In the field, a few females produced the second egg mass one month later than did ordinary females. Evidence available suggests that the potential of second oviposition is maintained as an adaptive plastic response to the loss of the first brood due to predation.

A toxic tale: evolution of the vertebrate toxin gene, a-latrotoxin, in black widow spiders

JE Garb, RG Gillespie, CY Hayashi
Department of Biology, University of California, Riverside, CA 92521 USA; jessicaga@ucr.edu

The venom of black widow spiders (Theridiidae: *Latrodectus*) contains multiple neurotoxic proteins, including the vertebrate neurotoxin alpha-latrotoxin (a-LTX). Though the function, structure and gene sequence of a-LTX has been thoroughly characterized in one species of the genus (*L. tredecimguttatus*), the phylogenetic distribution and evolutionary origin of the a-LTX gene is unknown. In addition to a-LTX, venom of *L. tredecimguttatus* contains insect and crustacean-specific neurotoxic proteins possessing structural motifs and sequence homology at the amino acid and nucleotide level similar to a-LTX. We hypothesize that these different toxins (expressed by a single individual) are products of a gene family whose members arose via duplication events. Here we investigated the evolution of the vertebrate specific a-LTX toxin gene by sequencing a 700 bp fragment of this gene from six *Latrodectus* species in addition to constructing an independent species phylogeny for the genus using the mitochondrial gene COI. Our data indicates that a-LTX occurs across a broad phylogenetic spectrum of *Latrodectus* species, suggesting that this gene existed in the common ancestor of the genus and that it likely occurs in closely related genera. Across the sequenced region, we observed substantial nucleotide variation, translating into amino acid differences, suggesting the gene is rapidly evolving.

Seasonal changes in glycerol content and enzyme activities in the overwintering larvae of *Ostrinia furnacalis* located in northern and southern part in Japan

M Goto, M Sakamoto, Y Shimada
997-8555 Tsuruoka 1-23, Japan; mgoto@tds1.tr.yamagata-u.ac.jp

Enzymes associated with glycogen metabolism and glycerol synthesis in larvae of *Ostrinia furnacalis* located in Shonai and Hyogo district, which are northern and southern part in Japan, respectively. The profiles of cold hardiness of natural populations of larvae of the northern and southern part of Japan, seem different. In the present study, seasonal changes in the level of glycerol, cold hardiness and enzyme activity in the overwintering larvae were investigated over the winter in 2002. Glycerol content and cold hardiness (survival rate at various treatment days under -15 °C) of the Shonai larvae were low in October, rapidly increased in November and December, peaked in January, while in Hyogo larvae, glycerol content and cold hardiness peaked in February. Glycerol accumulation was accomplished by activation of α-glycerophosphate dehydrogenase and polyol dehydrogenase with glyceraldehyde activity and inhibition of glyceraldehyde kinase in Shonai larvae.

Evolution of reproductive strategies of flour beetles (Coleoptera: Tenebrionidae)

L Arnaud, Y Brostaux
Department Of Pure And Applied Zoology, Gembloux Agricultural University, B-5030 Gembloux, Belgium; haubruge.e@fsagx.ac.be

Although, they first evolved as saprophylic insects and naturally occur under the bark of trees, in dead wood and even in the nest of some Hymenoptera, *Tribolium* flour beetles have been adapted to stored products environment since several thousands years. In this study we aimed to observe if as a secondary adaptation to this ecosystem similar reproductive strategies were adopted by these species. Intra- and inter-specific allometric relationships were examined between several reproductive traits, e.g. egg mass, adult mass, development time and fecundity, in eight *Tribolium* flour beetles. Experiments were conducted under the same conditions for every species. Univariate and multivariate statistical analysis were first performed. Common life history traits were not observed between the different species and univariate analysis highlighted strong differences between the species for most traits examined. Some species presenting reproductive traits allowing an efficient development in the environment of stored products are likely to have occur in this ecosystem for longer periods than the others. A phylogeny of these species was established on DNA sequences of mitochondrial 16S rRNA gene. With this informative framework, the evolutionary pattern of these traits was studied using an explicit model of evolution and interspecific allometric relationships were examined, after controlling for phylogenetic independence.

Mechanisms of rapid cold hardening in *Drosophila melanogaster* - Are rapid changes in membrane phospholipids the explanation?

M Holmstrup, J Overgaard, SO Petersen, V Loeschcke, JG Sørensen
National Environmental Research Institute, Department of Terrestrial Ecology, Vejlsøvej 25, P.O. Box 314, DK-8600 Silkeborg, Denmark;
martin.holmstrup@dmu.dk

Low temperature mortality is not always associated with freezing in insects. In many insects it may also occur at temperatures above the freezing point of the hemolymph. Reasons for this chilling injury could be irreversible phase transitions of membranes or protein denaturation at low temperature. Rapid cold hardening (RCH) is a phenomenon in which insects achieve increased tolerance of low temperature during a brief (minutes to hours) exposure to low, but sublethal temperatures. So far, RCH has been shown in several insect species including *Drosophila melanogaster* but no convincing physiological explanation of the RCH mechanism has been shown. In a series of experiments we have studied the membrane phospholipid composition in *D. melanogaster* when exposed to a cooling regime increasing the chill tolerance by RCH. Flies cooled from 25°C to 5°C at 0.1°C h^{-1} displayed a shift in the C16 and C18 fatty acids towards a higher degree of unsaturation. The results indicated that these changes were probably not caused by new synthesis of membrane phospholipids but rather on modifications of existing fatty acids. The same material was analysed for Hsp70 levels, but RCH induced no increase in this stress response. In conclusion, even though the observed shifts in membrane phospholipid unsaturation degree were small, they are likely to have contributed to the rapid cold hardening in *D. melanogaster*.

Evolutionary trade-offs between reproduction and dispersal in populations at expanding range boundaries

CL Hughes, JK Hill, C Dytham
C.L. Hughes, Department of Biology (Area 3), University of York, Heslington, York, YO10 5YW,UK; clh121@york.ac.uk

During recent climate warming, some species have expanded their ranges northwards to keep track of climate changes. Evolutionary changes in dispersal have been demonstrated in these expanding populations and here we show that increased dispersal is associated with reduced investment in reproduction in populations of the speckled wood butterfly, *Pararge aegeri*a. Evolutionary changes in flight versus reproduction will affect the pattern and rate of expansion at range boundaries in the future, and understanding these responses will be crucial for predicting the distribution of species in the future as climates continue to warm.

Bacterium in the *Cytophaga-Flavobacterium-Bacteroides* phylum causes cytoplasmic incompatibility in spider mites

S Ito, H Noda, T Gotoh
Laboratory of Applied Entomology and Zoology, Faculty of Agriculture, Ibaraki University, Ami, Ibaraki 300-0393, Japan; gotoh@mx.ibaraki.ac.jp

Cytoplasmic incompatibility caused by *Wolbachia*, is widely observed in insects and mites. *Wolbachia* are also causative agents of parthenogenesis, feminization and male-killing. Recently, bacteria in the phylum *Cytophaga-Flavobacterium-Bacteroides* (CFB) have been reported to cause reproductive alteration in their hosts: parthenogenesis in parasitoid wasps (Zchori-Fein et al., 2001), feminization in false spider mites (Weeks et al., 2001), and cytoplasmic incompatibility in parasitoid wasps (Hunter et al., 2003). This group of bacteria is also called CLO (*Cytophaga*-like organisms) and is recently named as *Candidatus* Cardinium hertigii (Zchori-Fein et al., 2004). Our study aims to clarify whether CFB bacteria cause cytoplasmic incompatibility in spider mites. 16S rDNA sequencing data disclosed that CFB bacteria infect the spider mite, *Eotetranychus suginamensis*, *Oligonychus ilicis*, *Amphitetranychus quercivorus* and *Tetranychus pueraricola*. The CFB bacteria in the spider mites form a monophyletic group with those in the parasitoid wasps and the false spider mites. Crossing experiments between CFB-infected and uninfected colonies left reproduction unaltered in *O. ilicis*, *A. querciborus* and *T. pueraricola,* whereas in *E. suginamensis*, eggs hatchability and percentage daughters in the crosses between uninfected females and infected males were significantly lower than those in the reciprocal crosses. Therefore, CFB bacteria in *E. suginamensis* were related to the induction of cytoplasmic incompatibility.

Distribution and function of ankyrin domain proteins in the insect endosymbiont *Wolbachia pipientis*.

I Iturbe-Ormaetxe, G Burke, M Riegler, SL O'Neill
Department of Zoology and Entomology, School of Life Sciences. The University of Queensland, St. Lucia, QLD 4072, Brisbane, Australia;
inaki@sols.uq.edu.au

The endosymbiotic bacteria *Wolbachia pipientis* infects a wide range of arthropods and filarial nematodes inducing a variety of phenotypes including parthenogenesis, male killing, feminization and cytoplasmic incompatibility. The recent annotation and sequencing of the first *Wolbachia* genome is providing new insights into the molecular mechanisms used by this symbiont to infect and manipulate their eukaryotic hosts. One of the main features of *Wolbachia*'s genome is the presence of an unusually high number of proteins containing ankyrin repeats. These domains are typically involved in protein-protein interactions and they have never been found before in such numbers in any prokaryote genome. In this work we have determined the distribution and expression of the different ankyrin repeat genes found in the sequenced *Wolbachia w*Mel genome in various *Wolbachia* strains that induce different effects in their hosts. We found correlation between the distribution of some ankyrin domain proteins and the induction of cytoplasmic incompatibility. Some non-CI inducing strains showed a deletion of 22 kb surrounding one of the ankyrin domain genes. This deletion affects 13 ORFs and is probably the result of a transposition event. The possible role of ankyrin domain proteins and their interaction with host proteins is also discussed.

Cuticular lipids of the tsetse fly, *Glossina pallidipes*

R Jurenka, JS Terblanche, C Jaco Klok, SL Chown, E Krafsur
Iowa State University, Department of Entomology, 3222 Science II, Ames, IA, 50011, U.S.A.; rjurenka@iastate.edu

Cuticular lipids play a critical role in preventing desiccation and in chemical communication. This poster will present data indicating that cuticular lipid mass may not be directly correlated with rates of water loss in laboratory-reared and wild-caught tsetse flies. This is in agreement with previous research conducted by others using *Drosophila melanogaster*. We did find correlation with various protocols indicating a treatment effect. We will present the identification of the major cuticular lipids of which hydrocarbons make up a relatively small amount. Hydrocarbons are thus probably more important in chemical communication. However, we will compare hydrocarbon profiles between laboratory-reared and populations of wild-caught flies at several localities. Cuticular lipid amounts will also be compared amongst flies at several localities in Africa..

Development of microsatellite markers for molecular genetic analysis of *Tribolium castaneum* populations in a flour mill.

ZF Doyungan, S Kambhampati, SRW Beeman, JF Campbell
Department of Entomology, Kansas State University, Manhattan KS 66506, USA; srini@ ksu.edu

The red flour beetle, *Tribolium castaneum*, is a major pest of flour mills. Molecular genetics is a potentially useful tool to address questions about *T. castaneum* population structure, sources of infestation and mechanisms of population rebound after treatment. Beetles for DNA fingerprint analysis were collected in live traps, over the course of several years and from multiple locations within a commercial flour mill. As potential molecular markers, microsatellite regions with polymorphic di- and tri-nucleotide repeat motifs were identified from the literature, BAC-end sequence libraries, and initial data from the genome sequencing project. Polymorphism in these microsatellite markers is being analyzed among individual beetles collected over a range of spatial and temporal scales. To date, at least six polymorphic marker regions have been identified that are detectable on PAGE gels. A hyper-variable region of nuclear DNA was also identified that showed sequence variation among beetles collected within the same mill. These markers will be used to evaluate the amount of gene flow among different subpopulations within a mill and among different mills and grain storage and processing facilities.

Microsatellite markers for the population genetic study of the Indian meal moth, *Plodia interpunctella.*

T Grace, S Kambhampati, B Subramanyam.
123 Waters Hall, Dept. of Entomology, Kansas State University, Manhattan, KS-66506, USA; srini@ksu.edu.

The Indian meal moth, *Plodia interpunctella* Hübner, is a serious and widespread pest of stored food commodities throughout the world. The moth is resistant to most of the insecticides used to control it. Proper understanding of the breeding structure, migration, gene flow, and movement of resistant alleles has great implications for management of this pest. Therefore, we have initiated an investigation of the population genetics of Indian meal moth worldwide. As a first step, we developed twelve polymorphic microsatellite markers from genomic DNA enriched for microsatellite loci. Analysis of populations using these loci can give an insight into the population structure, dispersal, genetic relationship and extent of gene flow among the sub populations studied. These markers are an invaluable tool for population genetic studies of Indian meal moth and can be used in DNA fingerprinting for population level identification of this pest.

The mechanism for transmission acquisition of gut symbiotic bacteria in the broad-headed bug *Riptortus clavatus*

Y Kikuchi, T Fukatsu
Institute for Biological Resources and Functions, National Institute of Advanced Industrial Science and Technology (AIST) Tsukuba Central 6, 1-1-1 Higashi, Tsukuba, Ibaraki 305-8566, Japan; y-kikuchi@aist.go.jp

Almost all stinkbugs that feed exclusively on plant juice possess symbiotic bacteria in their midgut. Mechanisms for vertical transmission of the symbiont are impressively diverse among stinkbugs, including egg smearing, ovarial infection, proctophagy, etc. Here we report the discovery of a novel mechanism for transmission and acquisition of the symbiont in the Japanese broad-headed bug *Riptortus clavatus*. *R. clavatus* harbors *Burkholderia* sp. (Proteobacteria; beta-subdivision) as midgut symbiont. However, scanning electron microscopy and diagnostic PCR failed to detect the symbiotic *Burkholderia* from the eggs. Even when juveniles were reared with infected adults in small clean chambers, they did not acquire the symbiont, excluding the involvement of proctophagy. Notably, the symbiotic *Burkholderia* was frequently detected from rhizosphere of the soybean, the main host plant of *R. clavatus*. When hatchlings of *R. clavatus* were reared on potted soybean plants, surprisingly, almost all insects acquired the symbiont. These results strongly suggest that the stinkbug acquires the symbiont not through vertical transmission but from the environment every generation.

Structural analysis of BAC clones containing *Bmper*, *Bmclock*, *T15.180a* and *Rcf96* on the Z chromosome in *Bombyx mori*

Y Koike 1, T Shimada 1, MG Suzuki 2, K. Mita 3
Dept. of Agric. Environ. Biol., Univ. of Tokyo; 2. Riken; 3. Natl. Inst. Agrobiol. Sci., Japan; ykoikeinimcj@yahoo.co.jp

The sex chromosome constitution of the silkworm, *Bombyx mori*, is ZW in the female and ZZ in the male. Until now, the nucleotide sequence of the Z chromosome we determined came up to 1.1 Mb approximately. Construction of a 320-kb BAC contig around the *Bmkettin* gene on the Z chromosome in *Bombyx mori* and determination its nucleotide sequence by the shotgun method were already published. Furthermore, we constructed and determined sequence of a 270-kb BAC contig around the *Rcf96* gene. The nucleotide sequence of three BAC clones, *Bmper*, *Bmclock* and *T15.180a* are about 170-kb each other, were determined in addition, and found 8 novel protein-coding sequences. Analysis of a BAC clone containing *Bmclock* is in progress. All the transposable elements detected in the region were truncated, and no LTR retrotransposons were found, in stark contrast to the situation on the W chromosome. Real-time RT-PCR experiments demonstrated that transcripts of some Z-linked genes were accumulated in larger amounts in males than in female moths. On the other side, transcripts of some genes show larger amounts in females than in male moths, conversely. Consequently, dosage compensation of Z-linked genes was not showed at least in the analyzed region.

Bidirectional cytoplasmic incompatibility with asymmetric partial cross rescue caused by two *Wolbachia* strains in the adzuki bean beetle, *Callosobruchus chinensis*

N Kondo, M Shimada, T Fukatsu
Institute for Biological Resources and Functions, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba 305-8566, Japan; n-kondo@aist.go.jp

Rickettsia-like endosymbiotic bacteria of the genus *Wolbachia* are found in various arthropods. *Wolbachia* endosymbionts are known to induce a phenotype called cytoplasmic incompatibility (CI), one of the selfish strategies of *Wolbachia* to increase their infection frequency in host populations, where crosses between infected males and uninfected females result in lower hatch rates than the reciprocal crosses. We found that the adzuki bean beetle, *Callosobruchus chinensis*, is co-infected with two *Wolbachia* strains, wBruCon (C) and wBruOri (O). To examine whether C and O induce CI or not, mating experiments were performed among four host strains with different infection types: double infection (CO), single infections (C or O) and uninfection (U). C infection and O infection caused strong CI with hatch rates at 0% and 3.3% in incompatible crosses, respectively, while compatible crosses showed 82-92% hatch rates. Notably, while crosses between O females and C males produced no hatched eggs, crosses between C females and O males resulted in 45% hatch. These results could be explained by assuming that C can partially rescue the modification of O. CO females were compatible with males of all infection types, which agreed with the prevalence of CO infection in natural populations.

PCR detection for strand breaks of irradiated plasmid DNA is applied for structural analysis of rDNA cluster including retrotransposons

H Maekawa, M Oikawa, E Yamauchi, H Fujimoto, R Watanabe, K Saito, K Tsuchida, N Takada, M Nakagaki, M Kobayashi, Y Nakajima
National Inst. Infect. Diseases, Tokyo 162-8640, Japan; hidemae@nih.go.jp

"We verified that single strand breaks (SSBs) occurred by gamma ray irradiation were detected by polymerase chain reaction (PCR) method. The frequency of SSBs occurred on both strands of a plasmid DNA region flanked by a pair of primers used for PCR amplifications was calculated by Monte Carlo simulation. The practical data using the PCR reaction with linear shaped pBR322 plasmids irradiated by ^{137}Cs with a Tris-HCl buffer as a radical scavenger, could be almost coincident with patterns on the value, p=0.2, calculated as the case for open circular (OC) plasmids. At the case using closed circular (CC) and OC mixed solution, over 100% values for the non-irradiated mixed solution were observed on low dose condition around 30Gy. This phenomenon was simulated by simple differential equation with possible explanation that CC shape could be very difficult to be amplified by PCR. It is demonstrated that this PCR method using scavengers could also detect a highly complicated DNA structure in water solution. This method should be applied to determination of SSBs frequency for rDNA cluster region including retrotransposons of *Bombyx mori* genomic DNA. We will show the data from the PCR amplification for irradiated genomic DNAs.
"

A preliminary molecular phylogenetic investigation of the genera closely related to *Chironomus* Meigen (Diptera: Chironomidae)

J Martin, A Blinov, V Guryev, K Hirabayashi
Genetics Department, University of Melbourne, VIC 3010, Australia; j.martin@unimelb.edu.au

There is considerable uncertainty regarding the true systematic relationships of the genera *Chironomus* Meigen, *Kiefferulus* Goetgh., *Nilodorum* Kieffer, *Einfeldia* Kieffer, *Goeldichironomus* Fittkau. of the Tribe Chironomini of the Chironomidae. Several alternative placements have been suggested by different authors. We have used sequence from the mitochondrial (mt) Cox1 and CytB genes and the nuclear 18S-rDNA (18S) gene, to determine the molecular relationships shown by some members of these genera. The different mutation rates between the mt and the nuclear genes mean that they resolve different levels of the phylogenetic trees: Mt sequences resolve relationships at the tips of the branches, while 18S sequences resolve the deeper branches of the trees. By using both data sets we can obtain a better evaluation of the overall relationships within and between genera. These preliminary results support the inclusion of *Nilodorum* in the genus *Kiefferulus,* as well as the placement of *Kiefferulus* as sister genus to *Chironomus.* They further suggest that *Einfeldia dissidens* Walker is close to *Chironomus*, but distinct from *C. javanus* Kieffer, which was at one time considered to bean *Einfeldia* species, but which clusters here within *Chironomus,* as is more generally assumed.

The delay of mating time through long term mass-rearing in the melon fly, *Bactrocera cucurbitae* (Coquillett)

T Matsuyama, H Kuba
Okinawa Prefectural Agricultural Experiment Station, 4-222, Sakiyama-cho, Naha, Okinawa 903-0814, Japan; matsuymt@pref.okinawa.jp

The eradication of the melon fly, *Bactrocera cucurbitae* (Coquillett) from Okinawa Japan using the Sterile Insect Technique (SIT) was achieved in 1993. In the eradication program, three different mass-reared strains, named K strain, M strain and OY strain, were used for control in Kume Island, Miyako Islands and Okinawa/Yaeyama Islands, respectively. To prevent re-colonization by alien flies, OY strain is still culturing continuously and being released in the Ryukyu Islands. This strain has been reared for ca. 150 generations under artificial conditions. So we concern for loss of control efficiency in SIT because of the flies being domesticated. Herein, we compared the temporal changes of the mating behavior between Taiwan wild and OY strains of melon fly in order to examine whether the differences of the mating traits exist between them or not. Moreover, in order to estimate the changes of mating traits through the long term rearing, we also compared them between OY strain and K strain which has been reared continuously in small-scale for ca. 215 generations. We present the results of these tests and consider the serious changes which may occur through the long term mass-rearing.

Comparison of life history characters of arrhenotokous and *Wolbachia*-associated thelytokous *Trichogramma kaykai* Pinto & Stouthamer (Hymenoptera: Trichogrammatidae)

K Miura, Y Tagami
6-12-1 Nishifukatsu, Fukuyama 721-8514, Japan; miurak@affrc.go.jp

We analyzed the life history characters related to rate of potential population growth for two genetically identical lines of *Trichogramma kaykai* Pinto and Stouthamer. These lines differed in that one was infected with parthenogenesis-inducing *Wolbachia* (W^+), while the other was free of *Wolbachia* (W^-) through antibiotic treatment. For both lines the number of females emerging per day was the highest from eggs laid during the first two days of oviposition. Although adult longevity in W^- was shorter than that in W^+, number of eggs reaching the prepupal stage, adult emergence, and female emergence were significantly higher for W^- than for W^+. There were no significant differences in the number of mature ovarian eggs at emergence between W^- and W^+. The values of mean length of generation (T) in W^+ was similar to that in W^-, but the values of net reproduction rate (R_0) and intrinsic rate of natural increase (r_m) in W^+ were lower than those in W^-. In most field populations, the W^+ individuals form a small percentage (<5%) of the total population. The relative low growth rate caused by the *Wolbachia* infection may contribute to this low prevalence of the infection. Because differences in the relative population growth rates would soon result in the extinction of the infected population in the field, other factors must play a role allowing the infection to maintain itself in the field.

Expressed sequence tag (EST) approach to understand the host role in aphid bacteriocyte symbiosis

A Nakabachi, S Shigenobu, N Sakazume, T Shiraki, Y Hayashizaki, P Carninci, H Ishikawa, T Kudo, T Fukatsu
Environmental Molecular Biology Lab., Riken, Hirosawa 2-1, Wako, Saitama 351-0198, Japan; bachi@postman.riken.jp

Almost all aphid species (Homoptera, Aphididae) have bacteriocytes that are specifically differentiated to contain endocellular symbiotic bacteria of the genus *Buchnera*. Since the initial infection (150-250 million years ago), *Buchnera* have been vertically transmitted to eggs and embryos through host generations, and the mutualism between the host and *Buchnera* is so obligate that neither can reproduce independently. Complete genome sequencing of *Buchnera* from the pea aphid, *Acyrthosiphon pisum*, revealed that the genome is so small (640,681-bp chromosome and two small plasmids) that it lacks many genes that appear to be essential to bacterial function, whereas it retains genes for the biosyntheses of nutrients that are required by the host aphid. Our main focus is on the host's role in maintaining this symbiotic system. In an effort to understand this, we constructed a cDNA library of the host bacteriocyte using Cap-trapper method, and are performing expressed sequence tag (EST) analyses. So far, we have sequenced approximately 3,000 clones, among which BLAST similarity searches and subsequent real-time quantitative RT-PCR analyses detected a number of candidate gene products that may be essential to the symbiotic system.

Wolbachia infection and mt-DNA of the pierid butterfly, *Eurema hecabe*

S Narita, M Nomura, Y Kato
Fac. of Horticulture, Chiba University, Japan; narita3105@graduate.chiba-u.jp

Eurema hecabe (L.) thrives in the Oriental tropics as well as the subtropical to temperate zones. In Japan, the population in the subtropical southwestern islands differs from that in the temperate mainland in terms of the seasonal form of adult wing color pattern expression and larval food habits. We analyzed allozyme variation in populations from the mainland and the southwestern islands. Zymograms and allele frequencies differed between the two populations. Allozyme data of individuals with yellow fringe color of the forewing (yellow type) were also different from those of brown butterflies distributed sympatrically in Okinawa Island. In the present study, we used the DNA sequence data of the mitochondrial ND5 gene to clarify the phylogenetic relationship between the two types of *E. hecabe* Recently, it was reported that *Wolbachia* – a kind of rickettsia– could infect the cytoplasm of *E. hecabe.* We examined all individuals using molecular phylogenetic methods to determine infection with *Wolbachia.* It is surprising that of the two separate groups in the phylogenetic tree, one group consisted of *Wolbachia*-infected individuals and the other consisted of non-infected ones. It is therefore suggested that the mtDNA of *E. hecabe* is not a useful tool for molecular phylogenetic analyses.

Molecular cloning and expression analysis of the Bmfru gene, the *Bombyx* homologue of the *Drosophila* sex determination gene *fruitless*

F Ohbayashi, H Sotoshiro , K Mita , T Shimada
Department of Agricultural and Environmental Biology, University of Tokyo, Yayoi 1-1-1, Bunkyo-ku, 113-8657 Tokyo, Japan; toru@ss.ab.a.u-tokyo.ac.jp

The *Drosophila fruitless* (*fru*) gene has a key role in the sex determining cascade. The *fru* regulates male sexual behavior and motorneuron-dependent formation of the male specific abdominal muscle of Lowrence (MOL) through its functioning in the nervous system. We have isolated a homologue of *fru* in the *Bombyx mori*, which is referred as *Bmfru*. Four types of cDNA clones were isolated from cDNA libraries. All of these transcripts encodes proteins related to the BTB-ZF protein family. The BTB domain of *Bmfru* showed 91% of identity with that of *D. melanogaster*. Three of four BmFRU isoforms have variations in their carboxy terminus in which zinc finger motifs are contained. The *Bmfru* mRNAs are mainly expressed in gonads and heads of 5th inster larvae and pupae. From the results of in situ hybridization and immunohistochmical analysis, it is revealed that *Bmfru* mRNAs and proteins are expressed in gonadal epithelium, optic lobe and suboesophageal ganglion.

Mating interactions between the okra and cassava biotypes of *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae) on eggplant

BA Omondi, D Obeng-Ofori, RAK Kyerematen, EY Danquah
African Regional Postgraduate Programme in Insect Science (ARPPIS) University of Ghana, P. O. Box LG 82, Legon, Accra; omondiaman@yahoo.com

Bemisia tabaci is an important pest of field and horticultural crops worldwide. It displays wide host-spectrum, diverse types of crop damage and intraspecific variation, reported in the existence of over 20 biotypes. Genetic and biological variation within *B. tabaci* has great implications on its pest status, control and the integrity of the species as a single taxon. Reproductive isolation between biotypes has been demonstrated and perhaps illustrates the genetic relationships between biotypes, apart from influencing biotype interactions in nature. In this study, the biological consequences of mating between okra and cassava biotypes were assayed in clip cages on eggplant, by reciprocal crossing. Interbreeding had no significant influence on the fecundity of the mated females and survival of progeny (P.0.05). Female crosses were not morphologically different from purebred females ($p>0.05$), and oviposited normally. However, the sex ratio of hybrid progeny was significantly male dominated (<30 % females) compared to the pure bred progeny of each biotype. (>60% females) ($p < 0.01$). Therefore, there seems to be limited possibility of gene flow between the two biotypes on shared hosts. Still, some reproductive incompatibility exists, and perhaps buttresses ecological isolation in nature, hence maintains the genetic and biological identity of the two biotypes.

Rapid cold hardening increases aphid survival at low temperatures

SJ Powell, JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham, UK, B15 2TT; SJP822@Bham.ac.uk

Most studies on insect cold hardiness have focused on seasonal adaptations occurring within the overwintering stage of an insect's life cycle, triggered by decreasing temperature and photoperiod from summer through autumn to winter. Due to their short generation times, an aphid that enters winter is unlikely to be the same individual that survives until spring. For this reason, although aphids are able to cold harden when reared at lower temperatures (10° and 5°C), the ability to rapidly cold harden may be relatively more important than in other longer-lived overwintering insects, where seasonally-induced cold hardening is the dominant response. This study assesses the effects of sub-zero temperatures on the mortality of nymphs and adult *S. avenae*, provides evidence of rapid cold hardening in *S. avenae* and investigates the ecological costs of rapid cold hardening in terms of effects on development, longevity and fecundity. The hypothesis that rapid cold hardening can be induced during the cooling phase of natural diurnal temperature cycles is supported. Rapid cold hardening increases survival and extends the lower lethal temperature, allowing aphids to acquire maximum cold hardiness when it is most needed.

Wolbachia **replacement in global populations of** *Drosophila melanogaster*

M Riegler, M Sidhu, SL O'Neill
Department of Zoology and Entomology, School of Life Sciences, University of Queensland, St. Lucia, QLD 4072 Australia; mriegler@uq.edu.au

Wolbachia are endosymbiotic bacteria associated with a large variety of arthropod species. They are mainly inherited vertically and have successful strategies to colonise host populations by manipulating host reproduction. Recently the genome of the *Wolbachia* strain infecting *Drosophila melanogaster* has been sequenced. The small genome is unique for its large number of repetitive elements and also contains potential sites for variable number tandem repeats (VNTR). Analysis of *Wolbachia* in globally representative and historic populations of *D. melanogaster*, kept at several stock centres, revealed polymorphisms in repetitive element sites and VNTR sites, indicating the presence of two related but distinct *Wolbachia* strains in this host species. The distribution of the two strains is strongly correlated with the collection dates of the fly lines. The results strongly suggest that there has been a historic replacement of one *Wolbachia* strain by another, probably caused by different strengths of host reproductive manipulations. It is intriguing that the sweep of the present *Wolbachia* strain occurred in the period of the colonisation of the *D. melanogaster* genome by P elements.

Comparative analysis of *Anastrepha sororcula* (Diptera: Tephritidae) populations based on rDNA and karyotypes

LS Rocha, D Selivon
Institute of Biosciences, University of Sao Paulo, Brazil. Rua do Matao 277 - CEP 05508-900; linrocha@ib.usp.br

The true-fruit-fly *Anastrepha sororcula* is an important Brazilian fructicultural pest, since it attacks several commercial valuable fruits. Samples of *A. sororcula* from the Brazilian States, São Paulo (SP), Goiás (GO), Bahia (BA) and Rio Grande do Norte (RN), were submitted to a comparative study based on their karyotypes and ribosomal DNA. Mitotic metaphasic chromosomes were analysed after DAPI coloration. Number (2n=12) and sizes of chromosomes in all samples were similar, except SP sample which showed distinctive DAPI staining pattern. X chromosomes of SP sample showed a submedian interstitial and a pericentromeric DAPI+ band, whereas samples from GO, BA, RN presented only the submedian interstitial band. All populations exhibited autosomes with tiny pericentromeric DAPI+ bands and a dry chromosomes entirely heterochromatic. Differences among samples from SP, GO, BA, RN regarding rDNA were detected in Southern blots. DNA of males and females was cleaved with endonuclease *Hin*dIII and hybridised to rDNA 45S probe. The four samples were distinguished by hybridisation pattern although each sample was monomorphic. Hitherto, partial sequencing of 300 bp of 3´-end of ITS1 showed no differences among the samples. Results indicated genetic differences among geographically distant populations of *A. sororcula*, suggesting that this generalist species present low dispersion behaviour.

Value of the morphometric study in the discrimination of two species of the *flavida* complex (Hemiptera: Reduviidae).

J Rodríguez, O Fuentes.
Tropical Medicine Institute "Pedro Kourí", Autopista Novia del Mediodia, Km. 6, Arroyo Arenas, La Lisa, Ciudad Habana, Cuba; jinnay@ipk.sld.cu

The flavida complex, restricted to the Antillas, is composed of three related species: *Triatoma flavida, T. bruneri* and *T.obscura*. *T. flavida* and *T. bruneri* are species endemics from Cuba and *T. obscura* from Jamaica. The taxonomic status of *T. flavida* and *T. bruneri* has been very discussed by their similarity morfhological. We presented here, for the first time, a study morphometric comparative between these species using an discriminant analysis included and excluded size using the PADWIN program (Dujardin, 2002). We used characters of the head, thorax and wings for the analysis whrere the data were previous transformed to logarithms. The multivariate analysis showed broadly quantitative differences between both species, confirming the value of the morphometry in order to distinguish species closely related.

Phylogenetic characterization of primary symbionts associated with diverse whitefly species.

RC Rosell, H Costa, MT Coombs, P De Barro
Department of Biology, University of St Thomas, Houston TX, 77006 USA; rrosell@stthom.edu

Many insects, including whiteflies, have intracellular microorganisms that are considered symbiotic in nature. Primary endosymbiotic bacteria, housed in specialized cells of insect origin called mycetocytes or bacteriocytes, have primarily been associated with nutritional functions by providing essential nutrients to the insect. Although symbionts of whiteflies have been studied, those data focus primarily on only *Bemisia tabaci* biotypes and haplotypes. Little is known about the composition and diversity of the endosymbionts in other Aleyrodidae. We have examined over 50 different species of whiteflies by PCR amplification and subsequent sequencing of the products produced from primary symbiont 16S ribosomal DNA (rDNA) genes directly from insect tissue. Maximum parsimony analysis and congruence between the phylogeny of the symbionts and their insect hosts were examined. In addition, bacterial endosymbionts of several species were morphologically characterized to determine the relative number of organisms, the presence or absence of a cell wall, and the nature of the cell membranes. Variation in these characteristics, and diversity or abundance of organisms in the bacteriomes and bacteriocytes will be discussed.

Population variation in striped rice borer, *Chilo suppressalis* Walker (Lep.: Pyralidae) using geometric morphometrics

R Zahiri, L Salehi, A Sarafrazi F Alinia, J Hadjizadeh
Dept. of Plant Protection, Faculty of Agriculture, The Univ. of Guilan, Rasht, Iran; salehi@guilan.ac.ir

The morphological variation of a total of 311 forewings and 319 hind wings of the Striped Rice Borer collected from 6 different geographic localities in Iran were analysed using geometric morphometric techniques. 24 & 14 partial wrap scores and 2 & 2 uniform components calculated for each specimen in forewings and hind wings respectively and saved as a Weight Matrix using tpsRelw. In forewings and hindwings respectively 9 & 6 components extracted with eigenvalues greater than 1. Totally they accounted for 71.43% of variation were in forewings & 71.37% in hindwings. Amongst the 281 observations used to fit the model, 158 or 56.23% were correctly classified. Graphical options represented that the western geographical populations differ from eastern populations, also two near localities named Rasht and Anzali showed degrees of differentiation between them. Then performed DFA for hindwings and the results showed that amongst 300 observations used to fit the model, 129 or 43.8% were correctly classified. Graphical options represent the same results like forewings, also Anzali population showed very clearly separation among other populations. The results of Cluster analyses on the mean of populations and the dendrogram confirmed results.

Genetic factors affecting egg size in a migrant skipper, *Parnara guttata guttata* (Lepidoptera: Hesperiidae): genetic relation with life history traits and variation in pattern of reaction norms

T Seko, T Miyatake, N Fujioka, F Nakasuji
Postal address: National Agricultural Research Center for Western Region, 6-12-1 Nishifukatsu, Fukuyama, Hiroshima 721-8514, Japan; sekot@affrc.go.jp

Genetic factors controlling egg size were examined in the migrant skipper, *Parnara guttata guttata* to detect the genetic basis of egg size variation which is needed for a discussion of the evolution of egg size. First, phenotypic and genetic correlations and heritabilities were estimated for egg size, fecundity and body size (forewing length) under the different day-length conditions (16L8D and 14L10D at 25 ^{0}C). Second, genotype-environment interactions were estimated by comparing reaction norms to day-length of these traits among families. Negative phenotypic and genetic correlations between egg size and fecundity were estimated in both environments. High negative correlations were found between body size and egg size under 14L10D at phenotypic and genetic levels. Narrow sense heritabilities estimated by parent-offspring regression were significantly differed from zero for egg size and fecundity. These results show that egg size varies genetically and it can be affected by the genetic relation with other life history traits. Two-way ANOVAs showed significant genotype-environment interactions in egg size. The variation observed in phenotypic plasticity of egg size is discussed in relation to optimal allocation strategy for energies to produce eggs and seasonal migration strategy in *P. g. guttata*.

Occurrence of nematode inside the malpighian tubules of *Hypocryphalus mangiferae* (Coleoptera: Scolytidae).

JE Serrão, CC Rocha-Silva, AMM Viana-Bailez
Department of General Biology, Federal University of Viçosa, 36570-000 Viçosa, MG, Brazil; jeserrao@ufv.br.

Hypocryphalus mangiferae is considered the vector of the fungus *Ceratocystis fimbriata* from mango tree. As part of an ongoing study to locate the presence of a mycangium in the body of this beetle, we found the occurrence in all 50 dissected specimens of a dilated region in one Malpighian tubule containing great amounts of nematodes. In freshly dissected beetles was possible to verify the movement of nematode towards the hindgut of beetle. This structure was found in both sexes and apparently the beetles were not affected because they were feeding and reproductive as determined by histological analysis of digestive and reproductive tracts. The structure containing nematodes were always in the same Malpighian tubule, which was characterized by the flattening of its epithelium in comparison with Malpighian tubules without nematodes. We suggest a phoretic association between the nematode and the beetle. The identification of the nematode species remains to be determined.

Analysis of population structure of *Bactrothrips brevitubus* (Thysanoptera : Phlaeothripidae) using DNAmicrosatellite marker

T Shibata, BD Kranz, K Tsuchida
Laboratory of Entomology, Faculty of Agriculture, Gifu University, Yanagido 1-1, Gifu 501-1193, Japan; h4112013@guedu.cc.gifu-u.ac.jp

Bactrothrips brevitubus is haplodiploid, facultatively ovoviviparous, Japanese thrips. Females can control the sex of their offspring. Individual females can produce both sexes in a mass of eggs oviparously and only males by single eggs ovoviviparously. Sex ratios are split according to the dominant reproductive mode within a patch (Kranz et al. 2002). Local mate competition (LMC), local resource competition (LRC) for food and egg laying sties, and parasites are possible factors influencing reproductive mode. In this study, we tested for LMC by estimating relatedness in patches using microsatellite DNA. Microsatellites also permit detailed analyses of the local population structure. For primer development, we used the dual-supression-PCR technique of Lian et al. (2002). This technique is simple and effective for organisms with a low frequency of microsatellites. Our microsatelite data for gene frequency and relatedness indicate that individuals disperse between patches but not between populations, providing support for our hypothesis that LMC influences sex allocation and reproductive mode in these thrips. (160 words)

Male-male mounting behavior in *Ptomascopus morio* (Coleoptera: Silphidae)

S Suzuki, M Nagano
Ecology & Systematics, Graduate School of Agriculture, Hokkaido University, Sapporo, 060-8589 Japan; seizi@res.agr.hokudai.ac.jp

Ptomascopus, a sister genus of *Nicrophorus*, uses small vertebrate carrion as food for their young but shows no parental behavior like *Nicrophorus*. When we investigated sexual behavior of *Ptomascopus morio,* we found curious behavior which male mount another male like copulation. In some trials, the mounting male extended his aedeagus in the copulatory orientation (facing forward). We call this behavior as mounting, and the level of male-male mounting was compared in the presence of two different stimuli (a large female versus a resource for breeding). In almost all cases the larger male mounted the smaller male. Number of copulation was not different whether carrion was present or absent. However, presence of carrion elicited more aggressive acts and mounting than absence of carrion. Thus we hypothesize that male-male mounting behavior is not misidentified males as females, but reflects aggression in some cases.

The isolation mechanism of *Drosophila albomicans* & *D. nasuta*

Y-T Tai, H Chang
Department of Entomology, National Taiwan University, 106, Taipei aira@ms1.url.com.tw

Drosophila albomicans and *D. nasuta* show a little but not significant postmating reproductive isolation. However, no hybrids have ever been found in nature anywhere including the area near the border according to their distinct karyotypes (2n=6 in *D. albomicans* and 2n=8 in *D. nasuta*). Studying the cause of preventing gene flow between them is important to realize population differentiation as well as speciation. Previously data showed the survival and fecundity of hybrids have no significant decrease, so we hypothesized the prezygotic isolation is the main events to prevent the gene flow in nature of this two species. Prezygotic mechanism was further divided into two periods: premating and postmating-prezygotic. The former was analyzed by the cage experiments of multiple-choice mating, further detect whether the *D. albomicans* and *D. nasuta* of different geographic regions have acquired different prezygotic reproductive isolation mechanisms.

Host plant specialisation governed by facultative endosymbiont

T Tsuchida, R Koga, T Fukatsu
Institute for Biological Resources and Functions, National Institute of Advanced Industrial Science and Technology (AIST), Tsukuba 305-8566, Japan; t-tsuchida@aist.go.jp

Host plant specialization of herbivorous insects has fascinated many entomologists as well as evolutionary biologists. Traditionally, the ecological trait has been attributed to genotype of the insects themselves, but here we found that plant adaptation of the pea aphid, *Acyrthosiphon pisum*, is strongly affected by a facultative endosymbiotic bacterium. Almost all aphids harbor an essential endosymbiotic bacterium, *Buchnera* sp.. In addition, many aphids possess facultative endosymbiotic bacteria, which are collectively called secondary symbionts. At three locations in central Japan, occurrence of a secondary symbiont, called pea aphid U-type symbiont (PAUS), was consistently higher on white clover than on vetch. By an antibiotic treatment, we created genetically identical aphid strains with and without PAUS infection. Whereas these strains exhibited similar levels of fecundity on vetch, the PAUS-eliminated strain lost almost 50% fecundity compared with the infected strain on white clover. When PAUS was reintroduced into the eliminated strain, the reduced fecundity on white clover recovered almost completely. These results indicate that PAUS infection improves the fitness of the host aphid specifically on white clover. This finding would shed new light on some aspects in evolutionary ecology of aphids and other herbivores, including host race, ecotype, and sympatric speciation.

Identification of primary tissues showing the lowest hardiness to freezing in larvae of the rice stem borer, *Chilo suppressalis* Walker (Lepidoptera: Pyralidae)

H Tsumuki, Y Izumi
Research Institute for Bioresources, Okayama University, Kurashiki 710-0046, Japan; htsumuki@rib.okayama-u.ac.jp

Even though overwintering larvae of the rice stem borer, *Chilo suppressalis* are freeze-tolerant; they can't survive below -30°C. Furthermore, non-diapausing larvae can't survive freezing. However, the cause of freezing death is unclear. To identify the cause of freezing-death of larvae, we tried to identify the primary tissues which were injured by low temperatures. Trypan blue dye was used to determine the injured tissues. In overwintering larvae, the midgut and silk glands of dead larvae were stained blue, and remarkable color density differences between dead and surviving larvae were observed in the midgut. In non-diapausing larvae incubated at -10°C for several hours, the fat body of dead larvae was strongly stained. Furthermore, increases in mortality with treatment time for larvae corresponded with increases in the area of the fat body stained. Sterile non-diapausing larvae with a lower supercooling point of below -20°C did not freeze at -10°C and survived the treatment. However, all the larvae died when subjected to inoculative freezing at -10°C, and the fat body was stained blue. These results suggest that the midgut in overwintering larvae and the fat body in non-diapausing larvae have the lowest hardiness to freezing.

Identification and sequence evolution of the gene encoding antimicrobial peptide defensin in ants

L. Viljakainen
University of Oulu, PO Box 3000, 90014 Oulu, Finland; lumi.viljakainen@oulu.fi

Organisms that live in social groups have greater susceptibility to infectious diseases compared to solitary organisms. In social insects the interaction with pathogens has led to a number of adaptations to reduce their deleterious effects. Such adaptations may be revealed by studying the existing diversity and long-term evolution of genes involved in insect immune system. One component of insect innate immune system, the humoral response, is triggered by the recognition of invading microorganisms resulting in the production of antimicrobial peptides. These peptides, and the microbes they target, may coevolve. In the nucleotide level this might be seen as directional selection or selection maintaining polymorphism. I have cloned and characterized the gene coding the antimicrobial peptide defensin from the ant *Formica aquilonia*. Sequence comparisons of several related ant species reveal that the gene is conservative in the group of species studied. The next step is to expand the comparison to phylogenetically more remote species and to other genes of the ant immune system.

Links between cold hardiness and desiccation resistance in an overwintering insect

JB Williams, NC Ruehl, RE Lee Jr.
Department of Zoology, Miami University, Oxford, Ohio 45056, USA

To investigate possible links between cold-hardiness and desiccation resistance in insects, we examined changes in seasonal parameters associated with these phenomena in overwintering larvae of the goldenrod gall fly *Eurosta solidaginis.* During the autumn, field-collected larvae gradually increased their capacity to survive freezing concomitantly with increases in cryoprotectants as measured by hemolymph osmolality (488 to 870 mOsm•Kg^{-1}). In contrast to gradual increases in larval cold hardiness, resistance to desiccation increased in two distinct phases. An initial 6-fold decrease in rates of water loss occurred in a two-week period in early October, reaching 0.57 μg•mm^{-2}•h^{-1}; this phase was primarily due to a reduction in respiratory water loss as the larvae entered diapause. The second phase was a more subtle 4-fold reduction that occurred over eight weeks beginning in mid-October. Interestingly, the second phase of reduced rates of water loss correlated strongly with increased hemolymph osmolality (568 to 870 mOsm•Kg^{-1}). In addition, we acclimated larvae at various temperatures in order to manipulate cryoprotectant concentrations. Our preliminary results suggest a trend exists between higher hemolymph osmolalities and lower rates of water loss. Taken together these data suggest that cryoprotectants may promote desiccation resistance as well as cold-hardiness in overwintering insects. Supported by NSF#IBN-0090204.

Species-diagnostic traits unravel under the heat: Hybrid zone dynamics and cryptic mountain species revealed by changing thermal landscapes

Prof. J. M. Scriber and G. J. Ording
"Department Of Entomology, Michigan State University,East Lansing, Mi 48824,USA scriber@msu.edu"

Recently (and probably directly related to extensive regional global warming in the region since 1998) considerable northward and rapid interspecific introgression (150-350 km in 6 years) into historical *P. canadensis* populations has been observed for several autosomal species-diagnostic traits such as detoxification of tulip tree leaves, morphological wing traits, and *Hk*-100 allozymes . In addition, some X-linked traits such as *Pgd*-100 alleles and tulip tree oviposition preference behavior have moved extensively northward. However, there has been little introgression of certain other sex-linked *P. glaucus* traits (such as facultative diapause, dark morph females, and LDH-100 allozymes). Recombination and strong selection on some undetermined trait (and close linkage of *Ldh*-100 with that trait on the X-chromosome) seem to limit gene flow North of this interspecific hybrid zone whereever fewer than 2700 degree-days accrue. We have created recombined/introgressed hybrids that largely match the morphological and delayed post-diapause emergences of the new mountain swallowtail species, *P. appalachiensis* (Pavulaan & Wright 2002). In the lab, diapausing backcrossed hybrids are delayed in post-diapause spring emergences by 2-3 weeks after the parental species. The new species expresses an introgressed mix of both *glaucus* and *canadensis*. diagnostic traits and may represent the high altitude version of our high latitude northern "false second generation" populations. GIS mapping of thermal accumulations allows prediction of the geographic location of the purportedly new species *P. apppalachiensis* (Pavulaan and Wright 2002) in West Virginia as well as for Georgia in the southern Appalachian Mts

Evolutionary trade-offs between reproduction and dispersal in populations at expanding range boundaries

C.L. Hughes, J.K. Hill, C. Dytham
C.L. Hughes, Department of Biology (Area 3), University of York, Heslington, York, YO10 5YW,UK, E-mail: clh121@york.ac.uk

During recent climate warming, some species have expanded their ranges northwards to keep track of climate changes. Evolutionary changes in dispersal have been demonstrated in these expanding populations and here we show that increased dispersal is associated with reduced investment in reproduction in populations of the speckled wood butterfly, *Pararge aegeri*a. Evolutionary changes in flight versus reproduction will affect the pattern and rate of expansion at range boundaries in the future, and understanding these responses will be crucial for predicting the distribution of species in the future as climates continue to warm.

Cold tolerance and feeding behaviour in the Tasmanian scorpionfly *Apteropanorpa* Carpenter (Mecoptera: Apteropanorpidae)

C. M. Palmer and D. K. Yeates
"School of Botany and Zoology, Australian National University, Canberra ACT 0200, Australia Email address: chris.palmer@anu.edu.au"

The Apteropanorpidae is a small family of scorpion flies endemic to Tasmania, comprising two described species. The biology of the family is almost completely unknown. Adults of both species are found on shrubs in the alpine zone and can be active in winter, although the peak in adult abundance is autumn. Experiments cooling individuals from 3°C to −10°C at 1°C/3 mins and measuring body temperature using infrared video thermography show that live *Apteropanorpa* freeze at an average temperature of −4.9°C (n=20). However, stress response behaviour is triggered at an average temperature of −1.1°C (n=20), and no individuals survived freezing to −10°C. Combined behavioural and physiological data indicate that *Apteropanorpa* does not possess a physiological mechanism to survive freezing, and instead employs freeze avoidance behaviour as the insect seeks microhabitats with favourable temperatures. *Apteropanorpa* is apparently well-adapted to its natural environment; the maritime climate of the Tasmanian alpine zone is relatively warm and stable compared to that of mainland Australia. Adults are most likely saprophagous in nature, predominantly feeding on dead and decaying invertebrates. Thirty-three adults were included in a feeding choice experiment in which twenty-two adults showed a statistically significant preference for feeding on dead arthropods. A saprophagous feeding strategy in the Apteropanorpidae is supported by field observations, histological tests and gut contents analyses by light and electron microscopy.

Jumping Genes and AFLP Maps: Transforming Lepidopteran Color Pattern Genetics

J. M. Marcus
"Dept. Biology, Western Kentucky Univ., Bowling Green KY 42101 USA, jeffrey.marcus@wku.edu"

The color patterns on the wings of Lepidopterans are among the most striking patterns in nature and have inspired diverse biological hypotheses such as the ecological role of aposomatic coloration, the evolution of mimicry, the role of human activities in industrial melanism, and the developmental basis of phenotypic plasticity. Yet, the developmental mechanisms underlying color pattern development are not well understood for three reasons. First, few mutations that alter color patterns have been characterized at the molecular level, so there is little mechanistic understanding of how mutant phenotypes are produced. Second, while gene expression patterns resembling adult color patterns are suggestive, there is little data available showing that gene products have a functional role in color pattern formation. Finally, because with few exceptions (notably *Bombyx*), genetic maps for most species of Lepidoptera are rudimentary or nonexistent, making it very difficult to determine whether mutations with similar phenotypes are due to lesions in the same gene or different genes. This presentation will show how a combination of germ line transformation using transposon vectors and genetic mapping employing variation between closely related species is rapidly resolving these difficulties and providing much new information about the development and evolution of these color patterns.

CARDINIUM HERTIGII, A NEWLY DISCOVERED SYMBIONT IN THE *BACTEROIDETES* CAUSES MULTIPLE REPRODUCTIVE MANIPULATIONS OF ITS HOSTS

M.S. Hunter, S.J. Perlman, E. Zchori-Fein and S.E. Kelly
Department of Entomology, 410 Forbes Bldg., University of Arizona, Tucson, AZ 85721, USA
mhunter@ag.arizona.edu

Vertically transmitted symbionts of arthropods have been implicated in several reproductive manipulations of their hosts, including cytoplasmic incompatibility (CI), parthenogenesis induction in haplodiploid species (PI), feminization, and male killing. *Wolbachia*, an a-proteobacterium is the only symbiont known to cause all of these effects, and has been thought to be unique in causing parthenogenesis and CI. We found a symbiont lineage in the *Bacteroidetes* group, recently described as *Cardinium hertigii*, causes PI and CI in parasitoids in the genus *Encarsia. Cardinium* is strongly associated with parthenogenesis in *Encarsia*, and in *E. hispida,* observations indicate it is the causative agent. In a sexual population of *E. pergandiella*, *Cardinium* induces CI. The 16S rDNA sequence of *Cardinium* in *E. pergandiella* is 99% identical to a parthenogenesis-inducing strain in another population of *E. pergandiella,* indicating that like *Wolbachia,* closely related strains can cause different phenotypes. *Cardinium* in *Encarsia* is also 96% identical to a feminizing symbiont in haplodiploid *Brevipalpus* mites. Thus, *Cardinium* has been found to induce three of the four principal manipulations of host reproduction known from *Wolbachia*. The discovery of *Cardinium* permits comparative analyses not possible when *Wolbachia* was thought to be unique.

The reproductive effects of infection by the intracellular bacterium *Cardinium* in mites

A. R. Weeks
"Centre for Environmental Stress and Adaptation Research, La Trobe University, Bundoora, Victoria, Australia 3086, A.Weeks@latrobe.edu.au"

The endosymbiont *Wolbachia* has received widespread notoriety over the past decade because of its high infection frequency among arthropods, and the unique heterogeneity of reproductive effects it has been implicated as causing to enhance its own spread. However, the newly described intracellular bacterium *Cardinium* has recently been implicated as causing a variety of reproductive manipulations in its host's that rivals *Wolbachia* for overall diversity. In addition, a recent screening study showed that a significant number of arthropods are infected with *Cardinium*, with the greatest number of infected species found in the Acari (mites). Here, I will talk about the reproductive effects induced by *Cardinium* in several different groups of mites, including feminization in *Brevipalpus* mites, fecundity enhancement in the predatory mite *Metaseiulus occidentalis* and parthenogenesis induction in several oribatid mite species. Finally, I will comment on the presence of double infections of *Wolbachia* and *Cardinium* in several host species and the implications of these infections for determining effects caused by these intracellular microorganisms.

Biological interplay between aphid, *Buchnera*, and facultative endosymbionts: importance of unrecognized players

T. Fukatsu
"Natl. Inst. Adv. Indust. Sci. Tech. (AIST), Tsukuba 305-8566, JAPAN, t-fukatsu@aist.go.jp"

Almost all aphids harbor the essential endosymbiotic bacterium *Buchnera*. In addition, many aphids possess additional endosymbiotic associates collective called "secondary symbionts". On the basis of physiological roles such as supply of essential amino acids, *Buchnera* is indispensable for life and reproduction of aphids. Although neglected for a long time, secondary symbionts have recently attracted much attention from researchers, and intensively investigated by using new techniques such as molecular phylogenetics, *in situ* hybridization, quantitative PCR, and artificial transfer and selective elimination, which shed new light on a variety of important biological roles carried by the unrecognized players. Here we report our new findings on the biology of secondary symbionts in aphids. 1) In Japanese pea aphids, a facultative symbiont called PAUS is involved in host plant specialization. 2) A facultative symbiont called PASS can support survival and reproduction of *Buchnera*-free pea aphids that will otherwise be completely sterile. 3) In some aphid groups like *Yamatocallis* spp. and *Colophina* spp., secondary symbionts are not facultative associates but are found from all individuals and populations of related species, suggesting that these secondary symbionts may play some important roles for the hosts and consequently be essential.

Theoretical and empirical studies of *Wolbachia* infections in mosquitoes

SL. Dobson
S-225 Agricultural Science Center North, Lexington, KY 40546, sdobson@uky.edu

Recent progress characterizing *Wolbachia* infections in medically important mosquito populations will be presented. *Wolbachia* is an obligate intracellular infection of invertebrates that is maternally transmitted through the host embryonic cytoplasm. *Wolbachia* can cause cytoplasmic incompatibility, which effectively penalizes females that lack infection by reducing their fecundity. In natural populations, cytoplasmic incompatibility can promote the spread and maintenance of *Wolbachia* infections. Artificial manipulation of *Wolbachia* infections and cytoplasmic incompatibility can be used in applied strategies for the suppression of economically important pest populations and for 'population replacement' of medically important disease vectors. The presentation will include recent characterization of *Wolbachia* infections in *Aedes* and *Culex* mosquitoes, research developing new molecular markers for discriminating between *Wolbachia* infections in the *Culex pipiens* complex, theoretical and empirical examination of *Wolbachia* effects on *Aedes albopictus* populations, and a new model for the evolution of new cytoplasmic incompatibility types.

The genetic basis of variation in butterfly wing patterns: Evolution, and development in *Bicyclus anynana*.

P. Beldade, A. D. Long
Eco. Evo. Bio., Univ. of California at Irvine. Irvine CA 92697-2525, USA., pbeldade@uci.edu

Heritable phenotypic variation is the raw material of adaptive evolution, and understanding its generation is a crucial issue in contemporary evolutionary biology. Furthermore, it is becoming widely recognized that variation should be of focal interest across all disciplines in biology. Genetic and phenotypic heterogeneity are a universal characteristic of living organisms, with variation across- and within-species existing for essentially all phenotypes. Studies in insects have made important technical and conceptual contributions to our understanding of phenotypic variation and its basis. Wing patterns of *Bicyclus* butterflies, in particular, have proven ideally suited to study the reciprocal interactions between evolutionary and developmental processes that shape variation within and across species for a morphological phenotype of ecological relevance. There is much variation in wing patterns in *B. anynana*, and detailed studies of the developmental pathways leading to pattern formation. To link these sets of data we need to know which genes within the implicated pathways contribute to variation in wing patterns in *B. anynana* and related species. Results of experiments exploring variation in wing patterns will be discussed, and so will our efforts to develop the genomic tools with which to dissect its genetic and developmental basis.

Sexual selection shapes genital morphology in a water strider: blurring the distinction between primary and secondary sexual traits.

D. J. Fairbairn and A. Bertin
Department of Biology, University of California, Riverside, California 92521-0427, USA, daphne.fairbairn@ucr.edu

Recent evidence that insect genitalia are subject to sexual selection has blurred the distinction between primary and secondary sexual characteristics. However, the extent to which genital morphology has been shaped by sexual selection remains controversial, as does the primary mode through which sexual selection acts on genital form and function. To discern the role of sexual selection in shaping genital evolution, we present a case study of the water strider, *Aquarius remigis* (Hemiptera, Gerridae), a species characterized by unique genital morphology, a polygynandrous mating system, and active female resistance to mating attempts. Our field assays demonstrate that sexual selection acting through differential mating success consistently favors males with long external genitalia, most probably because long external genitalia provide mechanical advantage to males as they try to position and insert the phallus. Video and microscopic studies of intromission, phallus inflation and insemination suggest that several features of the inflated phallus also enhance male paternity success more cryptically by anchoring the male in copula and by displacing and damaging sperm from previous males. Our results thus support the hypothesis that the unusual genital morphology of this species has evolved in response to sexual selection acting through both overt and covert intrasexual selection.

Genital variation in a dimorphic moth *Selenia tetralunaria*

M Mutanen & A Kaitala
PO Box 3000, FIN-90014 University of Oulu, Finland, marko.mutanen@oulu.fi

It is generally assumed that genitals do not vary within a species. We inspected morphologies of male and female genitalia of bivoltine geometrid moth *Selenia tetralunaria*. The two annual generations differ in morphology so that the second generation individuals are approximately 20% smaller than those of the first generation, and they also differ in wing patterns and shape. The morphs do occasionally co-occur. We found that that as reported in many insect and spider species genitalia show negative allometry in relation to body size. We found that this allometry is stronger in internal genital structures than in external genitalia. We also found that there is more variation in internal than in external genitalia. Thirdly, we found that the shape of genital structures differ between morphs in all three examined areas. *S. tetralunaria* is among the first reported cases of genitally dimorphic insect species. Considerable variation in internal genitalia and especially the presence of genital shape differences between morphs are not consistent with the predictions of lock-and-key hypothesis.

Genetic differentiation in three *Cryptophlebia* (Lepidoptera: Tortricidae) species of economic importance in South Africa

A.E. Timm, H. Geertsema & L. Warnich
Department of Entomology and Nematology, University of Stellenbosch, Private Bag X1, Matieland, South Africa, 7602; atim@sun.ac.za

The false codling moth, *Cryptophlebia leucotreta,* is one of the most damaging and catholic insect pests in South Africa. The pattern of genetic differentiation was studied in this species and compared with those of the litchi moth *C. peltastica* and the macadamia nut borer *C. batrachopa*. Populations of all three species were collected throughout their known range in South Africa from a variety of tropical, subtropical and deciduous hosts. Populations were studied using amplified fragment length polymorphism (AFLP) analysis and nucleotide sequence variation of the mitochondrial cytochrome oxidase 1 (COI) gene. Significant intraspecific variation was detected in all three species although *C. leucotreta* appeared as the most variable species, while *C. batrachopa* was the least variable. Analysis of molecular variance (AMOVA) revealed a high level of variation within populations for all three species. Estimates of the absolute number of migrants between populations (Nm) based on data obtained from mitochondrial and nuclear DNA markers indicate that *C. leucotreta* has a strong geographical structure with low gene flow between geographic populations. However, populations collected from different hosts differed only slightly. Furthermore, evidence was found for gender related dispersal. The results obtained are explained and used to provide insight into managing population levels of *Crytophlebia* spp. in different environments.

Population structure of *Plutella xylostella* (L.) investigated using microsatellite markers

NM Endersby, AR Weeks, H Vogel, SW McKechnie and PM Ridland
"Centre for Environmental Stress and Adaptation Research, School of Biological Sciences, Monash University VIC 3800, AUSTRALIA, Nancy.Endersby@sci.monash.edu.au Centre for Environmental Stress and Adaptation Research, La Trobe University VIC 3086, AUSTRALIA; Department of Primary Industries, Knoxfield, Private Bag 15, Ferntree Gully Delivery Centre VIC 3156, AUSTRALIA"

Diamondback moth (*Plutella xylostella*) is found throughout Australia infesting *Brassica* vegetables, canola, forage brassicas and weeds, but its long-range movement patterns in this country have not been ascertained. The species is considered highly migratory in the Northern Hemisphere and is known to be capable of travelling long distances on high altitude winds. Management of the pest in Australia and around the world would be facilitated by knowledge of its population genetic structure and dispersal patterns. We have developed six polymorphic microsatellite markers from a partial genomic library and an EST library of diamondback moth and are using them to investigate these factors. Populations of diamondback moth from around Australia will be compared with populations from Africa and Asia. Preliminary analysis of the Australian data indicates little genetic differentiation between diamondback moth populations within the country. However, a population from Kenya is showing a higher degree of microsatellite allele polymorphism than the Australian samples.

Drought responsive genes in the sleeping chironomid, *Polypedilum vanderplanki*

T. Kikawada, M. Watanabe, A. Fujita, M. Fujita, K. Snigorska and T. Okuda
"National Institute of Agrobiological Sciences, Ohwashi 1-2, Tsukuba, 305-8634 JAPAN, kikawada@affrc.go.jp"

"Organisms have evolved various mechanisms for adaptation to adverse environmental conditions. The sleeping chironomid, *Polypedilum vanderplanki*, is the largest multicellular animal known to tolerant almost complete dehydration without ill effect. The anhydrobiotic (cryptobiotic) larvae could survive at extreme temperatures from -270°C to +106°C (Hinton, 1968). We have demonstrated that rapid accumulation of trehalose coincided with loss of water form the larvae, also that cerebral regulation was not involved in the process of anhydrobiosis like plants or unicellular organisms. To address molecular events during desiccation going into anhydrobiosis in this insect, we cloned several genes concerning trehalose metabolism, water transport and so on by RT-PCR using degenerated primers and screening EST database of *P. vanderplanki*, and subsequently carried out Northern blot analysis to measure amounts of expressions of these genes during desiccation. Consequently, we obtained five drought responsive genes at least. We will discuss how these drought responsive genes orchestrate anhydrobiosis in *P. vanderplanki*.
"

Ecological adaptation of circadian activity rhythms: phase shift and loss of rhythmicity with the altitude change in Plusinae (Noctuidae) moths

M. Sasaki and S. Yamamura
Laboratory of Entomology, Faculty of Agriculture, Tamagawa University, Machida, Tokyo, 194-8610 Japan, sasaki@agr.tamagawa.ac.jp

Most of the Plusinae moths are nocturnal and the rhythms are driven by endogenous circadian rhythmicity. But it is also well known that the silver Y, Autographa gamma shows diurnal migration flight and Alpine species visits flowers in the daytime. We investigated the details of their rhythms using actographs. The Alpine Syngrapha nyiwonis was found to be essentially nocturnal but some, especially mated females, take flights in the daytime. Interestingly, their nocturnal activity is strictly limited in a few hours right after sunset, and they show no circadian component in the free-running state under DD or LL condition. Both of these natures seem to be adaptive to cool and unstable alpine weather. Rhythms of non- and sub-Alpine species are also discussed.

Morphometrics and insect development, genetics and evolution: integration in the *Drosophila* wing

C. P. Klingenberg
"School of Biological Sciences, University of Manchester, 3.614 Stopford Building, Oxford Road, Manchester M13 9PT, UNITED KINGDOM,
cpk@man.ac.uk"

The techniques for shape analysis have made substantial progress since the last symposium on Insect Morphometrics at the International Congress of Entomology in Florence (1996). Morphometrics has continued to become more flexible and powerful so that specific biological questions can be addressed. The main focus in morphometrics has therefore shifted from the development of entirely new techniques to adapting and applying the existing methods to the experimental designs and protocols in use in different biological disciplines. Particularly promising areas for such new applications include genetics, developmental biology and phylogenetics. I illustrate how morphometric methods can be customised for specific biological contexts with a study of morphological integration in the *Drosophila* wing. There has long been considerable interest in the hypothesis that the anterior and posterior compartments, which contain completely separate cell lineages, are units of development, inheritance and evolution. I use different approaches to re-examine this question. Analysis of integration of fluctuating asymmetry is a means to examine covariation due to direct developmental interactions. Analyses of covariation among subsets of landmarks suggest that the anterior and posterior compartment are not any more distinct than random subdivisions of the wing. Other analyses, including analyses of mutant effects and the reconstruction of phylogenetic shape changes among related species, will be used to complete the picture.

The evolution of seasonal polyphenism in African *Bicyclus* butterflies

P M. Brakefield
Institute of Biology, Leiden University, P.O. Box 9516, 2300 RA Leiden, The Netherlands; email: brakefield@rulsfb.leidenuniv.nl

Species of *Bicyclus* that live in environments with alternating dry and wet seasons show striking examples of seasonal polyphenism. We have studied the evolution of this extreme case of phenotypic plasticity using a multidisciplinary approach. The alternative seasonal phenotypes differ strongly in wing pattern, but also in life history traits. Field and laboratory experiments are used to test hypotheses about the adaptive nature of the wing patterns, whilst artificial selection provides a powerful tool for examining genetic variation and the underlying physiological and developmental bases of the polyphenism. The results will be summarized to illustrate how these different levels of biological organisation can be linked together, and to show how populations are likely to be able to modify their plasticity in response to a change in the relationship between climatic variables and the seasonal cycling in the ecological environment.

Quantitative Genetics and Geometric Morphometrics of Developmental Instability in *Drosophila subobscura*: Inbreeding, Crossbreeding and Temperature Stress using Isochromosomal Lines

M Santos, P Fernández Iriarte, W Céspedes
Dep Genètica I Microbiologia, Univ Autònoma De Barcelona, 08193 Bellaterra (Barcelona), Spain, mauro.santos@uab.es

Fluctuating asymmetry (FA) is often used as a measure of underlying developmental instability (DI), motivated by the idea that morphological variance is maladaptive. Whether or not DI has evolutionary potential is a highly disputed topic, marred by methodological problems and fuzzy prejudices. Here we report the results of the effects of karyotype, homozygosity and temperature on wing form and bilateral asymmetry by using a large set of isochromosomal lines of *Drosophila subobscura* and their crosses. Our approach uses the recently developed methodologies to analyze shape configurations of landmarks within the standard statistical framework employed in studies of bilateral asymmetries, and we have extended these methods to partition the individual variation and the variation in asymmetries into genetic and environmental causal components. The analyses have revealed that both inbreeding and (sub-optimal) temperature had a substantial effect on wing form (size and shape) and wing form FA, with increasing asymmetries in inbred lines and crosses cultured at suboptimal temperature. Directional asymmetry (DA) was highly significant for wing size (left wings were consistently bigger than the right ones) and shape regardless the level of inbreeding and rearing temperature, and temperature-dependent expression of genetic variation for wing shape DA was also revealed in heterozygous crosses. No genetic variation was generally detected for wing size FA. However, the presence of genetic variation for wing shape DA introduces a bias in the estimation of FA and makes very difficult to test for genetic effects on wing shape FA. Finally, we question the suggestions that the classical linear theory cannot account for transitions between FA and DA, and that developmental processes influencing wing shape generate random differences between body sides.

Evolution of wing color in butterflies: can local adaptation initiate ecological speciation?

J. Ellers
Animal Ecology, FALW, Vrije Universiteit, De Boelelaan 1085, 1081 HV Amsterdam, The Netherlands. Jacintha.Ellers@ecology.falw.vu.nl

The evolution of butterfly wing colouration is strongly affected by its multiple functions, such as thermoregulation, aposematic signalling and mate recognition. We investigated the genetic background of intraspecific variation in wing colour in the butterfly *Colias philodice eriphyle*, and its consequences for the role of wing colour in ecological speciation. In this species, divergent selection on wing colour across an elevational gradient in response to the thermal environment has led to increasing wing melanization at higher elevations. A breeding experiment demonstrated that wing melanization is heritable and strongly sex-linked. Also, controlled mate choice experiments in the field over a large elevational range showed an important role of wing colour in mate choice and mating success. However, a necessary condition for ecological speciation is correlated evolution of mate signals and mate preference, which may be constrained if traits have multiple functions. These results and wing colour-dependent fitness parameters obtained from several field experiments are integrated to predict the effect of multiple functions and genetic architecture on population divergence and the probability of ecological speciation.

The evolution of seasonal polyphenism in African *Bicyclus* butterflies

P M. Brakefield
Institute of Biology, Leiden University, P.O. Box 9516, 2300 RA Leiden, The Netherlands; email: brakefield@rulsfb.leidenuniv.nl

Species of *Bicyclus* that live in environments with alternating dry and wet seasons show striking examples of seasonal polyphenism. We have studied the evolution of this extreme case of phenotypic plasticity using a multidisciplinary approach. The alternative seasonal phenotypes differ strongly in wing pattern, but also in life history traits. Field and laboratory experiments are used to test hypotheses about the adaptive nature of the wing patterns, whilst artificial selection provides a powerful tool for examining genetic variation and the underlying physiological and developmental bases of the polyphenism. The results will be summarized to illustrate how these different levels of biological organisation can be linked together, and to show how populations are likely to be able to modify their plasticity in response to a change in the relationship between climatic variables and the seasonal cycling in the ecological environment.

Fruit fly outbreaks in Northwestern Australia

E Cameron, S Gilchrist, J Sved
Fruit Fly Research Centre, School Of Biological Sciences A12, University Of Sydney, NSW 2006, AUSTRALIA, ecameron@bio.usyd.edu.au

The Queensland fruit fly, *Bactrocera tryoni*, is Australia's worst fruit pest. Originally endemic to Queensland this species can now be found down the entire East coast where it infests most commercial crops. In contrast *B. aquilonis*, a sister species of *B. tryoni*, is found in the northwest and is not considered to be a pest. Despite this difference in pest status these two species are virtually indistinguishable by eye. It is these flies which have been implicated in recent outbreaks of fruit fly in developing horticultural regions of northwestern Australia. The outbreaks are either due to a change of behaviour in the endemic *B. aquilonis* so that they now infest commercial crops, alternatively *B. tryoni* may have been introduced into the area or there may have been a hybridisation event between the two species. We have used microsatellite analysis to firstly characterise the populations of fruit fly in the northwest and then used these profiles to identify the source of outbreak populations using assignment testing and cluster analysis. The mitotypes of outbreak flies and background populations were then used in simulations to provide a model of the outbreaks.

Assessment of bacteriophage WO involvement in *Wolbachia*-induced CI within the *Culex pipiens* complex

YO Sanogo, A Eitam and SL Dobson
Department of Entomology, University of Kentucky, S-225 Agricultural Science Center North, Lexington, KY-40546, USA yibosee@yahoo.com

The *Culex pipiens* complex include some of the most medically important mosquitoes due to their cosmopolitan distribution and their capacity to vector infectious diseases. Members of the complex differ in their ecology, behavior, physiology and vector competence. To date, no consensus has been achieved about the taxonomical status of representatives of this group. Opinions of their relationship range from distinct species with no gene flow to physiological forms with considerable introgression. Most populations of *Culex pipiens* are infected with *Wolbachia*, a maternally inherited bacterium, which causes cytoplasmic incompatibility (CI) resulting in embryonic mortality. In prior molecular characterization, we have demonstrated that *Culex* populations differ in the bacteriophage WO that is thought to infect *Wolbachia* (Sanogo and Dobson, 2004). To test the hypothesized involvement of bacteriophage WO in determining CI in *Culex*, crosses have been conducted between nine *Culex* strains that differ in their bacteriophage WO infection type. Here, we will present the crossing results and discuss the correlation between bacteriophage WO and CI type. We will also discuss the results in relation to the restriction of gene flow among naturally occurring *Culex pipiens* populations.

Intraspecific Transfer of Wolbachia In Mosquitoes By Microinjection

Z. Xi, J.L. Dean and S. L. Dobson
Department of Entomology, University of Kentucky, S-225 Ag. Science Center North. Lexington, KY 40546, USA, zxi2@uky.edu

Wolbachia are maternally transmitted intracellular bacteria that infect approximately 20% of insect species and over 30% of mosquito species examined. Through a mechanism known as cytoplasmic incompatibility (CI), *Wolbachia* infections can induce early embryo death when an infected male mates with uninfected female. The ability of *Wolbachia* to induce CI in its host has led to the proposal of strategies for the control of mosquitoes and the diseases that they transmit, including strategies for both the suppression and replacement of medically important mosquito populations. Both strategies require the ability to artificially generate novel *Wolbachia* infections, which will require techniques for transferring *Wolbachia* infections both interspecifically and intraspecifically (transfection). Although transfection techniques have been developed for a few other insects, there has been no successful *Wolbachia* transfection reported in mosquitoes. We have modified a transfection protocol previously used for *Drosophila*. Here we describe the development and initial tests of the modified protocol to transfer *Wolbachia* from superinfected *Aedes albopictus* (Asian tiger mosquito) into an uninfected strain of *Ae. albopictus*. Furthermore, we describe characterization of a transfected line via crosses to determine its CI phenotype. To date, the infection has been maintained in the transfected line for three generations and displays a pattern of CI consistent with *Wolbachia* transfection. We discuss the results in relation to *Wolbachia* /mosquito host interaction and its significance to applied mosquito control strategies.

Identification of source populations of invasive insects: implications for biological control, monitoring, and quarantine

RG Ahern, MJ Raupp, DJ Hawthorne
4112 Plant Sciences Building, College Park, Maryland 20742-4454, USA; rga@umd.edu

Invasive species cause severe economic and ecological damage in many regions around the world. Knowledge of an invasive species' origin benefits inspection and quarantine efforts and focuses the search for biological control agents. Cooley spruce gall adelgid (CSGA), *Adelges cooleyi*, is a native pest in the US that provides an excellent model organism for studying population genetics of invasive exotic species. The native range of CSGA resembles an inverted 'V', extending northward along the Rocky Mountains into Canada and back down the West Coast into northern California. CSGA has invaded the eastern US through an unknown number of introductions during the 20th century. Here, we report efforts to identify sources of CSGA populations introduced into the eastern US. Comparison of mitochondrial and nuclear DNA sequences among source and introduced populations revealed that all east coast introductions originated from one region within the insect's extensive native range. As expected by theory, genetic variation was decreased in introduced populations relative to populations from the insect's native range. This work demonstrates a successful application of molecular genetic tools to determine the origin of invasive species and aspects of population genetic structure, thus facilitating the development of sound, sustainable pest management strategies.

Inbreeding leads to changes in allometry between egg size and larval characters in an eriosomatine aphid (Aphididae)

S Akimoto
Department of Ecology and Systematics, Graduate School of Agriculture, Hokkaido University, Sapporo, 060-8589 Japan; akimoto@res.agr.hokudai.ac.jp

A number of studies indicate that inbreeding has deleterious effects on the viability and reproduction of organisms, but it is still unknown what mechanisms are involved in the expression of deleterious effects. Because the effects of inbreeding are expressed from the early stage of development, it is necessary to focus on hatched larvae to understand the phenotypic effects of inbreeding. Aphids are useful for studying inbreeding effects because in aphids (1) it is easy to cross males and females of the same clone (that is, selfing) and (2) hatched larvae can be used for detailed morphometric analyses. Using the aphid *Prociphilus oriens*, this study prepared eggs resulting from outbreeding and selfing and compared the allometry between egg size and morphological characters of hatched larvae between outbred and selfed groups. The allometry of larval characters against egg size varied greatly between outbred and selfed groups. Selfed larvae had significantly larger allometric coefficients for appendages than did outbred larvae, showing that inbreeding accelerated the growth of appendages. However, the growth of gonads was suppressed in selfed larvae. It is suggested that inbreeding relaxed developmental canalization on larval appendages and resulted in reduction in gonad size via a trade-off between appendages and gonads.

Rapid chill coma recovery selection in *Drosophila melanogaster*

AR Anderson, AA Hoffmann, SW McKechnie
Monash University, Clayton, Victoria, 3800; alisha.anderson@sci.monash.edu.au

Resistance to low temperatures can vary markedly among invertebrate species and is directly related to their distribution. Despite the ecological importance of cold resistance this trait has rarely been studied genetically. One measure of cold resistance that varies geographically in *Drosophila melanogaster* and that is amenable to genetic analysis is chill-coma recovery. *D. melanogaster* have been selected for increased recovery time following exposure to 0°C. Selected lines responded rapidly to the selection and showed an increased resistance to a broad range of low temperatures. They also had a lower mortality following a more severe cold treatment, indicating that a general mechanism underlying cold resistance had been selected. The selection response was independent of plastic changes in cold resistance because the selected lines maintained their ability to acclimate. Life-history and stress resistance tradeoffs were also investigated showing only a tradeoff with ageing and one stress resistance trait. Selected lines were genotyped for clinally varying genes/markers and show associations with some candidate genes suggesting these genes may have a role in cold resistance.

Predicting shifts in timing of winter moth egg in response to climate change

M van Asch, PH van Tienderen, LJM Holleman, ME Visser
Netherlands Institute of Ecology, PO Box 40, 6666 ZG Heteren, The Netherlands; M.vanAsch@nioo.knaw.nl

Climate change can lead to mistiming in phenology between different components of food chains. For instance, winter moth (*Operophtera brumata*) egg hatch has advanced more than oak (*Quercus robur*) bud burst over the past two decades. The question is whether natural selection will lead to a restoration of synchrony between winter moth and oak. Using a half-sib design, we demonstrate here that egg hatching is a heritable trait, making adaptation through selection possible. We further use a model to predict the changes in reaction norm of egg hatching at different temperatures. This approach enabled us to predict the response in the next year, under different environmental conditions, to the selection in a given year. Due to selection, the reaction norm will change in intercept but not in slope: in future eggs will need more warmth before they can hatch, regardless of what the temperature is in a given year. Because of this, timing differences between egg hatch and oak bud burst will decrease rapidly. Changes in reaction norm in response to selection thus offer a possible way of restoring synchrony between different components of a food chain, winter moth and oak.

Use of thermal data as an establishment screen for non-native biocontrol agents in the UK

JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK; j.s.bale@bham.ac.uk

Most predatory insects and mites used in glasshouse biocontrol in the UK originate from tropical and semi-tropical climates. For this reason, the licensing system for the introduction of non-native species has operated under the assumption that winter would act as a natural barrier to the establishment of such species outside of glasshouse environments. This view has been challenged by the establishment in the wild of the predatory mite *Neoseiulus californicus* and the discovery of the predatory mirid *Macrolophus caliginosus* outside of glasshouses in winter. Whilst the impact of these species on native ecosystems is unknown, their establishment is considered undesirable. This paper describes a series of experiments used to determine a range of thermal characteristics (developmental threshold, day-degree requirement per generation, supercooling point, lethal times and temperatures, field survival) of four non-native biocontrol agents. The comparative data provide a retrospective ecophysiological explanation for the establishment of *N. californicus* and *M. caliginosus,* and also indicate that *Delphastus catalinae* and *Eretmocerus eremicus* would not survive outdoors in the UK under current climatic conditions. The experimental protocol applied to these species could be used as part of a routine screen for 'establishment potential' in the licensing system of non-native biocontrol agents in the UK.

Synchronous coadaptation in an ancient case of herbivory

JX Becerra
Department of Entomology, University of Arizona, Tucson AZ 85721, USA; becerra@ag.arizona.edu

Coevolution has long been considered a major force leading to the adaptive radiation and diversification of insects and plants. A fundamental aspect of coevolution is that adaptations and counteradaptations interlace in time. A discordant origin of traits long before or after the origin of the putative coevolutionary selective pressure must be attributed to other evolutionary processes. Despite the importance of this distinction to our understanding of coevolution, the macroevolutionary tempo of innovation in plant defenses and insect counterdefenses has not been documented. Molecular clocks for a lineage of chrysomelid beetles of the genus *Blepharida,* and their Burseraceae hosts were independently calibrated. Results show that these plant's defenses and the insect's counterdefensive feeding traits evolved roughly in synchrony, providing the first macroevolutionary confirmation of synchronous plant-herbivore coadaptation. The association between these two groups of organisms was determined to be about 112 million years old, the oldest age so far for a specialized plant-herbivore association.

Genetics and evolution of photoperiodism in temperate environments

WE Bradshaw, CM Holzapfel
CEEB, 5289 University of Oregon, Eugene, OR 97403-5289, USA; bradshaw@darkwing.uoregon.edu

Photoperiodism constitutes the major physiological mechanism by which arthropods adjust the seasonal programming of development and dormancy at temperate latitudes. Dispersal of the pitcher-plant mosquito, *Wyeomyia smithii*, from southern latitudes to northern Canada following recession of the Laurentide Ice Sheet 20,000 - 8,000 years ago has involved the evolution of longer critical photoperiods, thereby tracking the shorter growing seasons at increasingly more northern latitudes. Despite directional and stabilizing selection during post-glacial range expansion, the heritability of critical photoperiod increases with latitude. We attribute this increase in heritability to the release of additive from epistatic variance during sequential founder events. During rapid climate change over the last 30 years, critical photoperiod has shifted towards shorter, more southern day lengths as growing seasons have become longer. This genetic shift in photoperiodic response is detectable over a time interval as short as five years. Faster evolutionary response has occurred in northern populations where selection is stronger and genetic variation is greater. Our results suggest that other species may be in the process of analogous evolutionary responses to altered seasonality and that the composition of future biotic communities may depend on the relative abilities of their constituent species to adapt to altered seasonal interactions.

Fluctuating asymmetry of wing pattern elements and wing shape, and its relationship to migration in the butterfly *Melitaea cinxia*

CJ Breuker, PM Brakefield, I Hanski
Casper J. Breuker, School of Biological Sciences, 3.614 Stopford Building, University of Manchester, Oxford Road, M13 9PT, Manchester, UK; casper_j_breuker@yahoo.co.uk

When fitness depends on morphological traits, individuals that can develop the phenotype reliably should be more fit than those, which cannot. Fluctuating asymmetry (FA; minute differences between the left and right side of a bilateral trait due to developmental errors) has therefore been used to predict the fitness of individuals in natural and sexual selection studies. In this talk we discuss how the FA of wing pattern elements and shape of the wings of both the fruitfly *Drosophila melanogaster* and the butterfly *Melitaea cinxia* can be used to obtain information on how development is stabilized and how useful FA is in a natural selection experiment. In the butterfly species a mark-release-recapture experiment was carried out to obtain information on the relationship between FA of wing pattern elements and shape, migration, past and present population sizes, dispersal, survival and mating success. The results will be discussed taking recent results into account on the mechanisms of developmental stability as obtained with *D. melanogaster*.

The effect of a resistance gene on developmental stability and fitness in a flea beetle, *Phyllotreta nemorum*

CJ Breuker, PW de Jong, K Victoir, K Vrieling, PM Brakefield.
School of Biological Sciences, 3.614 Stopford Building, University of Manchester, Oxford Road, M13 9PT, Manchester, UK; casper_j_breuker@yahoo.co.uk

A resistance (R-) gene enables the flea beetle *Phyllotreta nemorum* L. (Coleoptera: Chrysomelidae: Alticinae) to use the otherwise toxic *Barbarea vulgaris* ssp. *arcuata* G-type plant as a host plant in Denmark. In this study, the pleiotropic effects of the dominant R-allele at a single autosomal gene, originating from the Danish region of Kværkeby, were investigated in an isogenic background from non-resistant beetles. The presence of the R-allele causes a high mortality at the early stages of development, when the toxic G-type plants cause the high mortality in non-resistant beetles. The presence of the R-allele has little or no effect, even under suboptimal conditions, on developmental stability (measured as fluctuating asymmetry of tibialength), body size, fecundity and longevity in the adult beetles. The distribution of the beetles in the field in Denmark will be discussed and its host plant use.

Contemporary evolutionary genetics: the breadth and depth of host race evolution in bugs on two continents.

SP Carroll, H Dingle, TR Famula, J Loye
Department of Zoology and Entomology, University of Queensland, St. Lucia 4072, Queensland, Australia.

Several species of seed bug (the soapberry bugs: Rhopalidae) from the Americas and Australia are specialized on the plant family Sapindaceae ("the 'soapberry family"), including exotic introductions and escapes. Studies on species in both Hemispheres reveal morphological, physiological, behavioral and life history adaptations to host fruits and phenologies. Many of these adaptations display rapid or contemporary evolution (in 30-50 years or 100 generations) on introduced hosts; they include traits from mouthpart morphology to wing muscle enzyme physiology. We document this evolution in soapberry bugs from Australia (*Leptocoris*) and North America (*Jadera*), showing geographic variation within continents and among host plants. The genetics underlying contemporary evolution has been analysed in a North American species using hybrids between populations adapted to different hosts as well as artificial selection. The analyses demonstrate that additive and non-additive genetic variation in the various traits contributes to contemporary evolution. Further, they reveal expected and some unexpected genetic correlations and interesting evolutionary pathways to adaptation.

A macrophysiological perspective on cold and desiccation tolerance

SL Chown
Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa; slchown@sun.ac.za

Macrophysiology, or the investigation of variation in physiological traits over large geographic and temporal scales and the ecological implications of this variation, is gaining increasing attention globally for several reasons. Here, I explore large-scale variation in cold tolerance and desiccation in insects and its implications. Perhaps unsurprisingly, rates of water loss vary in an environmentally consistent fashion, such that rates are lower in dry environments. This is true of both cuticular and respiratory water loss, even though the significance of the latter and its likely response to selection have been questioned. In several species it is clear that respiratory water loss is remarkably sensitive to environmental variation and adaptive variation thereof is not inconsistent with the data. Patterns in cold tolerance are more complicated, and reflect the variety of strategies animals can adopt to survive low temperatures. Nonetheless, two major patterns are emerging from the broad scale data. First, there is decoupling of upper and lower thermal limits. Second, there are pronounced and consistent differences in the way temperate species from the Northern and Southern Hemispheres respond to low temperatures. These major patterns not only provide insights into the mechanisms underlying insect responses to cold, but also have significant implications for understanding and predicting species responses to environmental change.

Costs of salicylate- and jasmonate-mediated induced responses in *Arabidopsis thaliana*

D Cipollini
Wright State Univ., Dept. of Biol. Sciences, Dayton, OH 45435; don.cipollini@wright.edu

Fitness costs of plant defenses to herbivores and pathogens are an important aspect of the evolutionary dynamics of plant resistance. Costs of defense have been increasingly reported in the literature, yet their mechanisms remain largely unexplored. Costs may arise from increased allocation of resources to defense production at the expense of growth, decreased assimilatory capacity in highly defended plants, or in the case of induced responses, negative interactions between defense pathways that compromise resistance to certain natural enemies. I explored costs of induced responses in several *Arabidopsis thaliana* genotypes that vary in their constitutive and inducible expression of resistance traits. In the absence of benefits, highly defended genotypes, such as the constitutive expressor of systemic acquired resistance mutant, *cep1*, had lower seed production than less defended genotypes, in general. Plants induced with either salicylic acid or jasmonic acid produced less seed than uninduced plants, and costs were quantitatively associated with the induction of such defenses as trypsin inhibitors and glucosinolates, coupled with decreased assimilatory capacity. In addition, jasmonate-mediated resistance to insects was compromised in plants simultaneously induced with salicylic acid due to inhibitory defense pathway crosstalk, and an inverse relationship between bacterial and insect resistance was demonstrated for several genotypes.

Forewing shape variation in the sand cricket *Gryllus firmus*

V Debat
Integrative Biology – School of Biological Sciences. 3.614 Stopford Building, University of Manchester, Oxford Road, Manchester, M13 9PT, United Kingdom

Populations of the sand cricket *Gryllus firmus* are composed of two wing morphs. Long winged individuals (LW) have functional hind wings, are able to fly, and thus might disperse. Short winged individuals (SW) have vestigial hind wings and cannot fly. It is commonly considered that this dimorphism is maintained by a trade-off between flight capacity and fecundity. Here, we focused on the male forewing. Since males use their forewings to produce courtship songs, this structure affects fecundity. Additionally, it is likely that some genes jointly affect the two pairs of wings. Selection for flight efficiency on the hind wings should thus indirectly affect the forewings. This implies that the fore wings might be influenced by both trading off parameters. Using geometric morphometrics we analyzed the forewing shape variations both within and among morphs. Then, using a full sib design we estimated the genetic and non genetic components of shape variation. We discuss our results in terms of selection and developmental constrains.

Molecular responses to cold and desiccation

DL Denlinger, JP Rinehart, SAL Hayward, MR Michaud
Department of Entomology, Ohio State University, 318 W. 12th Avenue, Columbus, OH USA 43210-1242; denlinger.1@osu.edu

Heat shock proteins (Hsps) are involved in responding to both low temperature and desiccation in flesh flies, but different sets of Hsps are involved in the responses to overwintering cold hardiness, rapid cold hardening, desiccation and rehydration. The use of RNAi to knock out Hsp70 has a dramatic effect on overwintering cold hardiness, but Hsp23 appears to be much more important for rapid cold hardening. Hsp23 and Hsp70 are both upregulated by desiccation, but two other Hsps, Hsp90 and Hsc70, are upregulated when a desiccated fly is rehydrated. The rehydration response is most similar to the Hsp response to cold recovery: Hsp90 and Hsc70 are upregulted in both cases. The deployment of different subsets of Hsps thus differs from the response to heat shock, where all are upregulated simultaneously. Microarray data indicates that a number of genes, in addition to the Hsps, are involved in the fly's response to low temperature.

Phylogenetic congruence of mealybugs and their P-endosymbonts

DA Downie, PJ Gullan
Department of Zoology and Entomology, Rhodes University, Grahamstown 6140, South Africa; d.downie@ru.ac.za

Tight interactions between unrelated organisms such as is seen in plant-insect, host-parasite, or host-symbiont associations may lead to speciation of the smaller partners when their hosts speciate. Totally congruent phylogenies of interacting taxa have not been observed often but a number of studies have provided evidence that various hemipteran insect taxa and their primary bacterial endosymbionts have shared phylogenetic histories. Like other hemipteroids, mealybugs (Pseudococcidae) harbor multiple intracellular bacterial symbionts that are thought to be strictly vertically inherited. Thus co-divergence of hosts and symbionts is expected. Here, robust estimates of phylogeny were generated from four fragments of three nuclear genes for mealybugs of the subfamily Pseudococcinae, and a substantial fragment of the 16S-23S rDNA of their P-endosymbionts. Phylogenetic congruence was significant, with 75% of nodes on the two trees identical. Congruence was not perfect however, and other evolutionary outcomes including host shifts could not be ruled out. It is shown that incongruence may be influenced by uncertainty in phylogenetic estimation.

Effects of short-term spontaneous mutation accumulation for life history traits in grape phylloxera

DA Downie
Department of Zoology and Entomology, Rhodes University, Grahamstown 6140, South Africa; d.downie@ru.ac.za

Mutation is the source of all genetic variation but the mutation rate, effects of new mutations, and their role in the maintenance of genetic variation are still subject to controversy. These parameters are important in models of the evolution of sex and recombination, the persistence of asexual populations, and the extinction of small populations. Most estimates have come from model organisms. Here, mutation accumulation experiments were conducted with 3 clones of grape phylloxera, *Daktulosphaira vitifoliae* Fitch, a gall forming herbivore of grapes, to estimate rate of input and effects of spontaneous mutation on life history traits. This is perhaps the first such experiment using a non-model organism of economic importance. Evidence was found that mutation rates are high enough to produce heritable genetic variation over short time scales, and that the effects of mutation on these quantitative traits are deleterious on fitness. Estimates of the parameters by the Bateman-Mukai method were within the range found in previous studies. Rapid accumulation of deleterious mutations suggest that for many pest species, adaptive response under agricultural conditions may depend more on standing variation from introductions than new mutation.

Insect antifreeze proteins

JG Duman
Department of Biological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA; duman.1@nd.edu

Although they have been identified in various animals, plants, fungi and bacteria, the most active antifreeze proteins (AFPs) yet discovered are found in insects. In larvae of the freeze avoiding Pyrochroid beetle *Denoides canadensis* AFPs function to prevent freezing by (1) inhibiting inoculative freezing initiated by external ice across the cuticle, and (2) by inactivating internal ice nucleators, thereby inhibiting spontaneous nucleation and promoting supercooling. Two types of insect AFPs are currently known. Those of *D. canadensis* (DAFPs) consist of 12-and 13-mer repeating units in which certain positions (especially those with threonine, serine and cysteine residues) are highly conserved. Threonines, in particular, appear to be involved in the ability of the DAFPs to hydrogen bond to ice or ice nucleators. There are tissue and temporal variations in the expression of the family of 13 variants of the DAFPs, suggesting variation in function. Optimal function of the DAFPs requires the presence of low molecular mass enhancers (glycerol, etc.) and/or certain other protein enhancers. Also, certain DAFPs have a synergistic effect on other DAFPs. In Alaska, AFPs similar to DAFPs play a role in the ability of larvae of the Cucujid beetle *Cucujus clavipes* to supercool to extreme temperatures, in some cases below -80C.

Canalization and cryptic variation in *Drosophila melanogaster*.

I Dworkin, G Gibson
3632 Gardner Hall, Department of Genetics, North Carolina State University, Raleigh, NC. 27695, USA

Canalization has been discussed a great deal with respect to evolutionary developmental biology, however there is a lack of consensus as to a precise definition of canalization itself. This has resulted in a large number of studies exploring different aspects of the same question with no common reference. I will discuss some methodological and statistical approaches to addressing questions of canalization, and cryptic genetic variation, and provide some empirical examples of how these can help to improve our understanding of canalization. Furthermore, I will summarize the results of a recent association mapping study designed to explore the genetic basis of cryptic variation.

Evolutionary and functional genomics of wing shape in *Drosophila melanogaster*.

I Dworkin, G Gibson
3632 Gardner Hall, Department of Genetics, North Carolina State University, Raleigh, NC. 27695, USA

While most organisms vary considerably in aspects of shape, surprisingly little is known about the genetic basis of shape variation. Using the wing of *Drosophila* as a model system, I will present the results of a functional genomics study of wing shape, and how mutants in known wing patterning genes affect shape. Furthermore I will discuss the results of association mapping studies between natural polymorphisms in two genes, *Epidermal growth factor receptor* and *hedgehog*, with wing shape.

Diversity in the weapons of sexual selection: horn evolution in the beetle genus *Onthophagus*.

DJ Emlen
Division of Biological Sciences, The University of Montana, Missoula MT 59812; doug.emlen@mso.umt.edu.

Both ornaments and weapons of sexual selection frequently exhibit prolific interspecific diversity of form. Yet, most studies of this diversity have focused on ornaments involved with female mate choice, rather than on the weapons of male competition. With few exceptions, the mechanisms of divergence in weapon morphology remain largely unexplored. Here, I examine the evolutionary radiation of one type of weapon: beetle horns. I use partial sequences from one nuclear and three mitochondrial genes to develop a phylogenetic hypothesis for a worldwide sample of 39 species from the dung beetle genus *Onthophagus* (Coleoptera: Scarabaeidae), and then use these data to trace the evolutionary radiation of horns. Although this limited sample of one of the world's most species-rich genera almost certainly underestimates the number of evolutionary events, it reveals prolific evolutionary lability of these exaggerated sexually selected weapons (over 24 separate gains and losses of five different horn types).

Genotype to phenotype: physiological control of trait size and scaling in insects.

DJ Emlen, CE Allen
Division of Biological Sciences, The University of Montana, Missoula MT 59812; doug.emlen@mso.umt.edu.

For almost a century, biologists have used trait scaling relationships (bi-variate scatter-plots of trait size versus body size) to characterize phenotypic variation within populations, and to compare animal shape across populations or species. Scaling relationships are a popular metric because they have long been thought to reflect underlying patterns of trait growth and development. However, the physiological mechanisms generating animal scaling are not well understood, and it is not yet clear how scaling relationships evolve. Here we review recent advances in developmental biology, genetics, and physiology as they pertain to the control of growth of adult body parts in insects. We summarize four mechanisms known to influence either the rate or the duration of cell proliferation within developing structures, and suggest how mutations in these mechanisms could affect the relative sizes of adult body parts. By reviewing what is known about these four processes, and illustrating how they may contribute to patterns of trait scaling, we reveal genetic mechanisms likely to be involved in the evolution of insect form.

Impact of 1997-1998 ENSO-induced fires and logging on the genetic diversity of *Upadia theda* Felder (Lycaenidae) in Borneo.

C Fauvelot, DFR Cleary, SBJ Menken
Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, 1098 SM Amsterdam, The Netherlands; fauvelot@science.uva.nl

Drastic changes in population size as a result of disturbance can severely affect genetic variation. However, although severe disturbance is assumed to reduce levels of diversity, intermediate levels of disturbance, on the contrary, can lead to elevated levels of diversity. Here, we investigated the temporal variation in genetic diversity in populations of the butterfly species *Upadia theda* Felder (Lycaenidae), that were differentially affected by disturbance in East Kalimantan, Indonesia. We focused on the two main forms of disturbance that affect tropical rain forests, namely logging and ENSO-induced drought and burning. The populations were sampled over a four-year period in pristine, logged and burned areas before and after 1997-1998 ENSO-induced event. We assessed genetic variation within and between samples by analysing mitochondrial DNA sequences (mtDNA control region+ 5'end of 12S) and five microsatellite loci. Both molecular markers gave concordant results with respect to the temporal pattern of genetic diversity within disturbed areas: a significant loss of genetic diversity was observed in burned areas compared to pristine areas, but there was an increase of observed genetic diversity within logged areas. Gene flow between *Upadia theda* populations appeared, furthermore, to be highly restricted at the geographic scales assessed (less than 100 km). Importantly, our genetic diversity results are in line with previous published studies on temporal and spatial patterns of butterfly species richness.

Human-induced changes in organism distributions and the evolution of insect diets

CW Fox
Department of Entomology, S-225 Ag Science Center North, University of Kentucky, Lexington, KY 40546-0091; cfox@uky.edu

Human activities have caused many species to expand their ranges and humans have introduced organisms into many new and often very novel environments. These human-induced changes in organism distributions create natural experiments with which we can study ecological and evolutionary processes that otherwise could only be inferred indirectly. I examine the consequences recent changes in plant distributions for the evolution of insect diet. Using a model system of diet evolution is seed beetles (Coleoptera: Chrysomelidae: Bruchinae) I examine evolutionary constraints on adaptation, the role of life history plasticity, and the importance community composition in mediating diet expansion and adaptation.

Investigating the genetic basis of phenotypic variation in *Drosophila* egg shell patterning.

LM Goering, G Gibson.
Box 7614, Dept of Genetics, North Carolina State University, Raleigh, NC 27695, USA. lmgoerin@unity.ncsu.edu

Patterning of the insect egg shell provides an excellent system for exploring the molecular basis of phenotypic variation. In *Drosophila melanogaster*, two dorsal-anterior respiratory appendages are produced in response to signaling through the *Epidermal growth factor receptor* (*Egfr*). Previous empirical and theoretical work implicates *Egfr* function in both intra-specific variation for dorsal appendage spacing on the eggshell, as well as inter-specific differences in dorsal appendage number and location. To test the hypothesis that genetic variation in *Egfr* contributes to variation in egg shell patterning, we have made use of naturally occurring intra-specific variation for dorsal appendage spacing as a model quantitative trait. An initial association study suggests that two common polymorphisms in *Egfr* are involved in trait expression. We will report on our efforts to confirm the involvement of these SNPs as well as efforts to identify additional loci that contribute to dorsal appendage spacing.

Microbial diversity in termite guts and their role in mineral transformation of soil

V Gomathi, K Ramasamy
Department of Agricultural Microbiology, Centre for Plant Molecular Biology, Tamil Nadu Agricultural University, Coimbatore - 641 003, India; kvgmathi@yahoo.co.in

Termite a macro invertebrate act as soil engineers in tropical ecosystem modifying the environment in both biotic and abiotic components. Termites have a major effect on the physical properties, increases water holding capacity, control soil erosion and also improves the crop sustainability. Polysaccharide producing bacteria *viz., Azotobacter* and *Beijerinckia* isolated from the foregut of termites which are responsible to fix atmospheric nitrogen. Soil aggregation improves the physical parameters - porosity (40.3%), bulk density (1.33 g/cc), particle density and water holding capacity (39.8%), chemical parameters – increased organic carbon (0.098%) and available nitrogen (70 ppm). Incorporation of *Beijerinckia* sp. in acid soils provides additional attributes for crop production and environmental sustainability. The fungi *viz., Termitomyces* isolated from the fungal garden involved in the degradation of leaf litter in terrestrial ecosystem and also used as edible mushroom due to its medicinal value. Hence termites, are not only pests, but also play an important role in sustaining soil ecosystems.

Costs and benefits of glandular trichomes in *Datura wrightii*: why be Sticky?

JD Hare
Department of Entomology, University of California – Riverside, Riverside, California, 92521-0001, USA; daniel.hare@ucr.edu

The relationship between costs and benefits of herbivore resistance predicts the evolution of resistance. *Datura wrightii* (Solanceae), is dimorphic for leaf trichome type. Some plants are covered with short, non-glandular trichomes ("velvety plants"), while others are covered by longer, glandular trichomes that secrete acyl sugars ("sticky plants"). Glandular trichomes confer resistance to many insects but not all. In the absence of herbivores, glandular trichomes are costly because sticky plants produce 45% fewer seeds than velvety plants. Sticky plants grow larger than velvety plants, and this may confer a competitive advantage. In a three-year field study, plant competition reduced plant seed production by 76 – 87% overall. Competition was asymmetrical and favored sticky plants because sticky plants produced 42% more seeds when competing with velvety plants than when competing with other sticky plants. Conversely, velvety plants produced 53% fewer seeds when competing with sticky plants than when competing with other velvety plants. Increased competitive ability is an additional potential benefit of the suite of traits associated with the production of glandular trichomes in *D. wrightii* and may contribute to the maintenance of the trichome dimorphism in natural *D. wrightii* populations.

The mating acceptance rate of female was higher for large males than for small males.
Males fought with other males over seeds using his fore legs, and the larger males won in all cases.
Females were attracted to some odour of male, and it was more effective when males were accompanied with seeds.

In this species, copulation interval is much longer in females, which makes OSR male-biased and competition over females severe. We conclude that males adopt Resource Defence Mating System, in which they defend seeds and/or area from other males, and attract females with some odour. Therefore, sexual selection favours larger male body size.

Wing shape, wing size and fitness in *Trichogramma* wasps

AA Hoffmann, UM Kolliker-Ott, F Bigler, DM Bennett
CESAR, La Trobe University, Bundoora, Victoria 3086; A.Hoffmann@latrobe.edu.au

Trichogramma wasps are tiny egg parasitoids widely released commercially to control moth pests. To evaluate the impact of wing shape and wing size on wasp fitness, we released wasps at a central point and compared the morphology of female wasps in a release sample with females that successfully located eggs of target hosts. Three species-host-plant combinations were evaluated: *T. carverae* attacking lightbrown apple moth (*Epiphyas postvittana*) on grapevines, *T.* nr. *brassicae* attacking *Helicoverpa* spp. on tomatoes, and *T. brassicae* attacking European corn borer (*Ostrinia nubilalis*) on corn. In each case, wing size was calculated as centroid size and wing shape was assessed using Procrustes superimposition. Wing size of wasps had an impact on field fitness in all cases, but in *T. brassicae* this association was complicated by the fact that wing size effects changed with distance from the release point and time since release. Wing shape had no impact on field fitness in *T. brassicae*, but did influence field fitness in *T. carverae* and *T.* nr. *brassicae*. Changes in wing shape associated with high fitness were different in the two situations. Rearing host influenced wing shape. In all cases shape effects appeared to be at least partly independent of allometry.

Clinal variation and the genetics of stress resistance

AA Hoffmann, L Rako, J Griffiths, J Shirriffs, R Hallas.
CESAR, La Trobe University, Bundoora, Victoria 3086; A.Hoffmann@latrobe.edu.au

Clinal variation for traits within species provide an outstanding resource to identify traits and genes under selection due to climatic factors. The most well known clines in insects are for body size, but clinal variation in a range of other traits has also been identified. One of the most intensively studied clines is the *Drosophila melanogaster* cline along the east coast of Australia where populations can be collected along a transect ranging from temperate Tasmania to tropical Far North Queensland. There are opposing patterns along this transect for resistance to cold and heat stress, as well as clinal variation for evasion of stressful winter conditions by altered patterns of egg production. We are now dissecting these patterns phenotypically and genetically to identify the physiological and genetic basis of adaptive shifts in these traits. QTL mapping following crosses between populations from cline ends indicate regions of the genome associated with traits, while QTL mapping and association studies from mid-latitude populations provide evidence for specific candidate locus-trait associations. We show how the performance of selected lines in field cages can validate traits under selection and how parallel clines in related species can validate the adaptive nature of the clines.

Cryoprotective dehydration – cold tolerance in permeable invertebrates

M Holmstrup
National Environmental Research Institute, Department of Terrestrial Ecology, Vejlsøvej 25, P.O. Box 314, DK-8600 Silkeborg, Denmark;
martin.holmstrup@dmu.dk

Besides the two well-known cold hardiness strategies, freeze avoidance and freeze tolerance, a third, and fundamentally different, mechanism to survive freezing temperatures by dehydration exists in organisms with highly permeable integument. When soil water in their environment freezes, they dehydrate due to the difference in water vapour pressure between the supercooled body fluids and the surrounding ice. Dehydration continues until vapour pressure equilibrium between internal fluids and the surrounding ice is reached. Recent studies have shown that this cold hardiness mechanism is widespread in soil invertebrates (e.g. Collembola) and coincides with high cuticular permeability to water. In such animals, supercooling capacity is of little or no importance for winter survival. Dehydration triggers physiological changes in Collembola, such as accumulation of sugars and polyols, expression of heat shock proteins, and shifts in the phospholipid composition of membranes. These changes are likely to promote cold tolerance in a dehydrated state.

Parasitoid foraging behavior in a life history context

G Hoogendoorn, P van der Velde, J van Alphen
PO Box 9516, 2300 RA, Leiden, Netherlands; hoogendoorn@rulsfb.leidenuniv.nl

In the 1980's a synthesis between Behavioral Ecology and Life History Theory was initiated by including life history parameters into state dependent optimal foraging models. To test these models, we collected empirical data showing that in the Australian parasitoid *Asobara persimilis* (Hymenoptera: Braconidae), genetic differences in life history traits correlate with differences in foraging behavior. *A. persimilis* occurs along the entire Australian east coast. We studied life span, patch time allocation and oviposition behavior of parasitoid populations from the Adelaide, Melbourne, Sydney and Brisbane regions. Life span increased along a gradient from Adelaide to Brisbane. Correlated to this, patch residence times and oviposition activity decreased along the same gradient. These results are in accordance with foraging models predicting a negative correlation between life expectancy of time-limited foragers and the degree to which they should exploit patches of a resource with a clumped distribution.

Exploring winter energy consumption as a limitation to the southern range limit of the goldenrod gall fly (*Eurosta solidaginis*) in late goldenrod (*Solidago gigantea*)

JT Irwin, WG Abrahamson
Department of Biology, Bucknell University, Lewisburg, PA USA 17837; jirwin@bucknell.edu

The goldenrod gall fly, *Eurosta solidaginis*, is a gall-forming insect that has diverged into two host races on its hosts *Solidago gigantea* and *S. altissima.* These host races show appreciable reproductive isolation and genetic differentiation. Both host plants range from Ontario to Florida in eastern North America. Flies of the *altissima* host race can be found virtually everywhere its host plant is present, but *gigantea* flies are only present in the northern tier of its host's range. We performed a series of experiments to identify factors restricting the *gigantea* host race to northern locales. Correlation analysis suggests that the southern limit of *gigantea* flies is constrained by warm winters, likely because warmth increases energy consumption. *Gigantea* flies are smaller and less fecund because *S. gigantea* senesces earlier (thus ceasing feeding earlier in the autumn) than does *S. altissima.* Being smaller, the *gigantea* host race has less energy to support metabolism during winter and egg production the following spring. We will present our ongoing efforts to produce a model of winter energy use for goldenrod gall flies across their range, and consequent range limitations. Our work will stand as a model for predicting shifts in geographic distributions with global climate change.

Sources of variation in costs of plant resistance to herbivores

J Koricheva
Section of Ecology, Department of Biology, University of Turku, FIN-20014, Turku, Finland; julkoric@utu.fi

A meta-analysis of 70 studies assessing the relationship between plant resistance and fitness has been conducted to examine the importance of several sources of variation in the fitness cots of resistance. The greatest costs were observed under uncontrolled environmental conditions in the field, at high levels of nutrient availability, and for defenses associated with alkaloids and phenolics. The prevalence of costs in the field and their persistence in the presence of herbivores both imply that fitness costs may arise not only due to trade-offs in the allocation of common limited resources between defense, growth and reproduction within an individual plant (direct allocation costs), but also through interactions between plants and external factors in their environment (ecological and opportunity costs). Cumulative meta-analysis revealed the evidence of publication and citation bias in studies on costs of plant resistance. The early studies conducted in 1975-1990 reported significant negative correlations between defense and fitness measures. However, after publication of several theoretical studies that have provided theoretical justification for the absence of costs, the magnitude of the reported costs decreased and became non-significant in the early 1990s. Furthermore, studies reporting significant costs of resistance received more citations than those, which reported no evidence of costs.

The evolution of egg retention and sex allocation: a study of facultatively ovoviviparous thrips

BD Kranz, T Shibata, S Okajima, K Tsuchida DC Morris
"School of Botany and Zoology, Australian National University, Canberra ACT 0200, Australia; armeniaca@bigpond.com (email addresses may be updated)"

Idolothripine thrips provide an unparalleled opportunity for investigating the evolution of reproduction. In many species, females are facultatively ovoviviparous/viviparous, and individuals choose among egg laying, live birth or both. As thrips are haplodiploid, females have some control over the sex of their offspring. We present our preliminary phylogeny and contrast work for the subfamily, and a case study of the Japanese idolothripine, *Bactrothrips brevitubus*. In this species, both sexes are produced by oviparity but only males are produced by ovoviviparity, so that sex allocation and reproductive mode act in tandem. Local resource competition between females for food and egg-laying sites may select for ovoviviparity, as females can retain their eggs until a better rearing site is located. Predatory mites could also select for ovoviviparity, as they consume the eggs but are non-fatal to larvae and adults. Population-wide sex ratios are generally unbiased, but our DNA and life history data indicate that the sex ratios are not Fisherian and are split according to the dominant reproductive mode in a patch. We consider how females tradeoff the best reproductive mode and sex allocation strategies. More broadly, we consider how egg retention and sex allocation may have coevolved in the subfamily.

Rapid cold-hardening: mechanisms and ecological significance

RE Lee
Department of Zoology, Miami University, Oxford, Ohio 45056 USA; leere@muohio.edu

More than 15 years ago we reported a rapid cold-hardening (RCH) response that protects various species of insects and related taxa against cold shock (non-freezing) injury. This swift acclimatory response to a brief exposure at a moderately low temperature allows the insect to survive a subsequent cold shock that would otherwise be lethal. Although little is known about the physiological mechanisms underpinning this response, recent evidence suggests that modifications of membrane fluidity and stress proteins play a role. RCH can also occur in isolated cells directly exposed to low temperature. Originally, we hypothesized that the RCH response allowed insects to enhance "instantaneously" their cold tolerance in a thermally variable environment. Recently, we obtained strong support for this hypothesis by demonstrating that RCH occurs under ecologically relevant cooling rates and diurnal thermoperiods. Furthermore, the rapid acclimatory response is not restricted to cryoprotection, but also functions to enhance organismal function at multiple levels, including courtship and mating, in response to environmental cooling at moderate to high temperatures. Thus, it is clear that RCH has broad ecological significance because it allows insects to continuously fine-tune organismal response to match even modest changes in environmental temperature that occur throughout the year.

Costs and benefits of resistance and tolerance to herbivores: the importance of gene x environment effects

RL Lindroth, MT Stevens
Dept. of Entomology, 237 Russell Labs, Univ. of Wisconsin, Madison, WI 53706, USA; linoth@entomology.wisc.edu

Trembling aspen (*Populus tremuloides*) is the most widespread tree species in North America and the most genetically variable plant species known to science. Extraordinary genetic variation of this clonal species extends to traits such as rates of growth and levels of chemical (salicylates and tannins) defense. Given that aspen is routinely subject to expansive defoliation events (e.g., large aspen tortrix, forest tent caterpillar) the question arises as to why defense polymorphisms persist in natural populations, i.e., why do not all genotypes express maximum levels of defense? The emerging answer involves both environmental and ontogenetic influences on the expression of chemical defense. For young aspen trees, high commitment to chemical defense incurs a significant cost in terms of growth in resource-poor, but not resource-rich, environments. Thus, in the absence of herbivory, highly defended trees are disadvantaged because slow growth may limit competitive ability. As trees mature, salicylate-based defenses tend to decline, extensive root systems develop, and trees appear to shift their defensive strategy to tolerance. Tolerance itself is also genetically variable and influenced by resource availability.

Sexual isolation in North American fruit flies: reinforcement, reproductive character displacement and the role of courtship song

ME Lineham, MG Ritchie
54 Johnston Street, Leeds, W.Yorks, LS6 2NQ, UK; lineham@tiscali.co.uk

Differences in the courtship song of *Drosophila* males, produced by wing vibrations, have been implicated in sexual isolation between several species and races through female discrimination. The range of *Drosophila persimilis,* California, Oregon and Washington State, is completely contained within that of its sibling species *D. pseudoobscura* which extends as far east as Texas. The species are morphologically identical but sexually isolated. Although male courtship appears to be indiscriminate, females of these species discriminate against mating with heterospecific males. Females from areas where they co-occur discriminate more than those collected from allopatric locations. This has been suggested to be an example of speciation by reinforcement. Despite identifying species differences in both major song parameters, interpulse interval (IPI) and intrapulse frequency, previous work has suggested that these song differences are not responsible for sexual isolation. In this study playback experiments of synthetic *D. pseudoobscura* and *D. persimilis* song demonstrate clearly that females do indeed discriminate between conspecific and heterospecific courtship song. Reinforcement may be as a result of a narrowing in female preferences in sympatry or of reproductive character displacement (RCD) in a male courtship trait. The courtship songs of *D. pseudoobscura* from both sympatric and allopatric locations are examined for evidence of RCD.

Adaptive responses by Australian burrowing cockroaches to fluctuating Neogene and Pleistocene environmental conditions: evolution in parallel and reverse?

N Lo, K Maekawa, H Rose
[1]DIPAV, Sezione di Patologia Generale and Parassitologia, Universita' di Milano, Via Celoria 10, Milan 20133 Italy; nathan.lo@unimi.it

Over the last ~15 million years, many areas in Australia once covered by rainforest have been transformed into zones of savanna, shrubland and sclerophyll forest, primarily due to long periods of arid climatic conditions. Understanding how the ancient ancestors of Australia's unique extant fauna responded to these changes is of singular interest. We have recently provided phylogenetic evidence that Australian-native soil-burrowing cockroaches evolved from wood-feeding ancestors following an invasion of the latter from Asia into Australia. The transition from wood to soil burrowing was most likely a result of aridification, which would have led to the disappearance in many areas of wood suitable for burrowing. We have extended our study to include all known soil-burrowing cockroach species, as well as most Australian burrowing cockroach species. Phylogenetic analyses based on mitochondrial COII data suggest that the soil-burrowing habit may have evolved on more than one occasion. An alternative explanation is that it evolved only once, but has been followed by 're-evolution' of the wood-burrowing habit. Approximate times of divergence between key taxa will be estimated using molecular dating methods, allowing a preliminary examination of whether these transitions occurred at similar or different times.

Does predation maintain plasticity in *Bicyclus anynana*?

A Lyytinen, PM Brakefield, L Lindström, J Mappes
Department Of Biological And Environmental Science, Po Box 35, Fi-40014 University Of Jyväskylä, Finland; alyytine@bytl.jyu.fi

The butterfly *Bicyclus anynana* exhibits phenotypic plasticity involving the wet season phenotype which possesses marginal eyespots on the ventral surface of the wings and the dry season form that lacks these eyespots. We examined the adaptive value of phenotypic plasticity of *B. anynana* in relation to the defence mechanisms of crypsis and deflection. We assessed the visibility differences between spotless and spotted butterflies against backgrounds of brown (y season) or green (wet season) leaves. Spotless butterflies were highly cryptic and less predated by adult bird predators than spotted ones when presented against brown leaf litter. The advantage of crypsis disappeared in the wet season habitat as both forms were equally visible. In later experiments, naïve birds presented with resting butterflies in the wet season habitat tended to learn more rapidly to capture spotless butterflies, suggesting a slight selective advantage of possessing eyespots. Marginal eyespots increased significantly the escape probability of butterflies that were attacked by naïve birds compared to adult birds, although there were no differences in prey capture success within naïve predators. Our results show that natural selection acts against eyespots in the dry season favouring crypsis whereas in the wet season it may favour eyespots as deflective patterns.

The peppered moth: decline of a Darwinian disciple

MEN Majerus
Department of Genetics, University of Cambridge, Downing Street, Cambridge, CB2 3EH, UK; mike.Majerus@gen.cam.ac.uk

The evolution of melanism in the peppered moth, following the industrial revolution in Britain, is the most cited example of an observed heritable change that resulted from Darwinian evolution. The reason for this is that the change was visually obvious, was observed, and could be explained by Darwin's central mechanism of evolution - natural selection. Further, the reason that the black form was fitter than the pale form was easy to understand: against lichen denuded and smoke blackened bark, the black moths were better camouflaged, and so were less often found and eaten by birds. Recently creationists have seized upon design flaws in Bernard Kettlewell's classical experiments in the 1950s. They claim that these flaws, and more recent allegations of fraud aimed at Kettlewell and a conspiracy of silence among evolutionary biologists, particularly in Britain, fatally undermine this cornerstone of Darwinian evolution, and therefore the basic theory of evolution by natural selection. Many schools in the U.S.A. have dropped the peppered moth case from biology teaching, and pressure is growing elsewhere. Most biologists who have worked on the peppered moth take the view that although Kettlewell's experiments did contain design flaws, these flaws would only have affected the quantitative accuracy of his tests; not the qualitative interpretation that differential bird predation has played a major role in the evolution of melanism in the peppered moth. The question I will address is whether melanism in the peppered moth should still be regarded as an example, par excellance, of Darwinian evolution in action.

Origin and evolution of seasonal adaptations: ground crickets in tropical, subtropical and temperate climatic conditions

S Masaki
Matsubara Higashi-1-12-13, Hirosaki, 036-8141, Japan; Sinzo.Masaki@mb4.seikyou.ne.jp

The ground cricket species complex, *Dianemobius nigrofasciatus* and *D. fascipes*, is probably of tropical origin and widely distributed from tropical to temperate regions in East Asia. It might be surmised that as peripheral populations dispersed northward, they encountered gradual changes in climatic conditions, evolved locally different types of seasonal life cycle, and egg diapause became the core of adaptation to overwintering in the northern climate. I pursued the origin of egg diapause and the associated patterns of nymphal development in local populations at low (tropical and subtropical) latitudes and found dual responses (egg diapause and delayed nymphal development) to short days in some of them. In other tropical populations a few eggs showed delayed hatching. The occurrence of such eggs might represent 'life-cycle polymorphism' to cope with unpredictable risks after hatching and might be the source of evolution for egg diapause and overwintering in the north.

Ontogenetics of QTL: the genetic architecture of trichome density over time in *Arabidopsis thaliana*

R Mauricio
Department of Genetics, Life Sciences Building, University of Georgia, Athens, GA 30602-7223 USA

Although much is known about the molecular genetic basis of trichome development in *Arabidopsis thaliana*, less is known about the underlying genetic basis of continuous variation in a trait known to be of adaptive importance: trichome density. The density of leaf trichomes is known to be a major determinant of herbivore damage in natural populations of *A. thaliana* and herbivores are a significant selective force on genetic variation for trichome density. A number of developmental changes occur during ontogeny in *A. thaliana*, including changes in trichome density. I used multiple interval mapping (MIM) analysis to identify QTL responsible for trichome density on both juvenile leaves and adult leaves in replicate, independent trials and asked whether those QTL changed with ontogeny. In both juvenile and adult leaves, I detected a single major QTL on chromosome 2 that explained much of the genetic variance. Although additional QTL were detected, there were no consistent differences in the genetic architecture of trichome density measured on juvenile and adult leaves. The finding of a single QTL of major effect for a trait of known adaptive importance suggests that genes of major effect may play an important role in adaptation.

Regulation of a plant allelochemical-inducible detoxification gene via the aryl hydrocarbon response cascade

CM McDonnell, R Petersen Brown, MA Schuler, MR Berenbaum
Department of Entomology, 320 Morrill Hall, University of Illinois Urbana-Champaign, Urbana, IL 61801; cmcdonne@uiuc.edu

The promoter of *CYP6B1*, a cytochrome P450 monooxygenase (P450s) that metabolizes furanocoumarins (i.e. xanthotoxin) found in the specialized diet of the swallowtail caterpillar *Papilio polyxenes*, utilizes several elements for basal and xanthotoxin-inducible expression, including the xenobiotic response elements to xanthotoxin (XRE-Xan) and aryl hydrocarbons (XRE-AhR). In mammalian systems, XRE-AhR mediates induction of *CYP1A1* by aryl hydrocarbons via the aryl hydrocarbon receptor (AhR) and its heterodimeric partner, ARNT. To determine if AhR-like and ARNT-like proteins from *Drosophila melanogaster*, spineless-aristapedia (Ss) and tango (Tgo), are capable of activating *CYP6B1* transcription via its XRE-AhR element, Ss and Tgo proteins were coexpressed with the wildtype *CYP6B1* promoter:CAT construct in an Sf9 cell transfection system. These studies indicate that basal and xanthotoxin-inducible expression are significantly increased in the presence of Ss and that xanthotoxin-inducible expression is increased in the presence of Tgo. Coexpression of Ss/Tgo with the *CYP6B1* promoter constructs containing mutations in the XRE-Xan or XRE-AhR elements indicate that mutations in the XRE-AhR element reduce basal and xanthotoxin inducible expression but retain low levels of activation in the presence of Ss/Tgo. These results suggest that the *CYP6B1* promoter employs conserved elements of the aryl hydrocarbon regulatory cascade for basal and xanthotoxin-inducible expression that are shared between vertebrates and invertebrates (XRE-AhR).

"*Drosophila melanogaster* gene expression in response to a virulent endosymbiont "

E McGraw, S O'Neill
Department of Zoology & Entomology, School of Life Sciences, University of Queensland, St. Lucia, QLD 4072 Australia; e.mcgraw@uq.edu.au

Wolbachia pipientis is an obligate intracellular bacterium present in a wide range of insect species. While the bacterium is known for its ability to manipulate host reproductive biology, most strains cause little direct harm to host tissues. One exception is a strain called "popcorn" that infects *Drosophila melanogaster*. As the fly ages the bacterium replicates to large numbers, leading to rupture of host cells and shortened insect lifespan. This over-replication is aberrant in comparison with other *Wolbachia* infections whose densities remain stable or decline with insect age. Previous work indicates that *Wolbachia* infections do not induce or actively suppress an innate immune response in *Drosophila melanogaster*. Because the popcorn infection leads to cell rupture we predicted that this strain would likely induce host defenses. Using a microarray approach we have examined the effect of popcorn infection on host gene expression as the host ages. Overall, gene expression decreases with age in response to popcorn infection. The bacterial specific response resulting in antimicrobial peptide production is not activated. The most common class of upregulated genes, however, were serine proteases; including elastases and trypsins. Serpins, the regulators of these proteases are also highly expressed, as are other genes encoding general defense response proteins.

Evolutionary dynamics of *w*Au-like *Wolbachia* strains in Neotropical *Drosophila* species

WJ Miller
Center of Anatomy and Cell Biology, Medical University of Vienna, AG General Genetics, Währingerstr. 10, A-1090 Vienna, Austria;
wolfgang.miller@meduniwien.ac.at

We have screened 29 American strains of the Neotropical species *Drosophila willistoni* for the infection status with the -proteobacterium *Wolbachia wsp* PCR diagnostics and Southerns blots. Although *Wolbachia* is absent in older strains of *D. willistoni* collected before the 1970s more recent samples derived from natural populations all over the American continent are universally infected with the A-group *Wolbachia* strain named *w*Wil. *w*Wil of *D. willistoni* is identical to *w*Au of *D. simulans*. Like *w*Au in *D. simulans w*Wil is not inducing cytoplasmatic incompatibility (CI) in *D. willistoni*. In contrast to *w*Au a strain infecting both germline and somatic tissues *w*Wil is exclusively targeting the primordial germline cells of *D. willistoni* embryos. This tissue tropism of *w*Wil and its temporal and spatial biogeographically pattern strongly support (*i*) a long-term evolutionary relationship between *w*Wil and its host species *D. willistoni* in some isolates; (*ii*) its modern day infective spreading throughout *D. willistoni* American populations, and (*iii*) our assumption that this Neotropical *Drosophila* species can be regarded as the most likely donor source for a recent *Wolbachia* infection of immigrating *D. simulans* with the strain *w*Au. Furthermore new *Wolbachia* strains derived from Neotropical *saltans* group species do harbor polymorphic *w*Au-like *Wolbachias*.

Mechanism and evolution of caste polyphenism in social insects

T Miura
Department of Biology, Graduate School of Arts and Sciences, University of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo 153-8902, Japan; cmiu@mail.ecc.u-tokyo.ac.jp

Phenotypes of organisms are not determined completely genetically, but vary according to environmental factors (phenotypic plasticity). Some organisms express several discrete adaptive phenotypes (polyphenism). Social insects possess a few types of individuals (castes) in their colonies, to which tasks are allocated. Here, I introduce our case studies related to caste polyphenism in ants and termites. We focus on the developmental mechanisms of cast-specific characters, such as alate wings or soldier mandibles. In ants, the developmental fate of caste is determined in the early stage of postembryonic development, but apoptotic degeneration occurs in the wing primordia of future workers. As apoptotic wing degeneration was observed in two phylogenetically distant groups of ants, this phenomenon is suggested to be common in many ant species. On the other hand, all termite species possess distinct sterile soldiers, which have specific morphology suitable for defense. We isolated genes related to soldier differentiation and analyzed the expression profiles of those genes, in order to understand the mechanism of caste differentiation and the link between molecular and social evolution. I will compare these studies, in terms of the alteration of body plan in response to environmental signals, and discuss the evolutionary process of the interaction between ontogeny and environment.

Possible reproductive isolation as an indirect consequence of adaptation to different environments: pleiotropic effect of clock genes

T Miyatake
Faculty Of Agriculture, Okayama University, Okayama 700-8530, Japan; miyatake@cc.okayama-u.ac.jp

Clock genes pleiotropically controlling development time, circadian rhythm and time of mating can cause an allochronic reproductive isolation in a model insect, the melon fly *Bactrocera cucurbitae*, which mate once a day at dusk. A series of experiments including artificial selection and behavioural analyses showed that flies with shorter developmental and circadian periods (ca 22 h of locomotor activity rhythm) mated 5 h earlier in the day than those with longer periods (ca 30 h). Mate choice tests demonstrated significant pre-mating isolation between populations with short and long circadian periods. Pre-mating isolation did not occur when the mating time was synchronized between the two populations by photoperiodic controls, indicating that reproductive isolation is due to variations in the time of mating and not any unidentified ethological difference between the two populations. The fluctuation of *per* gene mRNA expression under DD is closely correlated to the locomotor rhythm in each population with short and long periods in *B. cucurbitae.* The results suggest that a clock gene might be involved in the allochronic pre-mating isolation. I discuss allochronic reproductive isolations as an indirect consequence of adaptation to different environments in view of a pleiotropic effect of clock gene controlling time-related traits.

The development and evolution of novel phenotypes: a case study on beetle horns

AP Moczek
Center for Insect Science and Department of Molecular and Cellular Biology, University of Arizona, 1007 East Lowell Street, Tucson AZ, 85721, USA;arminmo@email.arizona.edu

How do ecological, developmental, and genetic mechanisms interact in the origin and diversification of novel phenotypes? This question is at the center of my research on the evolution and development of beetle horns, a morphological novelty that upon invention has undergone dramatic diversification on a variety of levels. Horn expression is modulated in the context of alternative male morphologies, sexual dimorphisms, between-population differences in allometric scaling, and between-species differences in the number and location of horn development. Combining morphometric, candidate-gene, and ecological approaches my research aims to integrate a genetic and developmental understanding of phenotype expression into the behavioral and ecological contexts within which different phenotypes function. In my talk I will first focus on how a developmental genetic understanding of horn expression can inform us about the origins of non-linear scaling relationships, sexual dimorphisms, and the parallel gain and loss of horns in similar and different body regions. I will then explore which ecological and social conditions contribute to and guide evolutionary changes in beetle horn development. Beetle horns and horned beetles emerge as an outstanding model system for studying the interplay between ecological and developmental mechanisms is the origins of phenotypic diversity.

Attempts to search for host genes affected by intracellular symbiotes in their expression level: transcriptome analyses with silkworm cDNA microarray

Y Nakamura, Y Kato, TJ Kurtti, S Imanishi, K Mita, T Gotoh, H Noda
Faculty of Agriculture, Ibaraki University, Ami, Ibaraki 300-0393, Japan; icc05598@nifty.com;

Arthropods harbor intracellular bacteria, such as *Wolbachia* and *Cardinium* (CFB [*Cytophaga-Flavobacterium-Bacteroides* phylum] bacteria). These facultative bacteria cause reproductive alteration in their hosts such as thelytokous parthenogenesis, male killing, feminization and cytoplasmic incompatibility. As a part of the attempt to investigate the effects of these bacteria on hosts, we examined gene expression in bacteria-infected and non-infected cells. *Wolbachia* of the small brown planthopper *Laodelphax striatellus* and Is-CFB (CFB bacteria isolated from *Ixodes scapularis*) were cultivated in silkworm cell lines (BmN4 and NIAS-Bm-aff3). A cDNA microarray, which contains about 6,000 cDNA clones of the silkworm, was used to identify the genes that were affected in the expression level by the infection of *Wolbachia* or Is-CFB. No clearly up-regulated genes were found by *Wolbachia* infection, but one transcript was down-regulated. Is-CFB infection raised expression level of a few genes.

Female genitalia and sexual selection: a morphological study of cockroach genitalia

MD Olsen, S Frank, R Meier, K-D Klass
Department of Entomology, Zoological Museum, University of Copenhagen, Universitetsparken 15, 2100 Copenhagen East, Denmark;
marie_djernaes@hotmail.com

The male genitalia of Hexapoda are often complex and species-specific in form. Several hypotheses have been proposed to explain this. This study tests three hypotheses; Lock-and-Key, Female Choice and Male-Female Conflict by studying the genitalia of four species of cockroaches. The interacting parts of cockroach genitalia are on the morphological outer side of the body and are partly sclerotised in both sexes. Furthermore, cockroach male genitalia are highly asymmetric and the direction of asymmetry has been reversed several times. These traits make cockroach genitalia easily accessible, morphologically variable, and thus highly suitable for the study of genitalic evolution.
Contrary to "Lock-and-Key," the asymmetry of the male genitalia is not matched by asymmetry in the female genitalia. As predicted by "Female Choice", mechanoreceptors are found in the areas of genitalic interaction, but a reversal of male genitalia asymmetry does not influence their placement. There is quite strong evidence against "Male-Female Conflict" as the female genitalia facilitate gripping by the male through a ledge or other holding points. However, in water-striders "Male-Female Conflict" is well documented. This suggests that none of the proposed hypotheses can explain genitalic evolution in the Hexapoda by itself, thus the ultimate explanation must be something different.

Genetic diversity and oviposition host preference of *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae) associated with four crops in Ghana

BA Omondi, D Obeng-Ofori, EY Danquah , SK Offei
African Regional Postgraduate Programme in Insect Science (ARPPIS), University of Ghana, Legon; omondiaman@yahoo.com

The genetic and behavioural diversity of populations of the polyphagous virus vector, *B. tabaci* infesting cassava, tomato, garden egg and okra in Ghana were assessed. Seventy-six individuals collected from four hosts in three locations were screened by RAPD-PCR, using five primers (OPA 02, OPB 08, OPC 05, OPD 16 and OPI 16). Cluster analysis using the Dice coefficient revealed two genetic clusters at the 45% level of similarity associated with cassava and okra. Crop association contributed more to the observed variability than geographical isolation. Two-choice oviposition preference bioassay was done in a petri-dish cage. Cassava whiteflies significantly ($p < 0.01$) preferred cassava to any other host, but preferred garden-egg or tomato in the absence of cassava. Tomato populations significantly ($p < 0.05$) preferred tomato and okra, while okra whiteflies did not oviposit on cassava. These results corroborate the existence of two distinct biotypes: the cassava biotype and the polyphagous biotype. Tomato, garden egg and eggplant are potential common hosts for the two and may be reservoir hosts for under intensive systems or in rotation programmes. It is suggested that whitefly management on the main hosts should accommodate the possible spill of resistance from these hosts into cassava and vegetable crops.

Molecular characterization of different biological forms of *Anopheles stephensi* **Liston in Iran**

F Yaaghoobi, MA Oshaghi, MR Abaei, K Akbarzadeh, N Noorjah, A Iranbakhsh, H Vatandoost
Dept. of Medical Entomology, School of Public Health and Institute of Health Researches, University of Tehran Medical Sciences, PoBox: 6446 Tehran 14155, I.R.Iran; oshaghima@yahoo.com

Malaria is still one of the main health problems in south and southeast provinces of Iran. Mosquitoes of *Anopheles stephensi* are the most important malaria vector in these regions. Based on egg ridges three biological forms of type, intermediate, and *mysorensis* has been reported within this species which shows different vector capacity and competence. Here we study the sequence variation of 1500 bp of mtDNA cytochrome oxidase subunit I (COI) of these biological forms to find molecular marker for diagnostic purposes. Different biological forms were collected from different parts of the country and were subjected to PCR-RFLP or PCR sequencing assays. Results of PCR-RFLP showed no polymorphism between different biological forms or populations. This was confirmed by comparing 1400 bp sequences of COI and COII regions which showed a high similarity between forms. However there were two haplotypes between populations of *mysorensis* form. These findings are in agreement with previous hybridization, cytological, and molecular studies stating a great gene flow between populations of *An. stephensi.*

mtDNA PCR-RFLP and PCR sequencing revealed significant genetic variation among *Anopheles superpictus* populations in Baluchistan, Iran

K Shemshad, MA Oshaghi, MR Yaghobi-Ershadi, H Vatandoost, MR Abaei, K Akbarzadeh, N Noorjah, H Laddoni
Dept. of Medical Entomology, School of Public Health and Institute of Health Researches, University of Tehran Medical Sciences, PoBox: 6446 Tehran 14155, I.R.Iran; oshaghima@yahoo.com

Mosquitoes of *Anopheles superpictus* are one of the main malaria vectors in Iran and present in most parts of the country. This taxa play different rules in malaria transmission in different areas of its geographical distribution. This study has been conducted to investigate rate of genetic variation between different populations of *An. Superpictus* in Baluchistan, the most important malarious region in Iran. A portion of about 1512 bp long of mitochondrial DNA cytochrome oxidase subunits I and II were amplified and were assayed by either RFLP or direct sequencing. Analysis RFLP of COI-II and sequences of 750 bp of 3' end of COI gene showed that there are two main groups within specimens. Rate of sequence variations were up to 5 percent which is far exceeding than inter-population or -species variation. It is suggested that presumably this species is a group species. The results of this study which is the first molecular study on *An. superpictus*, needs to be confirmed by further molecular, cytological, and morphological studies and checked with available epidemiological data to reveal the relationship between these haplotypes and malaria transmission in each locality.

Micromalthus debilis LeConte and its varied symbionts

MA Perotti, DK Young, HR Braig
[1]School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK; bssc13@bangor.ac.uk

The wood-boring telephone pole beetle, *Micromalthus debilis,* is the only member of the primitive family Micromalthidae. It has fascinated entomologists for years because of its unique life history features such as haplodiploidy, parthenogenesis, paedogenesis, and matriphagy. Many aspects of its biology still remain a mystery due to complications in rearing and manipulating the fragile individuals and broods. In spite of the scarce experimental data available, speculations on the evolutionary biology of this insect have been plentiful; for example, obligate matriphagy by males has been linked to the presence of a non-functional nutritional endosymbiont suggesting that *Micromalthus* is a case of Hamilton's hypothesis about the evolution of haplodiploidy, and the high cost of producing males has created a selective advantage for cyclic thelytoky. Using microscopical and molecular tools we are screening the symbiotic load of the different larvae and adults of *Micromalthus.* Several symbionts have been identified so far, including renowned reproductive parasites. We discuss the life history traits and evolutionary biology of this beetle in relation with our results and the comprehensive early literature.

Rapid cold hardening increases aphid survival at low temperatures.

SJ Powell, JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham, UK, B15 2TT; SJP822@Bham.ac.uk

Most studies on insect cold hardiness have focused on seasonal adaptations occurring within the overwintering stage of an insect's life cycle, triggered by decreasing temperature and photoperiod from summer through autumn to winter. Due to their short generation times, an aphid that enters winter is unlikely to be the same individual that survives until spring. For this reason, although aphids are able to cold harden when reared at lower temperatures (10° and 5°C), the ability to rapidly cold harden may be relatively more important than in other longer-lived overwintering insects, where seasonally-induced cold hardening is the dominant response. This study assesses the effects of sub-zero temperatures on the mortality of nymphs and adult *S. avenae*, provides evidence of rapid cold hardening in *S. avenae* and investigates the ecological costs of rapid cold hardening in terms of effects on development, longevity and fecundity. The hypothesis that rapid cold hardening can be induced during the cooling phase of natural diurnal temperature cycles is supported. Rapid cold hardening increases survival and extends the lower lethal temperature, allowing aphids to acquire maximum cold hardiness when it is most needed.

Using geometric morphometrics to investigate wing dimorphism in males and females of hymenoptera – a case study based on the genus *Tachysphex* (Sphecidae: Larrinae)

E Pretorius
BMW building, Room 6.27. Faculty of Medical Sciences, PO Box 2034, University of Pretoria, Pretoria, 0001 South Africa; resia.pretorius@up.ac.za

Traditional morphometrics are currently complimented by an additional statistical method, namely geometric morphometrics which is based on the quantification of shape using *x,y* coordinates. It is characterized by the obtaining of an exact geometric description of the morphology, and the ease to visually determine which landmarks are responsible for differences/similarities. The amount of variation between the forewings of males and females of the genus *Tachyshpex* (Hymenoptera) is investigated here. The research investigates the extent of morphological similarities/differences between males and females of the same species, in order to make recommendations regarding inclusion of both sexes in a systematic or geometric morphometrics study. Mantel statistics revealed a good correlation between the male and female dataset, and although visual analysis of the RWA plots of the two sexes indicated significant correlations between sexes of the same species, differences in the position of the species clusters suggests that sexual dimorphism in wings are present. Results from the thin-plate spline analysis of the mean shape of the male and female dataset revealed which landmarks are responsible for the differences. It is concluded that, in an analysis of members of a genus, only one of the sexes be used in the analysis, as small-scale differences may influence the results.

Glue protein in *Drosophila*: protein with an obscure function?

SR Ramesh
Drosophila Stock Centre, Department of Studies in Zoology, University of Mysore, Manasagangotri, MYSORE – 570 006, India; srramesh2000@yahoo.com

Perusal of literature from the first description of larval salivary gland secretory protein (Fraenkel & Brookes, 1953) in *Drosophila* namely "Glue Protein", to the recently published article suggests that the glue 'helps' pupa to 'fix' to a substratum. Several lines of genetic and biochemical investigations on this tissue specific and stage specific protein in different species/subspecies of *Drosophila nasuta* subgroup has revealed that (a) abundant glycosylated protein is synthesized (b) most protein fractions are synthesized by co-dominant X-chromosomal gene/s (c) SDS-PAGE mobility differences of major glue fractions probably reflect differences in amino acid composition (d) there is exuberant SDS-PAGE pattern polymorphism (e) there is heteroselection of X-chromosomal glue gene/s in females in the natural populations of *D. nasuta nasuta* and *D. sulfurigaster neonasuta*. Morphometric, quantitative and behavioural studies involving several *Drosophila* species revealed absence of correlation between larval/pupal/gland size and the quantity of secretions. Species producing abundant glue prefer to pupate in the medium, those producing lesser quantities pupate on solid surface, while those producing negligible quantities, pupate in cotton plugs. These results suggest that the larval salivary gland secretions in *Drosophila* have other functions, in addition/rather than to help the pupa to 'fix' to a solid surface.

The evolution of sexually-selected traits in the sand cricket, *Gryllus firmus*

DA Roff
Department of Biology, University of California, Riverside, California, 92521, USA; Derek.roff@ucr.edu

Sexually-selected traits typically consist of components of morphology, physiology and behavior. This is particularly evident in Orthoptera where males call to attract females. Male call song is determined by the morphology of the sound-generating structure, physiological costs of calling and female behavior. In this talk I explore the evolution of these components in the cricket, *Gryllus firmus.* I discuss the genetic basis of the morphological components that generate the song, the song components themselves and the underlying physiology. I show that female choice is determined by both presence/absence of song and by song components. Because of the physiological costs of calling, macropterous males call substantially less than macropterous males and attract fewer females. Thus sexual selection can act not only on the components of the traits involved in female attraction but also on traits necessary for dispersal and hence can potentially have far-reaching affects on fitness. A common garden experiment using three geographically separate populations shows that the components underlying female choice vary among populations. Further, comparison of female choice in a population maintained in the lab for twenty years shows that this choice is stable over time, suggesting that it is maintained due to pleiotropy and not linkage disequilibrium.

The evolution of genetic architecture in response to environmental change

DA Roff
Department of Biology, University of California, Riverside, California, 92521, USA; Derek.roff@ucr.edu

Environments are highly variable in both space and time. Insects, being ectothermic are particularly sensitive to changes in their thermal environment. Evolutionary response to changes in the thermal environment are contingent on the presence of available additive genetic variation and the direct effect of the environment on the expression of this variation. I discuss two methods of investigating these factors: the experimental manipulation of temperature and the analysis, using a common garden experiment, of genetic variation along clinal gradients. For the experimental work I describe work with the cricket *Gryllus firmus*, showing that changes in temperature can have highly significant effects on phenotypic expression but relatively little on the genetic variance-covariance matrix. However, there are differences between wing morphs suggesting that these morphs show differential canalization responses to temperature change. For the work on geographic variation I describe common garden experiments conducted on two species of grasshopper (*Melanoplus* spp). These experiments show that the clinal variation in phenotypic traits is matched by clinal variation in genetic variation and that the differences among populations is concordant with previous phylogenetic analysis.

Reinvestigation of the mechanism of the female–biased sex ratio in *Wolbachia*–infected *Ostrinia furnacalis* (Lepidoptera: Crambidae)

H Sakamoto, H Hoshizaki, D Kageyama, S Tatsuki Y Ishikawa
Department of Agricultural and Environmental Biology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Yayoi, Tokyo 113–8657, Japan; hirowol@yahoo.co.jp

Wolbachia-infected females of *Ostrinia furnacalis* and *O. scapulalis* produce all-female offspring. The all-female production was interpreted as feminization of genetic males, since the antibiotic elimination of *Wolbachia* resulted in all-male offspring. However, in *O. scapulalis*, observation of the sex chromatin suggested that male-killing is the cause of the all-female production and that female-specific death is the cause of the all-male production after *Wolbachia* elimination. In the present study, we observed chromosomes of infected and cured insects of *O. furnacalis* to reinvestigate mechanism of the all-female production in this species. Infected female adults were found to be genetic females based on the presence of the female-specific sex chromatin. Both genetic males and females were included in the hatched larvae in the broods derived from infected females. Likewise, both genetic males and females were found in the hatched larvae in most broods derived from cured females. In contrast, the last instar larvae derived from infected females were in the all-female condition, and those derived from cured females were in the all-male condition. These results suggested the occurrence of opposite sex specific lethality in *Wolbachia*-infected and cured females of *O. furnacalis*, as suggested in *O. scapulalis*.

Paropsis atomaria (Olivier) (Coleoptera: Chrysomelidae):The significance of genetic and ecological diversity in a wide-ranging insect species

MK Schutze
School of Natural Resource Sciences, Queensland University of Technology, GPO Box 2434, Brisbane, Qld, Australia, 4001

The *Paropsis atomaria* complex currently consists of three described species, *P. atomaria*, *P. deboeri* and *P. elytrura*. While the latter two species have restricted distributions (to Tasmania and South-west Western Australia, respectively), *P .atomaria* is widely distributed in temperate, sub-tropical and tropical eastern Australia. The species are all *Eucalyptus* herbivores and are morphologically and behaviourally similar. This paper reports on a detailed investigation of both inter- and intra-specific relationships within the complex. Using molecular, morphological and ecological approaches the specific status of the three named taxa, as well as population level differentiation within the widely distributed *P. atomaria,* is being investigated. Special attention is paid to *P. atomaria* as it is an important forestry pest and there is potential that elucidation of population characteristics may reveal genetically distinct populations, possibly cryptic species, within the taxon. Assessment of the mitochondrial genome (COI, 550 b.p.) revealed approximately 9% differentiation between mainland *P. atomaria* and *P. deboeri*, whilst demonstrating a maximum of approximately 1.5% differentiation within *P. atomaria.* This supports current morphological classification. Such a multi-disciplinary, holistic approach will ultimately provide a robust foundation for the understanding of species boundaries and population dynamics in this economically important complex.

The water insoluble core of the silk filament is a polymer of proteins produced in the posterior section of silk glands. Polymerization into a fiber occurs via weak molecular interactions between amino acid residues that are arranged in specific repeats of a large protein called heavy chain fibroin (H-fibroin). Short non-repetitive ends of the H-fibroin molecule are similar in different Lepidoptera but the repetitive region, which accounts for about 95% of the H-fibroin length, has diversified under selection pressure for diverse physical properties of the silk and efficient deployment of available nutrients in its production. In some cases, silk may be used as a temporal depot of energetically rich and essential amino acids. In the "bombycoid" type of H-fibroin, the repeats vary in length and include concatenations of short crystalline motifs such as GlyAlaGlyAlaGlySer in the silkworms (Bombycidae) and stretches of about ten alanine residues in the silkmoths (Saturniidae). Owing to iterations of simple motifs, some amino acid residues of adjacent peptide chains are always in positions allowing intermolecular interactions even when the repeats do not exactly match. H-fibroins of the "pyraloid" type lack the strings of simple motifs and consist of complex repeats encompassing in some cases more than one huned amino acid residues. The uniformity of repeats throughout the H-fibroin molecule facilitates precise alignment of the widely distributed amino acid residues that form intermolecular links.

In most Lepidoptera, two small proteins called light-chain fibroin and P25 interact with H-fibroin in fibre formation.. The small components have been lost in the silkmoths (Saturniidae), whose silk fiber core consists of H-fibroin alone. Analysis of the dominant gene transcripts in the silk glands of two species representing two out of three caddisfly suborders, revealed presence of a product that is Gly-rich and may be regarded as a homologue of H-fibroin with very specific repeat structure. Another abundant mRNA seems to represent a homologue of light-chain fibroin. No sequence resembling the P25 component of lepidopteran silk was detected.

The core of silk fibre is enveloped by several sericins that are derived from two or more genes expressed in the middle silk gland section. Differential splicing and probably also different extent of glycosylation provide for the diversity of sericins that serve as a glue for fiber adherence. There are at least six different sericins in the silks of the examined Lepidoptera and apparently a similar number in the Trichoptera. Sericins are rich in serine and some of them consists largely of species-specific repetitive motifs.

Additional silk proteins of the lepidopteran silk include structurally diversified seroins and two types of relatively conserved proteinase inhibitors. These proteins are largely produced in the middle silk gland section prior to cocoon spinning and are believed to be responsible for the cocoon resistance to predators, molds, and microbes. Homologous proteins have not so far been detected in the caddisflies. Caddisfly silk contains several components whose relationship to the silk proteins of Lepidoptera remains to be elucidated. These caddisfly-specific silk proteins, which range in size from 13 to nearly 40 kDa, contain repetitive regions and structurally fall into three categories. One is characterized by high contents of Gly, Pro, Gln, and Trp, the second contains four short repeats rich in Cys, and the third includes repeats rich in Pro, Thr, and Lys. Some of other proteins encoded by the identified mRNAs could also be secreted into silk. They include a serpin (401 amino acids), a protein (140 residues) characterized by regular spacing of Glu, a protein (104 residues) with seven Cys residues, and a ProAla rich protein (61 residues). Taken as a whole, available data demonstrate that only the very basic composition of the caddisfly silk is similar to that known from Lepidoptera. Structures of the major proteins are different and several auxiliary compounds seem to be specific for Trichoptera. (The study was supported by grant A5007402 from the Grant Agency of the Czech Academy of Sciences).

Adaptation to environmental gradients.

CM Sgrò, MW Blows
"Centre for Environmental Stress and Adaptation Research, La Trobe University, Melbourne 3083, Victoria, Australia; c.sgro@latrobe.edu.au"

Latitudinal clines are widespread and provide a natural framework within which to examine natural selection. Repeated clines in different geographic areas or in related taxa strongly implicate the occurrence of natural selection. Clinal variation at the phenotypic level therefore provides an opportunity to examine the way in which genetic variation may also be influenced by natural selection. Despite the widespread occurrence of latitudinal clines, there are few empirical data that address the question of how quantitative genetic variation varies along such clines. We have combined comparisons of clinal populations of *Drosophila serrata* collected from the eastern coast of Australia with laboratory natural selection experiments to examine the genetic basis of adaptation to environmental gradients. We show that clinal selection under natural conditions does result in changes in both the additive and nonadditive genetic variances. Furthermore, we show that adaptation to clinal environments may involve a number of distinct genetic responses along the length of the cline, the complexity of which may not be fully revealed by focussing primarily on populations at the ends of the cline.

Metabolism of the sub-Antarctic caterpillar *Pringleophaga marioni* during cooling, freezing and thawing

BJ Sinclair, CJ Klok, SL Chown
Spatial, Physiological and Conservation Ecology, Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa, bjs@sun.ac.za

Although general models of the processes involved in insect survival of freezing exist, there have been few studies directly investigating physiological processes during cooling, freezing and thawing, without which those models remain hypothetical. Here we use open-flow respirometry to investigate metabolism of the freeze-tolerant sub-Antarctic caterpillar *Pringleophaga marioni* Viette (Lepidoptera: Tineidae) during cooling, freezing and thawing, and to compare animals exposed to non-lethal (-5.8 °C), and lethal (-6.0 °C, after which caterpillars are moribund for several days; and -18 °C, after which caterpillars are completely unresponsive) freezing stress. We found a large decrease in metabolic rate (that is not associated with freezing) at -0.6 ± 0.1 °C, and calculated a Q_{10} of 2.14×10^3 at this breakpoint. This breakpoint is coincident with the critical thermal minimum, and is hypothesised to be a metabolic manifestation of the latter. Caterpillars froze at -4.6 ± 0.1 °C, and had non-zero metabolic rates when frozen. Post-thaw, metabolic rates were lower than pre-freezing measurements. Post-thaw metabolic rates did not differ between temperatures that did and did not kill the caterpillars, which suggests that mortality may be a result of a breakdown in processes at the organismal, rather than cellular, level of organization.

Evolutionary implications of infection with parthenogenesis inducing *Wolbachia*

R Stouthamer
Department of Entomology, University of California, Riverside, CA 92521, USA

The presence of Parthenogenesis Inducing (PI) *Wolbachia* infected individuals can have a strong impact on both the infected individuals as well as on the uninfected individuals present in a population. Two situations exist, the infection remains at some equilibrium or the infection goes to fixation. In this presentation I will present a model showing that an equilibrium infection frequency can only exist at a low level of infection if there are some factors present in the population that counteract the *Wolbachia* by modifying its expression /transmission (suppressor), or when other genetic elements are present that exploit the female biased sex ratio caused by the infection. If populations have gone to fixation for the infection with PI *Wolbachia* this generally is accompanied by a change in the females mating behavior and/or fertilization behavior. These changes are such that females from infected lines are unable to successfully mate and/or fertilize their eggs, whereas males derived from these same infected lines (through antibiotic treatment) are still functional and capable of fathering offspring.

Does environmental stress increase genetic structure in the springtail *Orchesella cincta***?**

MJTN Timmermans, J Ellers, NM Van Straalen
De Boelelaan 1085, 1081 HV Amsterdam, The Netherlands; timmerm@bio.vu.nl

Environmental stress can alter the genetic composition of natural populations by directional selection towards tolerant genotypes, by causing bottlenecks and by changing gene flow to and from stressed locations. Especially when gene flow is low, environmental stress is expected to increase levels of genetic differentiation among populations. We examined the effect of environmental pollution on population genetic structure for the soil dwelling species *Orchesella cincta* **by comparing Isolation by Distance relationships. First, population genetic structure of sixteen NW European populations was estimated using six polymorphic microsatellite loci. A significant Isolation By Distance relationship was revealed, indicating gene flow is relatively high in this small soil arthropod species. Secondly, comparisons between stressed and pristine populations versus pristine populations revealed no differences in Isolation by Distance relationships. Our results indicate environmental pollution does not play a significant role in shaping population genetic structures within this species, most likely due to its migration capacity. Gene flow might, by filling up reduced genetic variability in stressed populations, be an evolutionary force maintaining versatility of stressed populations.**

"Effects of eugregarine parasites on adult longevity in the polymorphic damselfly *Mnais costalis* Selys"

Y Tsubaki
"Biodiversity Conservation Research Group, National Institute for Environmental Studies, Tsukuba, 305-8506 Japan; tsubaki@nies.go.jp"

Males of *M. costalis* show a genetic polymorphism linked to mate-securing strategies, typically existing as orange-winged territorial fighters and clear-winged nonterritorial sneaks (the former are larger in size) (Tsubaki 2003). Orange-winged males have a higher daily mating rate, however, their reproductive life span and longevity is less than that of clear winged males. As a result, the estimated lifetime reproductive success is the same (Tsubaki *et al.*, 1997). In this paper I will compare the survival cost of eugregarine infection for the two morphs looking at the relationship between the abundance of mid-gut parasites and the survival of field-collected males in captivity. Orange-winged males suffered higher parasite infection and showed shorter longevity than clear-winged males when they were fed at lower levels than the natural feeding rate, or when they were deprived of food. In contrast, morph longevity did not differ when they were fed until satiation. The survival of damselflies was negatively correlated with the parasite abundance except when damselflies were fed until satiation. The results suggest that the abundance of eugregarine parasites exerts a substantial cost, which is associated with the maintenance of alternative mating strategies, together with the higher developmental cost and energy expenditure of the fighter morph.

An evolutionary view of the sex communication in *Melittobia* spp.

FL Cônsoli, HJ Williams, J Gonzalez, RW Matthews, SB Vinson
Department of Entomology, Texas A&M University, College Station, TX, 77843-2475, USA; f-consoli@tamu.edu; bvinson@tamu.edu

Melittobia are ectoparasitoids of late larval and pupal stages of several species of solitary bees and wasps. Females locate their hosts on which they will lay their eggs, and will represent the only nutritional resource to the developing larvae. Sex dimorphism is remarkable and males will fight to death to eliminate competing males as they mate emerging females. Males remain in the confines of the host's nest they developed in, while females may disperse to locate new hosts. Mating occurs after an elaborate courtship behavior, in which a male produced sex pheromone is involved, and is supposed to play an important role in mate recognition. We will describe the differences in the male pheromone of 4 species of *Melittobia* and evaluate the attractiveness of females to interspecific males, and discuss the role of the male sex pheromone and the cuticular hydrocarbon composition of these 4 species in sex mate recognition. We will discuss the evolutionary process involved in the chemical communication of this parasitoid and provide supportive molecular data.

The sociobiology of plant defense

AE Weis
Department of Ecology and Evolutionary Biology, University of California-Irvine, Irvine, CA 92697-2525, USA

"Social context" can inflate or diminish the evolutionary success of a resistance gene by making genetic variance in fitness density/frequency-dependent. Three models illustrate. First, a plant growth model shows that intraspecific competition increases the benefit of resistance when attack levels are high (resistant plants usurp resources that damaged susceptible plants need for recovery), but also increases the costs when attack is absent (undamaged susceptible plants outgrow resistant ones). Next, a game theory model shows that the fitness benefit of resistance can vary through the interaction of enemy behavior with local genotype frequency: susceptible genotypes can gain associational resistance when at low frequency if enemies can move freely to more palatable patches; however, if enemies are restricted to single patches, the susceptibles are eventually found. Finally, plants with high allocation to resistance flower late, causing assortative mating for resistance under low herbivory. Heavy attack retards susceptibles, bringing them into flowering synchrony with resistants. A population genetic model shows that assortative mating inflates genetic variance during zero-herbivory periods when costs exceed benefits, but not during high herbivory periods when benefits exceed costs. This causes asymmetric selection responses that prevent fixation of resistance even if average benefit exceeds average cost.

The role of the hedgehog pathway in polyembryonic development

MA White, LS Corley
P.O. Box 646382, Department of Entomology, Washington State University, Pullman, WA 99164-6382 USA; mwhite10@wsu.edu

Copidosoma floridanum is a polyembryonic parasitoid wasp that produces over 1000 individuals from a single egg. This clonal proliferative process is remarkable for a number of reasons but primarily because this insect system has evolved clonal proliferation as an adaptive strategy; therefore, understanding how cellular proliferation can occur without causing disease in this organism will increase our understanding of how the cell cycle is regulated in animals and how it might be possible to mimic this natural system. The Hedgehog (HH) signal transduction cascade is a candidate gene pathway that may be regulating proliferation within the dividing cells. Among metazoan taxa, one function of HH is to regulate cellular proliferation during development. Within *Drosophila,* for instance, HH has been shown to control the proliferation and differentiation of somatic stem cells and progeny within the ovary. To determine whether HH is implicated in polyembryonic proliferation in *C. floridanum*, we cloned the C. floridanum HH gene. Ultimately, we are interested in determining the role the *C. floridanum* HH signal transduction pathway has in polyembryonic proliferation. We predict that in areas of active cellular proliferation, high levels of HH will be translated, while in areas with no proliferation, HH expression will be absent.

The genetic basis of divergent gene expression in *Drosophila*

PJ Wittkopp, BK Haerum, AG Clark
Department of Molecular Biology and Genetics, 227 Biotechnology Building, Cornell University, Ithaca, NY 14853 USA; pw72@cornell.edu

Differences in gene expression play a central role in evolution. Both *cis*- and *trans*-regulatory changes contribute to divergent gene expression, but their respective contributions remain largely unknown. Using closely related *Drosophila* species, we examined *cis*- and *trans*-regulatory changes underlying interspecific expression differences. Functional *cis*-regulatory changes were detected by comparing the relative abundance of *D. melanogaster* and *D. simulans* transcripts in F_1 hybrids, whereas differences in *trans*-regulatory activity were inferred by comparing the ratio of allelic expression in hybrids to the ratio of gene expression between species. We found that interspecific expression differences were almost always accompanied by changes in *cis*-regulatory function. In addition, *trans*-regulatory divergence affected approximately half of the genes we examined. These data contrast with recent studies of intraspecific gene expression, which found that expression variation was caused primarily by differences in *trans*-regulation. Distinct patterns of *cis*- and *trans*-regulatory changes appear to underlie expression differences within and between species.

Phenotype matching in wild parsnips and parsnip webworms: costs and consequences.

AR Zangerl, MR Berenbaum
Department of Entomology, University of Illinois at Urbana-Champaign, 320 Morrill Hall, 505 S. Goodwin, Urbana, IL 61801, USA; azangerl@life.uiuc.edu

The coevolutionary consequences of present-day interactions between plants and their insect herbivores may vary among populations as envisioned in the Geographic Mosaic Model of Coevolution. The interaction between wild parsnip, *Pastinaca sativa*, and its principal herbivore, the parsnip webworm (*Depressaria pastinacella*), is mediated by the amounts of furanocoumarins produced in the plant and the ability of the insect to detoxify them. Within 20 midwestern U.S. populations, trait frequencies in parsnips frequently were matched by trait frequencies in webworms. Exceptions were found in populations of parsnips with high xanthotoxin chemotypes, which are difficult for webworms to utilize, and in regions where an alternative host, *Heracleum lanatum*, which has a different furanocoumarin profile from wild parsnip, is abundant. The maintenance of more susceptible genotypes of wild parsnip in all populations is presumably due to the high cost of furanocoumarin production, while mismatching in alternate host populations is likely due to the cost of adaptation by webworms.

Use of thermal data as an establishment screen for non-native biocontrol agents in the UK

JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K.,
j.s.bale@bham.ac.uk

Most predatory insects and mites used in glasshouse biocontrol in the UK originate from tropical and semi-tropical climates. For this reason, the licensing system for the introduction of non-native species has operated under the assumption that winter would act as a natural barrier to the establishment of such species outside of glasshouse environments. This view has been challenged by the establishment in the wild of the predatory mite *Neoseiulus californicus* and the discovery of the predatory mirid *Macrolophus caliginosus* outside of glasshouses in winter. Whilst the impact of these species on native ecosystems is unknown, their establishment is considered undesirable. This paper describes a series of experiments used to determine a range of thermal characteristics (developmental threshold, day-degree requirement per generation, supercooling point, lethal times and temperatures, field survival) of four non-native biocontrol agents. The comparative data provide a retrospective ecophysiological explanation for the establishment of *N. californicus* and *M. caliginosus,* and also indicate that *Delphastus catalinae* and *Eretmocerus eremicus* would not survive outdoors in the UK under current climatic conditions. The experimental protocol applied to these species could be used as part of a routine screen for 'establishment potential' in the licensing system of non-native biocontrol agents in the UK.

Learning affects adaptation to novel environments: evidence from experimental evolution using *Drosophila*

TJ Kawecki, F. Mery
Department of Biology, University of Fribourg, Chemin du Musée 10, CH-1700 Fribourg, Switzerland, tadeusz.kawecki@unifr.ch

Verbal arguments and models suggest that the ability to learn should affect the evolution of genetically determined components of behavior. Depending on the author and model, learning should either hinder or facilitate the response to natural selection. These contrasting predictions had not been addressed experimentally. To fill this gap we exposed replicated populations of *D. melanogaster* to directional selection on preference for a novel oviposition substrate (orange or pineapple), with or without an opportunity to use aversion learning to decide which medium to avoid. This additional opportunity to learn affected the genetic response to selection, but the sign of this effect depended on the direction of selection: it slowed down the response to selection to prefer orange, but accelerated the response to selection to prefer pineapple. Furthermore, for both directions of selection, populations given an opportunity to learn evolved a higher learning ability. This last results indicates that learning may also be favored under directional selection, in contrast to the usual argument that learning is only adaptive if fitness consequences of a given behavioral action vary in time or space. The results can be explained as consequence of the way learning affects the genotype-phenotype map.

Molecular phylogeny of Antarctic Chironomidae investigated by 28S rDNA sequencing

G Allegrucci, G Carchini, P Convey, V Sbordoni
British Antarctic Survey, NERC, High Cross, Madingley Road, Cambridge CB3 0ET, UK

Two indigenous chironomid midges exist on the Antarctic continent, *Belgica antarctica* and *Parochlus steinenii steinenii*. A third, *Eretmoptera murphyi*, endemic to sub-Antarctic South Georgia, was recently accidentally introduced to maritime Antarctic Signy Island (South Orkney Islands). *B. antarctica* and *E. murphyi* share several morphological and ecological characteristics and are classified in the same subfamily, Orthocladiinae. This study aimed to clarify the relationships of *B. antarctica* and *E. murphyi* and to evaluate whether vicariance or dispersal have been the main factors shaping their current distributions. Nucleotide sequences from the large subunit (28S) ribosomal RNA were used to compare the two species with other chironomids (Orthocladiinae, Chironominae, Telmatogetoninae) collected in Tierra del Fuego. Drawing on regional geological reconstruction, we attempt to match the timing of cladogenetic and geological events. Our results suggest a monophyletic familial origin. However at subfamily level, relationships are unclear. This is not surprising, as Orthocladiinae represents the residue of Chironomidae after the removal of other better-defined taxonomic groups. To further clarify relationships within Orthocladiinae, comparisons are currently being made with a species of the genus *Smittia* that may be the closest ancestor to both *B. antarctica* and *E. murphyi*.

High local endemism of a saproxylic 'giant' springtail (Collembola) from south eastern Australia

R Garrick, C Sands, D Rowell, N Tait, P Greenslade, P Sunnucks
Dept of Genetics, La Trobe University, Melbourne 3086, Australia; r.garrick@latrobe.edu.au

Comparative phylogeography can reveal processes and historical events that shape the biodiversity of species and communities. As part of a comparative research program, the phylogeography of a new endemic Australian genus and species of log-dependent (saproxylic) Collembola was investigated using a variety of genetic markers. Owing to the species' ecological specialisation and sedentary lifestyle, and the palaeoclimatic history of the study site (Tallaganda State Forest, NSW), we predicted genetic structure would correspond with five *a priori* microbiogeographic regions. Significant genetic differences exist among regional samples ('populations'). Closely related mitochondrial DNA haplotypes are co-distributed within a single region or occur in adjacent regions, nuclear allele frequencies are more similar among more proximate populations, and inter-population immigration is rare. The signature of historical vicariance was also evident: the spatial distribution of populations corresponds with four of the five putative microbiogeographic regions, and genetic contact zones are abrupt. The present-day distribution of genetic diversity in this species seems to have been impacted by three major climatic events: Pliocene cooling and drying (2.5-6 mybp), early Pleistocene wet-dry oscillations (1.2 mybp), and the more recent glacial-interglacial cycles that have characterised the latter part of the Quaternary (<0.4 mybp).

Morphometric, genetic & ecological variation in *Aphis gossypii*

RH Miller, RL Foottit, and KS Pike
College of Natural and Applied Sciences, University of Guam, Mangilao, Guam 96923; rmiller@uog.edu

Aphis gossypii Glover was collected from a range of crop and non-crop plant hosts at various times during the year on Guam. *A. gossypii* was also collected from the Commonwealth of the Northern Marianas Islands in Saipan, Tinian and Rota, from the Republic of Palau islands of Koror and Babeldaup, from the Republic of the Marshall Islands, from five of the Hawaiian Islands, and from Japan, Canada, USA, and Syria. Aphid/plant host associations were determined. Morphometric analysis of slide-mounted specimens using principal components analysis suggested that aphid variation was most closely related to geographic provenance, followed by host plant. However, results from microsatellite flanking region sequence analysis (MFRS) performed on aphids from the same collections indicated that genetic variation was most closely related to the host plant from which the aphids had been collected. Field observations made on Guam suggest that the physical appearance of aphids may be altered by altering the host plant upon which the aphids develop. Collecting and analysis of variation in *A. gossypii* populations from various sites continues.

Comparison of *mariner*-like elements among *Bombyx mandarina* individuals inhabiting east Asia in the light of the segregation of *B.mori* and *B. mandarina*

Y Nakajima, T Nakamura, Y Banno, H Fujimoto, K Sahara, K Hashido, T Shiino, K Tsuchida, N Takada, H Maekawa
Division of Functional Genomics, Center of Molecular Biosciences (COMB), University of the Ryukyus, Nishihara, Okinawa 903-0213, Japan; yumiko28@comb.u-ryukyu.ac.jp

"Individuals of *Bombyx mandarina* were collected from three area of east Asia, Japan, Korea and China, observed for chromosome number (*n*) and subjected to PCR against their genomic DNA with the inverted terminal repeats of *Hyalophora cecropia* MLE as a primer. Each specimen gave several bands with different sizes. The 1.3-kb band, expected to cover a full-length MLE, was ubiquitous in all of the *B. mandarina* specimens as in *B. mori*. However, in some cases, the bands of *B. mandarina* were inserted with other sequences. The MLE making a complex was found to be situated in the same phylogenetic group as that of the previously analyzed MLE clone (*BmTNML*) from *B. mori*, indicating that the insertion had occurred in the ancestor of *B. mori* before the genomic segregation of *B. mandarina* between the Japanese/Korean types (*n* = 27) and the Chinese/Korean types (*n* = 28). One individual from China had a discrete 4.2-kb band containing a *BMC1* retrotransposon, which is a unique fragment detected in almost all of the silkworm races and strains. Thus, the 4.2-kb unit might be made spontaneously by crossing with *B. mori* after the segregation of *B. mori* genome.
"

Possible horizontal transfer of *mariner*-like sequences into some invertebrates including lepidopteran insects, grasshopper & a coral among Japan islands

Y Nakajima, T Nakamura, Y Banno, H Fujimoto-Kusakabe, K Hashido, T Shiino, K Tsuchida, N Takada, H Maekawa
Division of Functional Genomics, Center of Molecular Biosciences (COMB), University of the Ryukyus, Nishihara, Okinawa 903-0213, Japan;
yumiko28@comb.u-ryukyu.ac.jp;

Mariner-like elements (MLEs) were amplified by PCR against genomic DNAs from several Japanese insects including lepidopteran lepidopteran species, using the inverted terminal repeats (IR) of the *Hyalophora cecropia* MLE as a primer. Clones thus obtained were of a size of about 1.3 kb, and expected to contain the full-length MLE. These clones were highly similar to each other and classified into the *Cecropia* subfamily of MLEs. The coral MLE was found to have a complete ORF coding for transposase, a situation similar to that previously found in the Emperor moth, *Attacus atlas*, from the Ryukyu Island. These findings, together with the fact that all of the insects and coral species that exhibited a positive signal for the full-length MLE were collected in relatively close regions around Japan, indicated that the horizontal transfer of MLEs has taken place even among phylogenetically remote organisms. We will also report the results regarding as to the transposition activity from one of these type of *mariner*-element isolated form *A. atlas* using the *Bombyx* cultured cell.

Use of thermal data as an establishment screen for non-native biocontrol agents in the UK

JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham B15 2TT, U.K., j.s.bale@bham.ac.uk

Most predatory insects and mites used in glasshouse biocontrol in the UK originate from tropical and semi-tropical climates. For this reason, the licensing system for the introduction of non-native species has operated under the assumption that winter would act as a natural barrier to the establishment of such species outside of glasshouse environments. This view has been challenged by the establishment in the wild of the predatory mite *Neoseiulus californicus* and the discovery of the predatory mirid *Macrolophus caliginosus* outside of glasshouses in winter. Whilst the impact of these species on native ecosystems is unknown, their establishment is considered undesirable. This paper describes a series of experiments used to determine a range of thermal characteristics (developmental threshold, day-degree requirement per generation, supercooling point, lethal times and temperatures, field survival) of four non-native biocontrol agents. The comparative data provide a retrospective ecophysiological explanation for the establishment of *N. californicus* and *M. caliginosus,* and also indicate that *Delphastus catalinae* and *Eretmocerus eremicus* would not survive outdoors in the UK under current climatic conditions. The experimental protocol applied to these species could be used as part of a routine screen for 'establishment potential' in the licensing system of non-native biocontrol agents in the UK.

Development of males in thrips – a bacterial decision

S Kumm, R Kranz, G Moritz
Martin-Luther-University of Halle-Wittenberg, Domplatz 4, D-06099 Halle, Germany; kumm@zoologie.uni-halle.de

In thrips the mechanism of reproduction usually involves either arrhenotoky where females develop from fertilized and males from unfertilized eggs, or thelytoky where females hatch from unfertilized, diploid eggs. Thysanoptera are the only insect order besides Hymenoptera showing a haplodiploid reproduction mode. To find out more about the mechanism determining sex in thrips, several thrips species were tested for the presence of parthenogenesis-inducing bacteria of the genus *Wolbachia* using specific 16S rDNA primers. Tested species show either arrhenotoky (*Frankliniella occidentalis*, *Echinothrips americanus*) or thelytoky (*Parthenothrips acaenae, Hercinothrips femoralis*), but *Thrips tabaci* is arrhenotokous in some areas and thelytokous in others. The thelytokous species *H. femoralis* and *P. acaenae* possess *Wolbachia*, and presence of this bacterium in *H. femoralis* was shown to be responsible for thelytoky since male offspring could be generated by treating females with antibiotics. After mating, sperm was found in the spermatheca of female *H. femoralis*, and mated females produced only female progeny. The arrhenotokous species *E. americanus* also harbours *Wolbachia*, but the bacterium was not detected in either *F. occidentalis* or *T. tabaci*.

Reproductive isolation & genitalic divergence in *Ciulfina*: a praying mantid genus from tropical Australia

GI Holwell, ME Herberstein
Department of Biological Sciences, Macquarie University, NSW, 2109, Australia; gholwell@bio.mq.edu.au

Populations of animals can be reproductively isolated from one another at a variety of levels: from precopulatory species recognition through to hybrid dysfunction. Genitalic characters are often used to define divergent populations as distinct species, particularly in the insects. However, the correlation between genitalic divergence and reproductive isolation in insect species is rarely tested. Mantids in the genus *Ciulfina* are small trunk-dwelling predators found in high densities in a variety of forest types throughout coastal Queensland, Australia. The degree of polymorphism found in both the male genitalia, and sequences of the ITS region of ribosomal DNA in *Ciulfina*, suggested that particular populations were reproductively isolated from one another. Using choice experiments, we found that males were unable to differentiate between females from their own population and those from populations that were genetically different. Once copulation was attempted, however, the duration and mechanics of interpopulation matings varied from those of intrapopulation matings. Most importantly, populations with some level of sympatry/parapatry were more effectively isolated from one another than entirely allopatric populations, suggesting that genitalia do serve an important role in species reinforcement. These results have implications for our understanding of the evolution of animal genitalia, and of the role of genitalic divergence in reproductive isolation.

Comparative evolutionary ecology of limestone & lava caves in tropical Queensland

FG Howarth
Bishop Museum, 1525 Bernice St., Honolulu, HI 96817, USA; fhowarth@bishopmuseum.org

Recent discoveries of obligate cavernicoles from tropical caves and lava tubes have opened new areas for research. The Chillagoe limestone caves and Undara lava tubes, 100 kilometers south, provide exceptional systems to compare evolutionary ecology between limestone and lava caves since their communities evolved from the same source fauna within the same climatic regime. The 5 to 25 million year-old limestone caves formed slowly by solution. The Undara lava tubes formed within a 190,000 year-old eruption, but intermittent volcanism has maintained interconnected cave habitats for possibly five million years. Despite the very different substrates and modes of formation, the food resources and physical environments within the caves are similar. Both cave types contain numerous passages with different physical shapes and environments, allowing multiple comparisons in environmental ecology. The adaptations and distribution of cave species are correlated with the physical environment rather than with cave age or type, with the most cave-adapted species being restricted to the harshest environment. Over 40 obligate cavernicoles are known, but the fauna is potentially much larger, especially given the vast number of uninvestigated caves. Obligate cavernicoles evolve to exploit environments stressful for surface animals wherever suitable habitats and resources have been available for evolutionary time.

Identification of source populations of invasive insects: implications for biological control, monitoring, and quarantine

RG Ahern, MJ Raupp, DJ Hawthorne
4112 Plant Sciences Building, College Park, Maryland 20742-4454, USA; rga@umd.edu

Invasive species cause severe economic and ecological damage in many regions around the world. Knowledge of an invasive species' origin benefits inspection and quarantine efforts and focuses the search for biological control agents. Cooley spruce gall adelgid (CSGA), *Adelges cooleyi*, is a native pest in the US that provides an excellent model organism for studying population genetics of invasive exotic species. The native range of CSGA resembles an inverted 'V', extending northward along the Rocky Mountains into Canada and back down the West Coast into northern California. CSGA has invaded the eastern US through an unknown number of introductions during the 20th century. Here, we report efforts to identify sources of CSGA populations introduced into the eastern US. Comparison of mitochondrial and nuclear DNA sequences among source and introduced populations revealed that all east coast introductions originated from one region within the insect's extensive native range. As expected by theory, genetic variation was decreased in introduced populations relative to populations from the insect's native range. This work demonstrates a successful application of molecular genetic tools to determine the origin of invasive species and aspects of population genetic structure, thus facilitating the development of sound, sustainable pest management strategies.

Inbreeding leads to changes in allometry between egg size and larval characters in an eriosomatine aphid (Aphididae)

S Akimoto
Department of Ecology and Systematics, Graduate School of Agriculture, Hokkaido University, Sapporo, 060-8589 Japan; akimoto@res.agr.hokudai.ac.jp

A number of studies indicate that inbreeding has deleterious effects on the viability and reproduction of organisms, but it is still unknown what mechanisms are involved in the expression of deleterious effects. Because the effects of inbreeding are expressed from the early stage of development, it is necessary to focus on hatched larvae to understand the phenotypic effects of inbreeding. Aphids are useful for studying inbreeding effects because in aphids (1) it is easy to cross males and females of the same clone (that is, selfing) and (2) hatched larvae can be used for detailed morphometric analyses. Using the aphid *Prociphilus oriens*, this study prepared eggs resulting from outbreeding and selfing and compared the allometry between egg size and morphological characters of hatched larvae between outbred and selfed groups. The allometry of larval characters against egg size varied greatly between outbred and selfed groups. Selfed larvae had significantly larger allometric coefficients for appendages than did outbred larvae, showing that inbreeding accelerated the growth of appendages. However, the growth of gonads was suppressed in selfed larvae. It is suggested that inbreeding relaxed developmental canalization on larval appendages and resulted in reduction in gonad size via a trade-off between appendages and gonads.

Rapid chill coma recovery selection in *Drosophila melanogaster*

AR Anderson, AA Hoffmann, SW McKechnie
Monash University, Clayton, Victoria, 3800; alisha.anderson@sci.monash.edu.au

Resistance to low temperatures can vary markedly among invertebrate species and is directly related to their distribution. Despite the ecological importance of cold resistance this trait has rarely been studied genetically. One measure of cold resistance that varies geographically in *Drosophila melanogaster* and that is amenable to genetic analysis is chill-coma recovery. *D. melanogaster* have been selected for increased recovery time following exposure to 0°C. Selected lines responded rapidly to the selection and showed an increased resistance to a broad range of low temperatures. They also had a lower mortality following a more severe cold treatment, indicating that a general mechanism underlying cold resistance had been selected. The selection response was independent of plastic changes in cold resistance because the selected lines maintained their ability to acclimate. Life-history and stress resistance tradeoffs were also investigated showing only a tradeoff with ageing and one stress resistance trait. Selected lines were genotyped for clinally varying genes/markers and show associations with some candidate genes suggesting these genes may have a role in cold resistance.

Predicting shifts in timing of winter moth egg in response to climate change

M van Asch, PH van Tienderen, LJM Holleman, ME Visser
Netherlands Institute of Ecology, PO Box 40, 6666 ZG Heteren, The Netherlands; M.vanAsch@nioo.knaw.nl

Climate change can lead to mistiming in phenology between different components of food chains. For instance, winter moth (*Operophtera brumata*) egg hatch has advanced more than oak (*Quercus robur*) bud burst over the past two decades. The question is whether natural selection will lead to a restoration of synchrony between winter moth and oak. Using a half-sib design, we demonstrate here that egg hatching is a heritable trait, making adaptation through selection possible. We further use a model to predict the changes in reaction norm of egg hatching at different temperatures. This approach enabled us to predict the response in the next year, under different environmental conditions, to the selection in a given year. Due to selection, the reaction norm will change in intercept but not in slope: in future eggs will need more warmth before they can hatch, regardless of what the temperature is in a given year. Because of this, timing differences between egg hatch and oak bud burst will decrease rapidly. Changes in reaction norm in response to selection thus offer a possible way of restoring synchrony between different components of a food chain, winter moth and oak.

Use of thermal data as an establishment screen for non-native biocontrol agents in the UK

JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham B15 2TT, UK; j.s.bale@bham.ac.uk

Most predatory insects and mites used in glasshouse biocontrol in the UK originate from tropical and semi-tropical climates. For this reason, the licensing system for the introduction of non-native species has operated under the assumption that winter would act as a natural barrier to the establishment of such species outside of glasshouse environments. This view has been challenged by the establishment in the wild of the predatory mite *Neoseiulus californicus* and the discovery of the predatory mirid *Macrolophus caliginosus* outside of glasshouses in winter. Whilst the impact of these species on native ecosystems is unknown, their establishment is considered undesirable. This paper describes a series of experiments used to determine a range of thermal characteristics (developmental threshold, day-degree requirement per generation, supercooling point, lethal times and temperatures, field survival) of four non-native biocontrol agents. The comparative data provide a retrospective ecophysiological explanation for the establishment of *N. californicus* and *M. caliginosus,* and also indicate that *Delphastus catalinae* and *Eretmocerus eremicus* would not survive outdoors in the UK under current climatic conditions. The experimental protocol applied to these species could be used as part of a routine screen for 'establishment potential' in the licensing system of non-native biocontrol agents in the UK.

Synchronous coadaptation in an ancient case of herbivory

JX Becerra
Department of Entomology, University of Arizona, Tucson AZ 85721, USA; becerra@ag.arizona.edu

Coevolution has long been considered a major force leading to the adaptive radiation and diversification of insects and plants. A fundamental aspect of coevolution is that adaptations and counteradaptations interlace in time. A discordant origin of traits long before or after the origin of the putative coevolutionary selective pressure must be attributed to other evolutionary processes. Despite the importance of this distinction to our understanding of coevolution, the macroevolutionary tempo of innovation in plant defenses and insect counterdefenses has not been documented. Molecular clocks for a lineage of chrysomelid beetles of the genus *Blepharida*, and their Burseraceae hosts were independently calibrated. Results show that these plant's defenses and the insect's counterdefensive feeding traits evolved roughly in synchrony, providing the first macroevolutionary confirmation of synchronous plant-herbivore coadaptation. The association between these two groups of organisms was determined to be about 112 million years old, the oldest age so far for a specialized plant-herbivore association.

Genetics and evolution of photoperiodism in temperate environments

WE Bradshaw, CM Holzapfel
CEEB, 5289 University of Oregon, Eugene, OR 97403-5289, USA; bradshaw@darkwing.uoregon.edu

Photoperiodism constitutes the major physiological mechanism by which arthropods adjust the seasonal programming of development and dormancy at temperate latitudes. Dispersal of the pitcher-plant mosquito, *Wyeomyia smithii*, from southern latitudes to northern Canada following recession of the Laurentide Ice Sheet 20,000 - 8,000 years ago has involved the evolution of longer critical photoperiods, thereby tracking the shorter growing seasons at increasingly more northern latitudes. Despite directional and stabilizing selection during post-glacial range expansion, the heritability of critical photoperiod increases with latitude. We attribute this increase in heritability to the release of additive from epistatic variance during sequential founder events. During rapid climate change over the last 30 years, critical photoperiod has shifted towards shorter, more southern day lengths as growing seasons have become longer. This genetic shift in photoperiodic response is detectable over a time interval as short as five years. Faster evolutionary response has occurred in northern populations where selection is stronger and genetic variation is greater. Our results suggest that other species may be in the process of analogous evolutionary responses to altered seasonality and that the composition of future biotic communities may depend on the relative abilities of their constituent species to adapt to altered seasonal interactions.

Fluctuating asymmetry of wing pattern elements and wing shape, and its relationship to migration in the butterfly *Melitaea cinxia*

CJ Breuker, PM Brakefield, I Hanski
Casper J. Breuker, School of Biological Sciences, 3.614 Stopford Building, University of Manchester, Oxford Road, M13 9PT, Manchester, UK; casper_j_breuker@yahoo.co.uk

When fitness depends on morphological traits, individuals that can develop the phenotype reliably should be more fit than those, which cannot. Fluctuating asymmetry (FA; minute differences between the left and right side of a bilateral trait due to developmental errors) has therefore been used to predict the fitness of individuals in natural and sexual selection studies. In this talk we discuss how the FA of wing pattern elements and shape of the wings of both the fruitfly *Drosophila melanogaster* and the butterfly *Melitaea cinxia* can be used to obtain information on how development is stabilized and how useful FA is in a natural selection experiment. In the butterfly species a mark-release-recapture experiment was carried out to obtain information on the relationship between FA of wing pattern elements and shape, migration, past and present population sizes, dispersal, survival and mating success. The results will be discussed taking recent results into account on the mechanisms of developmental stability as obtained with *D. melanogaster*.

The effect of a resistance gene on developmental stability and fitness in a flea beetle, *Phyllotreta nemorum*

CJ Breuker, PW de Jong, K Victoir, K Vrieling, PM Brakefield.
School of Biological Sciences, 3.614 Stopford Building, University of Manchester, Oxford Road, M13 9PT, Manchester, UK;
casper_j_breuker@yahoo.co.uk

A resistance (R-) gene enables the flea beetle *Phyllotreta nemorum* L. (Coleoptera: Chrysomelidae: Alticinae) to use the otherwise toxic *Barbarea vulgaris* ssp. *arcuata* G-type plant as a host plant in Denmark. In this study, the pleiotropic effects of the dominant R-allele at a single autosomal gene, originating from the Danish region of Kværkeby, were investigated in an isogenic background from non-resistant beetles. The presence of the R-allele causes a high mortality at the early stages of development, when the toxic G-type plants cause the high mortality in non-resistant beetles. The presence of the R-allele has little or no effect, even under suboptimal conditions, on developmental stability (measured as fluctuating asymmetry of tibialength), body size, fecundity and longevity in the adult beetles. The distribution of the beetles in the field in Denmark will be discussed and its host plant use.

Contemporary evolutionary genetics: the breadth and depth of host race evolution in bugs on two continents.

SP Carroll, H Dingle, TR Famula, J Loye
Department of Zoology and Entomology, University of Queensland, St. Lucia 4072, Queensland, Australia.

Several species of seed bug (the soapberry bugs: Rhopalidae) from the Americas and Australia are specialized on the plant family Sapindaceae ("the 'soapberry family"), including exotic introductions and escapes. Studies on species in both Hemispheres reveal morphological, physiological, behavioral and life history adaptations to host fruits and phenologies. Many of these adaptations display rapid or contemporary evolution (in 30-50 years or 100 generations) on introduced hosts; they include traits from mouthpart morphology to wing muscle enzyme physiology. We document this evolution in soapberry bugs from Australia (*Leptocoris*) and North America (*Jadera*), showing geographic variation within continents and among host plants. The genetics underlying contemporary evolution has been analysed in a North American species using hybrids between populations adapted to different hosts as well as artificial selection. The analyses demonstrate that additive and non-additive genetic variation in the various traits contributes to contemporary evolution. Further, they reveal expected and some unexpected genetic correlations and interesting evolutionary pathways to adaptation.

A macrophysiological perspective on cold and desiccation tolerance

SL Chown
Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa; slchown@sun.ac.za

Macrophysiology, or the investigation of variation in physiological traits over large geographic and temporal scales and the ecological implications of this variation, is gaining increasing attention globally for several reasons. Here, I explore large-scale variation in cold tolerance and desiccation in insects and its implications. Perhaps unsurprisingly, rates of water loss vary in an environmentally consistent fashion, such that rates are lower in dry environments. This is true of both cuticular and respiratory water loss, even though the significance of the latter and its likely response to selection have been questioned. In several species it is clear that respiratory water loss is remarkably sensitive to environmental variation and adaptive variation thereof is not inconsistent with the data. Patterns in cold tolerance are more complicated, and reflect the variety of strategies animals can adopt to survive low temperatures. Nonetheless, two major patterns are emerging from the broad scale data. First, there is decoupling of upper and lower thermal limits. Second, there are pronounced and consistent differences in the way temperate species from the Northern and Southern Hemispheres respond to low temperatures. These major patterns not only provide insights into the mechanisms underlying insect responses to cold, but also have significant implications for understanding and predicting species responses to environmental change.

Costs of salicylate- and jasmonate-mediated induced responses in *Arabidopsis thaliana*

D Cipollini
Wright State Univ., Dept. of Biol. Sciences, Dayton, OH 45435; don.cipollini@wright.edu

Fitness costs of plant defenses to herbivores and pathogens are an important aspect of the evolutionary dynamics of plant resistance. Costs of defense have been increasingly reported in the literature, yet their mechanisms remain largely unexplored. Costs may arise from increased allocation of resources to defense production at the expense of growth, decreased assimilatory capacity in highly defended plants, or in the case of induced responses, negative interactions between defense pathways that compromise resistance to certain natural enemies. I explored costs of induced responses in several *Arabidopsis thaliana* genotypes that vary in their constitutive and inducible expression of resistance traits. In the absence of benefits, highly defended genotypes, such as the constitutive expressor of systemic acquired resistance mutant, *cep1*, had lower seed production than less defended genotypes, in general. Plants induced with either salicylic acid or jasmonic acid produced less seed than uninduced plants, and costs were quantitatively associated with the induction of such defenses as trypsin inhibitors and glucosinolates, coupled with decreased assimilatory capacity. In addition, jasmonate-mediated resistance to insects was compromised in plants simultaneously induced with salicylic acid due to inhibitory defense pathway crosstalk, and an inverse relationship between bacterial and insect resistance was demonstrated for several genotypes.

Forewing shape variation in the sand cricket *Gryllus firmus*

V Debat
Integrative Biology – School of Biological Sciences. 3.614 Stopford Building, University of Manchester, Oxford Road, Manchester, M13 9PT, United Kingdom

Populations of the sand cricket *Gryllus firmus* are composed of two wing morphs. Long winged individuals (LW) have functional hind wings, are able to fly, and thus might disperse. Short winged individuals (SW) have vestigial hind wings and cannot fly. It is commonly considered that this dimorphism is maintained by a trade-off between flight capacity and fecundity. Here, we focused on the male forewing. Since males use their forewings to produce courtship songs, this structure affects fecundity. Additionally, it is likely that some genes jointly affect the two pairs of wings. Selection for flight efficiency on the hind wings should thus indirectly affect the forewings. This implies that the fore wings might be influenced by both trading off parameters. Using geometric morphometrics we analyzed the forewing shape variations both within and among morphs. Then, using a full sib design we estimated the genetic and non genetic components of shape variation. We discuss our results in terms of selection and developmental constrains.

Molecular responses to cold and desiccation

DL Denlinger, JP Rinehart, SAL Hayward, MR Michaud
Department of Entomology, Ohio State University, 318 W. 12th Avenue, Columbus, OH USA 43210-1242; denlinger.1@osu.edu

Heat shock proteins (Hsps) are involved in responding to both low temperature and desiccation in flesh flies, but different sets of Hsps are involved in the responses to overwintering cold hardiness, rapid cold hardening, desiccation and rehydration. The use of RNAi to knock out Hsp70 has a dramatic effect on overwintering cold hardiness, but Hsp23 appears to be much more important for rapid cold hardening. Hsp23 and Hsp70 are both upregulated by desiccation, but two other Hsps, Hsp90 and Hsc70, are upregulated when a desiccated fly is rehydrated. The rehydration response is most similar to the Hsp response to cold recovery: Hsp90 and Hsc70 are upregulted in both cases. The deployment of different subsets of Hsps thus differs from the response to heat shock, where all are upregulated simultaneously. Microarray data indicates that a number of genes, in addition to the Hsps, are involved in the fly's response to low temperature.

Phylogenetic congruence of mealybugs and their P-endosymbonts

DA Downie, PJ Gullan
Department of Zoology and Entomology, Rhodes University, Grahamstown 6140, South Africa; d.downie@ru.ac.za

Tight interactions between unrelated organisms such as is seen in plant-insect, host-parasite, or host-symbiont associations may lead to speciation of the smaller partners when their hosts speciate. Totally congruent phylogenies of interacting taxa have not been observed often but a number of studies have provided evidence that various hemipteran insect taxa and their primary bacterial endosymbionts have shared phylogenetic histories. Like other hemipteroids, mealybugs (Pseudococcidae) harbor multiple intracellular bacterial symbionts that are thought to be strictly vertically inherited. Thus co-divergence of hosts and symbionts is expected. Here, robust estimates of phylogeny were generated from four fragments of three nuclear genes for mealybugs of the subfamily Pseudococcinae, and a substantial fragment of the 16S-23S rDNA of their P-endosymbionts. Phylogenetic congruence was significant, with 75% of nodes on the two trees identical. Congruence was not perfect however, and other evolutionary outcomes including host shifts could not be ruled out. It is shown that incongruence may be influenced by uncertainty in phylogenetic estimation.

Effects of short-term spontaneous mutation accumulation for life history traits in grape phylloxera

DA Downie
Department of Zoology and Entomology, Rhodes University, Grahamstown 6140, South Africa; d.downie@ru.ac.za

Mutation is the source of all genetic variation but the mutation rate, effects of new mutations, and their role in the maintenance of genetic variation are still subject to controversy. These parameters are important in models of the evolution of sex and recombination, the persistence of asexual populations, and the extinction of small populations. Most estimates have come from model organisms. Here, mutation accumulation experiments were conducted with 3 clones of grape phylloxera, *Daktulosphaira vitifoliae* Fitch, a gall forming herbivore of grapes, to estimate rate of input and effects of spontaneous mutation on life history traits. This is perhaps the first such experiment using a non-model organism of economic importance. Evidence was found that mutation rates are high enough to produce heritable genetic variation over short time scales, and that the effects of mutation on these quantitative traits are deleterious on fitness. Estimates of the parameters by the Bateman-Mukai method were within the range found in previous studies. Rapid accumulation of deleterious mutations suggest that for many pest species, adaptive response under agricultural conditions may depend more on standing variation from introductions than new mutation.

Insect antifreeze proteins

JG Duman
Department of Biological Sciences, University of Notre Dame, Notre Dame, IN 46556, USA; duman.1@nd.edu

Although they have been identified in various animals, plants, fungi and bacteria, the most active antifreeze proteins (AFPs) yet discovered are found in insects. In larvae of the freeze avoiding Pyrochroid beetle *Denoides canadensis* AFPs function to prevent freezing by (1) inhibiting inoculative freezing initiated by external ice across the cuticle, and (2) by inactivating internal ice nucleators, thereby inhibiting spontaneous nucleation and promoting supercooling. Two types of insect AFPs are currently known. Those of *D. canadensis* (DAFPs) consist of 12-and 13-mer repeating units in which certain positions (especially those with threonine, serine and cysteine residues) are highly conserved. Threonines, in particular, appear to be involved in the ability of the DAFPs to hydrogen bond to ice or ice nucleators. There are tissue and temporal variations in the expression of the family of 13 variants of the DAFPs, suggesting variation in function. Optimal function of the DAFPs requires the presence of low molecular mass enhancers (glycerol, etc.) and/or certain other protein enhancers. Also, certain DAFPs have a synergistic effect on other DAFPs. In Alaska, AFPs similar to DAFPs play a role in the ability of larvae of the Cucujid beetle *Cucujus clavipes* to supercool to extreme temperatures, in some cases below -80C.

Canalization and cryptic variation in *Drosophila melanogaster*.

I Dworkin, G Gibson
3632 Gardner Hall, Department of Genetics, North Carolina State University, Raleigh, NC. 27695, USA

Canalization has been discussed a great deal with respect to evolutionary developmental biology, however there is a lack of consensus as to a precise definition of canalization itself. This has resulted in a large number of studies exploring different aspects of the same question with no common reference. I will discuss some methodological and statistical approaches to addressing questions of canalization, and cryptic genetic variation, and provide some empirical examples of how these can help to improve our understanding of canalization. Furthermore, I will summarize the results of a recent association mapping study designed to explore the genetic basis of cryptic variation.

Evolutionary and functional genomics of wing shape in *Drosophila melanogaster*.

I Dworkin, G Gibson
3632 Gardner Hall, Department of Genetics, North Carolina State University, Raleigh, NC. 27695, USA

While most organisms vary considerably in aspects of shape, surprisingly little is known about the genetic basis of shape variation. Using the wing of *Drosophila* as a model system, I will present the results of a functional genomics study of wing shape, and how mutants in known wing patterning genes affect shape. Furthermore I will discuss the results of association mapping studies between natural polymorphisms in two genes, *Epidermal growth factor receptor* and *hedgehog*, with wing shape.

Diversity in the weapons of sexual selection: horn evolution in the beetle genus *Onthophagus*.

DJ Emlen
Division of Biological Sciences, The University of Montana, Missoula MT 59812; doug.emlen@mso.umt.edu.

Both ornaments and weapons of sexual selection frequently exhibit prolific interspecific diversity of form. Yet, most studies of this diversity have focused on ornaments involved with female mate choice, rather than on the weapons of male competition. With few exceptions, the mechanisms of divergence in weapon morphology remain largely unexplored. Here, I examine the evolutionary radiation of one type of weapon: beetle horns. I use partial sequences from one nuclear and three mitochondrial genes to develop a phylogenetic hypothesis for a worldwide sample of 39 species from the dung beetle genus *Onthophagus* (Coleoptera: Scarabaeidae), and then use these data to trace the evolutionary radiation of horns. Although this limited sample of one of the world's most species-rich genera almost certainly underestimates the number of evolutionary events, it reveals prolific evolutionary lability of these exaggerated sexually selected weapons (over 24 separate gains and losses of five different horn types).

Genotype to phenotype: physiological control of trait size and scaling in insects.

DJ Emlen, CE Allen
Division of Biological Sciences, The University of Montana, Missoula MT 59812; doug.emlen@mso.umt.edu.

For almost a century, biologists have used trait scaling relationships (bi-variate scatter-plots of trait size versus body size) to characterize phenotypic variation within populations, and to compare animal shape across populations or species. Scaling relationships are a popular metric because they have long been thought to reflect underlying patterns of trait growth and development. However, the physiological mechanisms generating animal scaling are not well understood, and it is not yet clear how scaling relationships evolve. Here we review recent advances in developmental biology, genetics, and physiology as they pertain to the control of growth of adult body parts in insects. We summarize four mechanisms known to influence either the rate or the duration of cell proliferation within developing structures, and suggest how mutations in these mechanisms could affect the relative sizes of adult body parts. By reviewing what is known about these four processes, and illustrating how they may contribute to patterns of trait scaling, we reveal genetic mechanisms likely to be involved in the evolution of insect form.

Impact of 1997-1998 ENSO-induced fires and logging on the genetic diversity of *Upadia theda* Felder (Lycaenidae) in Borneo.

C Fauvelot, DFR Cleary, SBJ Menken
Institute for Biodiversity and Ecosystem Dynamics, University of Amsterdam, 1098 SM Amsterdam, The Netherlands; fauvelot@science.uva.nl

Drastic changes in population size as a result of disturbance can severely affect genetic variation. However, although severe disturbance is assumed to reduce levels of diversity, intermediate levels of disturbance, on the contrary, can lead to elevated levels of diversity. Here, we investigated the temporal variation in genetic diversity in populations of the butterfly species *Upadia theda* Felder (Lycaenidae), that were differentially affected by disturbance in East Kalimantan, Indonesia. We focused on the two main forms of disturbance that affect tropical rain forests, namely logging and ENSO-induced drought and burning. The populations were sampled over a four-year period in pristine, logged and burned areas before and after 1997-1998 ENSO-induced event. We assessed genetic variation within and between samples by analysing mitochondrial DNA sequences (mtDNA control region+ 5'end of 12S) and five microsatellite loci. Both molecular markers gave concordant results with respect to the temporal pattern of genetic diversity within disturbed areas: a significant loss of genetic diversity was observed in burned areas compared to pristine areas, but there was an increase of observed genetic diversity within logged areas. Gene flow between *Upadia theda* populations appeared, furthermore, to be highly restricted at the geographic scales assessed (less than 100 km). Importantly, our genetic diversity results are in line with previous published studies on temporal and spatial patterns of butterfly species richness.

Human-induced changes in organism distributions and the evolution of insect diets

CW Fox
Department of Entomology, S-225 Ag Science Center North, University of Kentucky, Lexington, KY 40546-0091; cfox@uky.edu

Human activities have caused many species to expand their ranges and humans have introduced organisms into many new and often very novel environments. These human-induced changes in organism distributions create natural experiments with which we can study ecological and evolutionary processes that otherwise could only be inferred indirectly. I examine the consequences recent changes in plant distributions for the evolution of insect diet. Using a model system of diet evolution is seed beetles (Coleoptera: Chrysomelidae: Bruchinae) I examine evolutionary constraints on adaptation, the role of life history plasticity, and the importance community composition in mediating diet expansion and adaptation.

Investigating the genetic basis of phenotypic variation in *Drosophila* egg shell patterning.

LM Goering, G Gibson.
Box 7614, Dept of Genetics, North Carolina State University, Raleigh, NC 27695, USA. lmgoerin@unity.ncsu.edu

Patterning of the insect egg shell provides an excellent system for exploring the molecular basis of phenotypic variation. In *Drosophila melanogaster*, two dorsal-anterior respiratory appendages are produced in response to signaling through the *Epidermal growth factor receptor* (*Egfr*). Previous empirical and theoretical work implicates *Egfr* function in both intra-specific variation for dorsal appendage spacing on the eggshell, as well as inter-specific differences in dorsal appendage number and location. To test the hypothesis that genetic variation in *Egfr* contributes to variation in egg shell patterning, we have made use of naturally occurring intra-specific variation for dorsal appendage spacing as a model quantitative trait. An initial association study suggests that two common polymorphisms in *Egfr* are involved in trait expression. We will report on our efforts to confirm the involvement of these SNPs as well as efforts to identify additional loci that contribute to dorsal appendage spacing.

Microbial diversity in termite guts and their role in mineral transformation of soil

V Gomathi, K Ramasamy
Department of Agricultural Microbiology, Centre for Plant Molecular Biology, Tamil Nadu Agricultural University, Coimbatore - 641 003, India; kvgmathi@yahoo.co.in

Termite a macro invertebrate act as soil engineers in tropical ecosystem modifying the environment in both biotic and abiotic components. Termites have a major effect on the physical properties, increases water holding capacity, control soil erosion and also improves the crop sustainability. Polysaccharide producing bacteria *viz., Azotobacter* and *Beijerinckia* isolated from the foregut of termites which are responsible to fix atmospheric nitrogen. Soil aggregation improves the physical parameters - porosity (40.3%), bulk density (1.33 g/cc), particle density and water holding capacity (39.8%), chemical parameters – increased organic carbon (0.098%) and available nitrogen (70 ppm). Incorporation of *Beijerinckia* sp. in acid soils provides additional attributes for crop production and environmental sustainability. The fungi *viz., Termitomyces* isolated from the fungal garden involved in the degradation of leaf litter in terrestrial ecosystem and also used as edible mushroom due to its medicinal value. Hence termites, are not only pests, but also play an important role in sustaining soil ecosystems.

Costs and benefits of glandular trichomes in *Datura wrightii*: why be Sticky?

JD Hare
Department of Entomology, University of California – Riverside, Riverside, California, 92521-0001, USA; daniel.hare@ucr.edu

The relationship between costs and benefits of herbivore resistance predicts the evolution of resistance. *Datura wrightii* (Solanceae), is dimorphic for leaf trichome type. Some plants are covered with short, non-glandular trichomes ("velvety plants"), while others are covered by longer, glandular trichomes that secrete acyl sugars ("sticky plants"). Glandular trichomes confer resistance to many insects but not all. In the absence of herbivores, glandular trichomes are costly because sticky plants produce 45% fewer seeds than velvety plants. Sticky plants grow larger than velvety plants, and this may confer a competitive advantage. In a three-year field study, plant competition reduced plant seed production by 76 – 87% overall. Competition was asymmetrical and favored sticky plants because sticky plants produced 42% more seeds when competing with velvety plants than when competing with other sticky plants. Conversely, velvety plants produced 53% fewer seeds when competing with sticky plants than when competing with other velvety plants. Increased competitive ability is an additional potential benefit of the suite of traits associated with the production of glandular trichomes in *D. wrightii* and may contribute to the maintenance of the trichome dimorphism in natural *D. wrightii* populations.

The mating acceptance rate of female was higher for large males than for small males.
Males fought with other males over seeds using his fore legs, and the larger males won in all cases.
Females were attracted to some odour of male, and it was more effective when males were accompanied with seeds.

In this species, copulation interval is much longer in females, which makes OSR male-biased and competition over females severe. We conclude that males adopt Resource Defence Mating System, in which they defend seeds and/or area from other males, and attract females with some odour. Therefore, sexual selection favours larger male body size.

Wing shape, wing size and fitness in *Trichogramma* wasps

AA Hoffmann, UM Kolliker-Ott, F Bigler, DM Bennett
CESAR, La Trobe University, Bundoora, Victoria 3086; A.Hoffmann@latrobe.edu.au

Trichogramma wasps are tiny egg parasitoids widely released commercially to control moth pests. To evaluate the impact of wing shape and wing size on wasp fitness, we released wasps at a central point and compared the morphology of female wasps in a release sample with females that successfully located eggs of target hosts. Three species-host-plant combinations were evaluated: *T. carverae* attacking lightbrown apple moth (*Epiphyas postvittana*) on grapevines, *T.* nr. *brassicae* attacking *Helicoverpa* spp. on tomatoes, and *T. brassicae* attacking European corn borer (*Ostrinia nubilalis*) on corn. In each case, wing size was calculated as centroid size and wing shape was assessed using Procrustes superimposition. Wing size of wasps had an impact on field fitness in all cases, but in *T. brassicae* this association was complicated by the fact that wing size effects changed with distance from the release point and time since release. Wing shape had no impact on field fitness in *T. brassicae*, but did influence field fitness in *T. carverae* and *T.* nr. *brassicae*. Changes in wing shape associated with high fitness were different in the two situations. Rearing host influenced wing shape. In all cases shape effects appeared to be at least partly independent of allometry.

Clinal variation and the genetics of stress resistance

AA Hoffmann, L Rako, J Griffiths, J Shirriffs, R Hallas.
CESAR, La Trobe University, Bundoora, Victoria 3086; A.Hoffmann@latrobe.edu.au

Clinal variation for traits within species provide an outstanding resource to identify traits and genes under selection due to climatic factors. The most well known clines in insects are for body size, but clinal variation in a range of other traits has also been identified. One of the most intensively studied clines is the *Drosophila melanogaster* cline along the east coast of Australia where populations can be collected along a transect ranging from temperate Tasmania to tropical Far North Queensland. There are opposing patterns along this transect for resistance to cold and heat stress, as well as clinal variation for evasion of stressful winter conditions by altered patterns of egg production. We are now dissecting these patterns phenotypically and genetically to identify the physiological and genetic basis of adaptive shifts in these traits. QTL mapping following crosses between populations from cline ends indicate regions of the genome associated with traits, while QTL mapping and association studies from mid-latitude populations provide evidence for specific candidate locus-trait associations. We show how the performance of selected lines in field cages can validate traits under selection and how parallel clines in related species can validate the adaptive nature of the clines.

Cryoprotective dehydration – cold tolerance in permeable invertebrates

M Holmstrup
National Environmental Research Institute, Department of Terrestrial Ecology, Vejlsøvej 25, P.O. Box 314, DK-8600 Silkeborg, Denmark; martin.holmstrup@dmu.dk

Besides the two well-known cold hardiness strategies, freeze avoidance and freeze tolerance, a third, and fundamentally different, mechanism to survive freezing temperatures by dehydration exists in organisms with highly permeable integument. When soil water in their environment freezes, they dehydrate due to the difference in water vapour pressure between the supercooled body fluids and the surrounding ice. Dehydration continues until vapour pressure equilibrium between internal fluids and the surrounding ice is reached. Recent studies have shown that this cold hardiness mechanism is widespread in soil invertebrates (e.g. Collembola) and coincides with high cuticular permeability to water. In such animals, supercooling capacity is of little or no importance for winter survival. Dehydration triggers physiological changes in Collembola, such as accumulation of sugars and polyols, expression of heat shock proteins, and shifts in the phospholipid composition of membranes. These changes are likely to promote cold tolerance in a dehydrated state.

Parasitoid foraging behavior in a life history context

G Hoogendoorn, P van der Velde, J van Alphen
PO Box 9516, 2300 RA, Leiden, Netherlands; hoogendoorn@rulsfb.leidenuniv.nl

In the 1980's a synthesis between Behavioral Ecology and Life History Theory was initiated by including life history parameters into state dependent optimal foraging models. To test these models, we collected empirical data showing that in the Australian parasitoid *Asobara persimilis* (Hymenoptera: Braconidae), genetic differences in life history traits correlate with differences in foraging behavior. *A. persimilis* occurs along the entire Australian east coast. We studied life span, patch time allocation and oviposition behavior of parasitoid populations from the Adelaide, Melbourne, Sydney and Brisbane regions. Life span increased along a gradient from Adelaide to Brisbane. Correlated to this, patch residence times and oviposition activity decreased along the same gradient. These results are in accordance with foraging models predicting a negative correlation between life expectancy of time-limited foragers and the degree to which they should exploit patches of a resource with a clumped distribution.

Exploring winter energy consumption as a limitation to the southern range limit of the goldenrod gall fly (*Eurosta solidaginis*) in late goldenrod (*Solidago gigantea*)

JT Irwin, WG Abrahamson
Department of Biology, Bucknell University, Lewisburg, PA USA 17837; jirwin@bucknell.edu

The goldenrod gall fly, *Eurosta solidaginis*, is a gall-forming insect that has diverged into two host races on its hosts *Solidago gigantea* and *S. altissima.* These host races show appreciable reproductive isolation and genetic differentiation. Both host plants range from Ontario to Florida in eastern North America. Flies of the *altissima* host race can be found virtually everywhere its host plant is present, but *gigantea* flies are only present in the northern tier of its host's range. We performed a series of experiments to identify factors restricting the *gigantea* host race to northern locales. Correlation analysis suggests that the southern limit of *gigantea* flies is constrained by warm winters, likely because warmth increases energy consumption. *Gigantea* flies are smaller and less fecund because *S. gigantea* senesces earlier (thus ceasing feeding earlier in the autumn) than does *S. altissima.* Being smaller, the *gigantea* host race has less energy to support metabolism during winter and egg production the following spring. We will present our ongoing efforts to produce a model of winter energy use for goldenrod gall flies across their range, and consequent range limitations. Our work will stand as a model for predicting shifts in geographic distributions with global climate change.

Sources of variation in costs of plant resistance to herbivores

J Koricheva
Section of Ecology, Department of Biology, University of Turku, FIN-20014, Turku, Finland; julkoric@utu.fi

A meta-analysis of 70 studies assessing the relationship between plant resistance and fitness has been conducted to examine the importance of several sources of variation in the fitness cots of resistance. The greatest costs were observed under uncontrolled environmental conditions in the field, at high levels of nutrient availability, and for defenses associated with alkaloids and phenolics. The prevalence of costs in the field and their persistence in the presence of herbivores both imply that fitness costs may arise not only due to trade-offs in the allocation of common limited resources between defense, growth and reproduction within an individual plant (direct allocation costs), but also through interactions between plants and external factors in their environment (ecological and opportunity costs). Cumulative meta-analysis revealed the evidence of publication and citation bias in studies on costs of plant resistance. The early studies conducted in 1975-1990 reported significant negative correlations between defense and fitness measures. However, after publication of several theoretical studies that have provided theoretical justification for the absence of costs, the magnitude of the reported costs decreased and became non-significant in the early 1990s. Furthermore, studies reporting significant costs of resistance received more citations than those, which reported no evidence of costs.

The evolution of egg retention and sex allocation: a study of facultatively ovoviviparous thrips

BD Kranz, T Shibata, S Okajima, K Tsuchida DC Morris
"School of Botany and Zoology, Australian National University, Canberra ACT 0200, Australia; armeniaca@bigpond.com (email addresses may be updated)"

Idolothripine thrips provide an unparalleled opportunity for investigating the evolution of reproduction. In many species, females are facultatively ovoviviparous/viviparous, and individuals choose among egg laying, live birth or both. As thrips are haplodiploid, females have some control over the sex of their offspring. We present our preliminary phylogeny and contrast work for the subfamily, and a case study of the Japanese idolothripine, *Bactrothrips brevitubus*. In this species, both sexes are produced by oviparity but only males are produced by ovoviviparity, so that sex allocation and reproductive mode act in tandem. Local resource competition between females for food and egg-laying sites may select for ovoviviparity, as females can retain their eggs until a better rearing site is located. Predatory mites could also select for ovoviviparity, as they consume the eggs but are non-fatal to larvae and adults. Population-wide sex ratios are generally unbiased, but our DNA and life history data indicate that the sex ratios are not Fisherian and are split according to the dominant reproductive mode in a patch. We consider how females tradeoff the best reproductive mode and sex allocation strategies. More broadly, we consider how egg retention and sex allocation may have coevolved in the subfamily.

Rapid cold-hardening: mechanisms and ecological significance

RE Lee
Department of Zoology, Miami University, Oxford, Ohio 45056 USA; leere@muohio.edu

More than 15 years ago we reported a rapid cold-hardening (RCH) response that protects various species of insects and related taxa against cold shock (non-freezing) injury. This swift acclimatory response to a brief exposure at a moderately low temperature allows the insect to survive a subsequent cold shock that would otherwise be lethal. Although little is known about the physiological mechanisms underpinning this response, recent evidence suggests that modifications of membrane fluidity and stress proteins play a role. RCH can also occur in isolated cells directly exposed to low temperature. Originally, we hypothesized that the RCH response allowed insects to enhance "instantaneously" their cold tolerance in a thermally variable environment. Recently, we obtained strong support for this hypothesis by demonstrating that RCH occurs under ecologically relevant cooling rates and diurnal thermoperiods. Furthermore, the rapid acclimatory response is not restricted to cryoprotection, but also functions to enhance organismal function at multiple levels, including courtship and mating, in response to environmental cooling at moderate to high temperatures. Thus, it is clear that RCH has broad ecological significance because it allows insects to continuously fine-tune organismal response to match even modest changes in environmental temperature that occur throughout the year.

Costs and benefits of resistance and tolerance to herbivores: the importance of gene x environment effects

RL Lindroth, MT Stevens
Dept. of Entomology, 237 Russell Labs, Univ. of Wisconsin, Madison, WI 53706, USA; linoth@entomology.wisc.edu

Trembling aspen (*Populus tremuloides*) is the most widespread tree species in North America and the most genetically variable plant species known to science. Extraordinary genetic variation of this clonal species extends to traits such as rates of growth and levels of chemical (salicylates and tannins) defense. Given that aspen is routinely subject to expansive defoliation events (e.g., large aspen tortrix, forest tent caterpillar) the question arises as to why defense polymorphisms persist in natural populations, i.e., why do not all genotypes express maximum levels of defense? The emerging answer involves both environmental and ontogenetic influences on the expression of chemical defense. For young aspen trees, high commitment to chemical defense incurs a significant cost in terms of growth in resource-poor, but not resource-rich, environments. Thus, in the absence of herbivory, highly defended trees are disadvantaged because slow growth may limit competitive ability. As trees mature, salicylate-based defenses tend to decline, extensive root systems develop, and trees appear to shift their defensive strategy to tolerance. Tolerance itself is also genetically variable and influenced by resource availability.

Sexual isolation in North American fruit flies: reinforcement, reproductive character displacement and the role of courtship song

ME Lineham, MG Ritchie
54 Johnston Street, Leeds, W.Yorks, LS6 2NQ, UK; lineham@tiscali.co.uk

Differences in the courtship song of *Drosophila* males, produced by wing vibrations, have been implicated in sexual isolation between several species and races through female discrimination. The range of *Drosophila persimilis,* California, Oregon and Washington State, is completely contained within that of its sibling species *D. pseudoobscura* which extends as far east as Texas. The species are morphologically identical but sexually isolated. Although male courtship appears to be indiscriminate, females of these species discriminate against mating with heterospecific males. Females from areas where they co-occur discriminate more than those collected from allopatric locations. This has been suggested to be an example of speciation by reinforcement. Despite identifying species differences in both major song parameters, interpulse interval (IPI) and intrapulse frequency, previous work has suggested that these song differences are not responsible for sexual isolation. In this study playback experiments of synthetic *D. pseudoobscura* and *D. persimilis* song demonstrate clearly that females do indeed discriminate between conspecific and heterospecific courtship song. Reinforcement may be as a result of a narrowing in female preferences in sympatry or of reproductive character displacement (RCD) in a male courtship trait. The courtship songs of *D. pseudoobscura* from both sympatric and allopatric locations are examined for evidence of RCD.

Adaptive responses by Australian burrowing cockroaches to fluctuating Neogene and Pleistocene environmental conditions: evolution in parallel and reverse?

N Lo, K Maekawa, H Rose
[1]DIPAV, Sezione di Patologia Generale and Parassitologia, Universita' di Milano, Via Celoria 10, Milan 20133 Italy; nathan.lo@unimi.it

Over the last ~15 million years, many areas in Australia once covered by rainforest have been transformed into zones of savanna, shrubland and sclerophyll forest, primarily due to long periods of arid climatic conditions. Understanding how the ancient ancestors of Australia's unique extant fauna responded to these changes is of singular interest. We have recently provided phylogenetic evidence that Australian-native soil-burrowing cockroaches evolved from wood-feeding ancestors following an invasion of the latter from Asia into Australia. The transition from wood to soil burrowing was most likely a result of aridification, which would have led to the disappearance in many areas of wood suitable for burrowing. We have extended our study to include all known soil-burrowing cockroach species, as well as most Australian burrowing cockroach species. Phylogenetic analyses based on mitochondrial COII data suggest that the soil-burrowing habit may have evolved on more than one occasion. An alternative explanation is that it evolved only once, but has been followed by 're-evolution' of the wood-burrowing habit. Approximate times of divergence between key taxa will be estimated using molecular dating methods, allowing a preliminary examination of whether these transitions occurred at similar or different times.

Does predation maintain plasticity in *Bicyclus anynana*?

A Lyytinen, PM Brakefield, L Lindström, J Mappes
Department Of Biological And Environmental Science, Po Box 35, Fi-40014 University Of Jyväskylä, Finland; alyytine@bytl.jyu.fi

The butterfly *Bicyclus anynana* exhibits phenotypic plasticity involving the wet season phenotype which possesses marginal eyespots on the ventral surface of the wings and the dry season form that lacks these eyespots. We examined the adaptive value of phenotypic plasticity of *B. anynana* in relation to the defence mechanisms of crypsis and deflection. We assessed the visibility differences between spotless and spotted butterflies against backgrounds of brown (y season) or green (wet season) leaves. Spotless butterflies were highly cryptic and less predated by adult bird predators than spotted ones when presented against brown leaf litter. The advantage of crypsis disappeared in the wet season habitat as both forms were equally visible. In later experiments, naïve birds presented with resting butterflies in the wet season habitat tended to learn more rapidly to capture spotless butterflies, suggesting a slight selective advantage of possessing eyespots. Marginal eyespots increased significantly the escape probability of butterflies that were attacked by naïve birds compared to adult birds, although there were no differences in prey capture success within naïve predators. Our results show that natural selection acts against eyespots in the dry season favouring crypsis whereas in the wet season it may favour eyespots as deflective patterns.

The peppered moth: decline of a Darwinian disciple

MEN Majerus
Department of Genetics, University of Cambridge, Downing Street, Cambridge, CB2 3EH, UK; mike.Majerus@gen.cam.ac.uk

The evolution of melanism in the peppered moth, following the industrial revolution in Britain, is the most cited example of an observed heritable change that resulted from Darwinian evolution. The reason for this is that the change was visually obvious, was observed, and could be explained by Darwin's central mechanism of evolution - natural selection. Further, the reason that the black form was fitter than the pale form was easy to understand: against lichen denuded and smoke blackened bark, the black moths were better camouflaged, and so were less often found and eaten by birds. Recently creationists have seized upon design flaws in Bernard Kettlewell's classical experiments in the 1950s. They claim that these flaws, and more recent allegations of fraud aimed at Kettlewell and a conspiracy of silence among evolutionary biologists, particularly in Britain, fatally undermine this cornerstone of Darwinian evolution, and therefore the basic theory of evolution by natural selection. Many schools in the U.S.A. have dropped the peppered moth case from biology teaching, and pressure is growing elsewhere. Most biologists who have worked on the peppered moth take the view that although Kettlewell's experiments did contain design flaws, these flaws would only have affected the quantitative accuracy of his tests; not the qualitative interpretation that differential bird predation has played a major role in the evolution of melanism in the peppered moth. The question I will address is whether melanism in the peppered moth should still be regarded as an example, par excellance, of Darwinian evolution in action.

Origin and evolution of seasonal adaptations: ground crickets in tropical, subtropical and temperate climatic conditions

S Masaki
Matsubara Higashi-1-12-13, Hirosaki, 036-8141, Japan; Sinzo.Masaki@mb4.seikyou.ne.jp

The ground cricket species complex, *Dianemobius nigrofasciatus* and *D. fascipes*, is probably of tropical origin and widely distributed from tropical to temperate regions in East Asia. It might be surmised that as peripheral populations dispersed northward, they encountered gradual changes in climatic conditions, evolved locally different types of seasonal life cycle, and egg diapause became the core of adaptation to overwintering in the northern climate. I pursued the origin of egg diapause and the associated patterns of nymphal development in local populations at low (tropical and subtropical) latitudes and found dual responses (egg diapause and delayed nymphal development) to short days in some of them. In other tropical populations a few eggs showed delayed hatching. The occurrence of such eggs might represent 'life-cycle polymorphism' to cope with unpredictable risks after hatching and might be the source of evolution for egg diapause and overwintering in the north.

Ontogenetics of QTL: the genetic architecture of trichome density over time in *Arabidopsis thaliana*

R Mauricio
Department of Genetics, Life Sciences Building, University of Georgia, Athens, GA 30602-7223 USA

Although much is known about the molecular genetic basis of trichome development in *Arabidopsis thaliana*, less is known about the underlying genetic basis of continuous variation in a trait known to be of adaptive importance: trichome density. The density of leaf trichomes is known to be a major determinant of herbivore damage in natural populations of *A. thaliana* and herbivores are a significant selective force on genetic variation for trichome density. A number of developmental changes occur during ontogeny in *A. thaliana*, including changes in trichome density. I used multiple interval mapping (MIM) analysis to identify QTL responsible for trichome density on both juvenile leaves and adult leaves in replicate, independent trials and asked whether those QTL changed with ontogeny. In both juvenile and adult leaves, I detected a single major QTL on chromosome 2 that explained much of the genetic variance. Although additional QTL were detected, there were no consistent differences in the genetic architecture of trichome density measured on juvenile and adult leaves. The finding of a single QTL of major effect for a trait of known adaptive importance suggests that genes of major effect may play an important role in adaptation.

Regulation of a plant allelochemical-inducible detoxification gene via the aryl hydrocarbon response cascade

CM McDonnell, R Petersen Brown, MA Schuler, MR Berenbaum
Department of Entomology, 320 Morrill Hall, University of Illinois Urbana-Champaign, Urbana, IL 61801; cmcdonne@uiuc.edu

The promoter of *CYP6B1*, a cytochrome P450 monooxygenase (P450s) that metabolizes furanocoumarins (i.e. xanthotoxin) found in the specialized diet of the swallowtail caterpillar *Papilio polyxenes*, utilizes several elements for basal and xanthotoxin-inducible expression, including the xenobiotic response elements to xanthotoxin (XRE-Xan) and aryl hydrocarbons (XRE-AhR). In mammalian systems, XRE-AhR mediates induction of *CYP1A1* by aryl hydrocarbons via the aryl hydrocarbon receptor (AhR) and its heterodimeric partner, ARNT. To determine if AhR-like and ARNT-like proteins from *Drosophila melanogaster*, spineless-aristapedia (Ss) and tango (Tgo), are capable of activating *CYP6B1* transcription via its XRE-AhR element, Ss and Tgo proteins were coexpressed with the wildtype *CYP6B1* promoter:CAT construct in an Sf9 cell transfection system. These studies indicate that basal and xanthotoxin-inducible expression are significantly increased in the presence of Ss and that xanthotoxin-inducible expression is increased in the presence of Tgo. Coexpression of Ss/Tgo with the *CYP6B1* promoter constructs containing mutations in the XRE-Xan or XRE-AhR elements indicate that mutations in the XRE-AhR element reduce basal and xanthotoxin inducible expression but retain low levels of activation in the presence of Ss/Tgo. These results suggest that the *CYP6B1* promoter employs conserved elements of the aryl hydrocarbon regulatory cascade for basal and xanthotoxin-inducible expression that are shared between vertebrates and invertebrates (XRE-AhR).

"*Drosophila melanogaster* gene expression in response to a virulent endosymbiont "

E McGraw, S O'Neill
Department of Zoology & Entomology, School of Life Sciences, University of Queensland, St. Lucia, QLD 4072 Australia; e.mcgraw@uq.edu.au

Wolbachia pipientis is an obligate intracellular bacterium present in a wide range of insect species. While the bacterium is known for its ability to manipulate host reproductive biology, most strains cause little direct harm to host tissues. One exception is a strain called "popcorn" that infects *Drosophila melanogaster.* As the fly ages the bacterium replicates to large numbers, leading to rupture of host cells and shortened insect lifespan. This over-replication is aberrant in comparison with other *Wolbachia* infections whose densities remain stable or decline with insect age. Previous work indicates that *Wolbachia* infections do not induce or actively suppress an innate immune response in *Drosophila melanogaster.* Because the popcorn infection leads to cell rupture we predicted that this strain would likely induce host defenses. Using a microarray approach we have examined the effect of popcorn infection on host gene expression as the host ages. Overall, gene expression decreases with age in response to popcorn infection. The bacterial specific response resulting in antimicrobial peptide production is not activated. The most common class of upregulated genes, however, were serine proteases; including elastases and trypsins. Serpins, the regulators of these proteases are also highly expressed, as are other genes encoding general defense response proteins.

Evolutionary dynamics of *w*Au-like *Wolbachia* strains in Neotropical *Drosophila* species

WJ Miller
Center of Anatomy and Cell Biology, Medical University of Vienna, AG General Genetics, Währingerstr. 10, A-1090 Vienna, Austria;
wolfgang.miller@meduniwien.ac.at

We have screened 29 American strains of the Neotropical species *Drosophila willistoni* for the infection status with the -proteobacterium *Wolbachia wsp* PCR diagnostics and Southerns blots. Although *Wolbachia* is absent in older strains of *D. willistoni* collected before the 1970s more recent samples derived from natural populations all over the American continent are universally infected with the A-group *Wolbachia* strain named *w*Wil. *w*Wil of *D. willistoni* is identical to *w*Au of *D. simulans*. Like *w*Au in *D. simulans* *w*Wil is not inducing cytoplasmatic incompatibility (CI) in *D. willistoni*. In contrast to *w*Au a strain infecting both germline and somatic tissues *w*Wil is exclusively targeting the primordial germline cells of *D. willistoni* embryos. This tissue tropism of *w*Wil and its temporal and spatial biogeographically pattern strongly support (*i*) a long-term evolutionary relationship between *w*Wil and its host species *D. willistoni* in some isolates; (*ii*) its modern day infective spreading throughout *D. willistoni* American populations, and (*iii*) our assumption that this Neotropical *Drosophila* species can be regarded as the most likely donor source for a recent *Wolbachia* infection of immigrating *D. simulans* with the strain *w*Au. Furthermore new *Wolbachia* strains derived from Neotropical *saltans* group species do harbor polymorphic *w*Au-like *Wolbachias*.

Mechanism and evolution of caste polyphenism in social insects

T Miura
Department of Biology, Graduate School of Arts and Sciences, University of Tokyo, 3-8-1 Komaba, Meguro-ku, Tokyo 153-8902, Japan; cmiu@mail.ecc.u-tokyo.ac.jp

Phenotypes of organisms are not determined completely genetically, but vary according to environmental factors (phenotypic plasticity). Some organisms express several discrete adaptive phenotypes (polyphenism). Social insects possess a few types of individuals (castes) in their colonies, to which tasks are allocated. Here, I introduce our case studies related to caste polyphenism in ants and termites. We focus on the developmental mechanisms of cast-specific characters, such as alate wings or soldier mandibles. In ants, the developmental fate of caste is determined in the early stage of postembryonic development, but apoptotic degeneration occurs in the wing primordia of future workers. As apoptotic wing degeneration was observed in two phylogenetically distant groups of ants, this phenomenon is suggested to be common in many ant species. On the other hand, all termite species possess distinct sterile soldiers, which have specific morphology suitable for defense. We isolated genes related to soldier differentiation and analyzed the expression profiles of those genes, in order to understand the mechanism of caste differentiation and the link between molecular and social evolution. I will compare these studies, in terms of the alteration of body plan in response to environmental signals, and discuss the evolutionary process of the interaction between ontogeny and environment.

Possible reproductive isolation as an indirect consequence of adaptation to different environments: pleiotropic effect of clock genes

T Miyatake
Faculty Of Agriculture, Okayama University, Okayama 700-8530, Japan; miyatake@cc.okayama-u.ac.jp

Clock genes pleiotropically controlling development time, circadian rhythm and time of mating can cause an allochronic reproductive isolation in a model insect, the melon fly *Bactrocera cucurbitae*, which mate once a day at dusk. A series of experiments including artificial selection and behavioural analyses showed that flies with shorter developmental and circadian periods (ca 22 h of locomotor activity rhythm) mated 5 h earlier in the day than those with longer periods (ca 30 h). Mate choice tests demonstrated significant pre-mating isolation between populations with short and long circadian periods. Pre-mating isolation did not occur when the mating time was synchronized between the two populations by photoperiodic controls, indicating that reproductive isolation is due to variations in the time of mating and not any unidentified ethological difference between the two populations. The fluctuation of *per* gene mRNA expression under DD is closely correlated to the locomotor rhythm in each population with short and long periods in *B. cucurbitae.* The results suggest that a clock gene might be involved in the allochronic pre-mating isolation. I discuss allochronic reproductive isolations as an indirect consequence of adaptation to different environments in view of a pleiotropic effect of clock gene controlling time-related traits.

The development and evolution of novel phenotypes: a case study on beetle horns

AP Moczek
Center for Insect Science and Department of Molecular and Cellular Biology, University of Arizona, 1007 East Lowell Street, Tucson AZ, 85721, USA; arminmo@email.arizona.edu

How do ecological, developmental, and genetic mechanisms interact in the origin and diversification of novel phenotypes? This question is at the center of my research on the evolution and development of beetle horns, a morphological novelty that upon invention has undergone dramatic diversification on a variety of levels. Horn expression is modulated in the context of alternative male morphologies, sexual dimorphisms, between-population differences in allometric scaling, and between-species differences in the number and location of horn development. Combining morphometric, candidate-gene, and ecological approaches my research aims to integrate a genetic and developmental understanding of phenotype expression into the behavioral and ecological contexts within which different phenotypes function. In my talk I will first focus on how a developmental genetic understanding of horn expression can inform us about the origins of non-linear scaling relationships, sexual dimorphisms, and the parallel gain and loss of horns in similar and different body regions. I will then explore which ecological and social conditions contribute to and guide evolutionary changes in beetle horn development. Beetle horns and horned beetles emerge as an outstanding model system for studying the interplay between ecological and developmental mechanisms is the origins of phenotypic diversity.

Attempts to search for host genes affected by intracellular symbiotes in their expression level: transcriptome analyses with silkworm cDNA microarray

Y Nakamura, Y Kato, TJ Kurtti, S Imanishi, K Mita, T Gotoh, H Noda
Faculty of Agriculture, Ibaraki University, Ami, Ibaraki 300-0393, Japan; icc05598@nifty.com;

Arthropods harbor intracellular bacteria, such as *Wolbachia* and *Cardinium* (CFB [*Cytophaga-Flavobacterium-Bacteroides* phylum] bacteria). These facultative bacteria cause reproductive alteration in their hosts such as thelytokous parthenogenesis, male killing, feminization and cytoplasmic incompatibility. As a part of the attempt to investigate the effects of these bacteria on hosts, we examined gene expression in bacteria-infected and non-infected cells. *Wolbachia* of the small brown planthopper *Laodelphax striatellus* and Is-CFB (CFB bacteria isolated from *Ixodes scapularis*) were cultivated in silkworm cell lines (BmN4 and NIAS-Bm-aff3). A cDNA microarray, which contains about 6,000 cDNA clones of the silkworm, was used to identify the genes that were affected in the expression level by the infection of *Wolbachia* or Is-CFB. No clearly up-regulated genes were found by *Wolbachia* infection, but one transcript was down-regulated. Is-CFB infection raised expression level of a few genes.

Female genitalia and sexual selection: a morphological study of cockroach genitalia

MD Olsen, S Frank, R Meier, K-D Klass
Department of Entomology, Zoological Museum, University of Copenhagen, Universitetsparken 15, 2100 Copenhagen East, Denmark;
marie_djernaes@hotmail.com

The male genitalia of Hexapoda are often complex and species-specific in form. Several hypotheses have been proposed to explain this. This study tests three hypotheses; Lock-and-Key, Female Choice and Male-Female Conflict by studying the genitalia of four species of cockroaches. The interacting parts of cockroach genitalia are on the morphological outer side of the body and are partly sclerotised in both sexes. Furthermore, cockroach male genitalia are highly asymmetric and the direction of asymmetry has been reversed several times. These traits make cockroach genitalia easily accessible, morphologically variable, and thus highly suitable for the study of genitalic evolution.

Contrary to "Lock-and-Key," the asymmetry of the male genitalia is not matched by asymmetry in the female genitalia. As predicted by "Female Choice", mechanoreceptors are found in the areas of genitalic interaction, but a reversal of male genitalia asymmetry does not influence their placement. There is quite strong evidence against "Male-Female Conflict" as the female genitalia facilitate gripping by the male through a ledge or other holding points. However, in water-striders "Male-Female Conflict" is well documented. This suggests that none of the proposed hypotheses can explain genitalic evolution in the Hexapoda by itself, thus the ultimate explanation must be something different.

Genetic diversity and oviposition host preference of *Bemisia tabaci* (Gennadius) (Homoptera: Aleyrodidae) associated with four crops in Ghana

BA Omondi, D Obeng-Ofori, EY Danquah , SK Offei
African Regional Postgraduate Programme in Insect Science (ARPPIS), University of Ghana, Legon; omondiaman@yahoo.com

The genetic and behavioural diversity of populations of the polyphagous virus vector, *B. tabaci* infesting cassava, tomato, garden egg and okra in Ghana were assessed. Seventy-six individuals collected from four hosts in three locations were screened by RAPD-PCR, using five primers (OPA 02, OPB 08, OPC 05, OPD 16 and OPI 16). Cluster analysis using the Dice coefficient revealed two genetic clusters at the 45% level of similarity associated with cassava and okra. Crop association contributed more to the observed variability than geographical isolation. Two-choice oviposition preference bioassay was done in a petri-dish cage. Cassava whiteflies significantly ($p < 0.01$) preferred cassava to any other host, but preferred garden-egg or tomato in the absence of cassava. Tomato populations significantly ($p < 0.05$) preferred tomato and okra, while okra whiteflies did not oviposit on cassava. These results corroborate the existence of two distinct biotypes: the cassava biotype and the polyphagous biotype. Tomato, garden egg and eggplant are potential common hosts for the two and may be reservoir hosts for under intensive systems or in rotation programmes. It is suggested that whitefly management on the main hosts should accommodate the possible spill of resistance from these hosts into cassava and vegetable crops.

Molecular characterization of different biological forms of *Anopheles stephensi* Liston in Iran

F Yaaghoobi, MA Oshaghi, MR Abaei, K Akbarzadeh, N Noorjah, A Iranbakhsh, H Vatandoost
Dept. of Medical Entomology, School of Public Health and Institute of Health Researches, University of Tehran Medical Sciences, PoBox: 6446 Tehran 14155, I.R.Iran; oshaghima@yahoo.com

Malaria is still one of the main health problems in south and southeast provinces of Iran. Mosquitoes of *Anopheles stephensi* are the most important malaria vector in these regions. Based on egg ridges three biological forms of type, intermediate, and *mysorensis* has been reported within this species which shows different vector capacity and competence. Here we study the sequence variation of 1500 bp of mtDNA cytochrome oxidase subunit I (COI) of these biological forms to find molecular marker for diagnostic purposes. Different biological forms were collected from different parts of the country and were subjected to PCR-RFLP or PCR sequencing assays. Results of PCR-RFLP showed no polymorphism between different biological forms or populations. This was confirmed by comparing 1400 bp sequences of COI and COII regions which showed a high similarity between forms. However there were two haplotypes between populations of *mysorensis* form. These findings are in agreement with previous hybridization, cytological, and molecular studies stating a great gene flow between populations of *An. stephensi.*

mtDNA PCR-RFLP and PCR sequencing revealed significant genetic variation among *Anopheles superpictus* populations in Baluchistan, Iran

K Shemshad, MA Oshaghi, MR Yaghobi-Ershadi, H Vatandoost, MR Abaei, K Akbarzadeh, N Noorjah, H Laddoni
Dept. of Medical Entomology, School of Public Health and Institute of Health Researches, University of Tehran Medical Sciences, PoBox: 6446 Tehran 14155, I.R.Iran; oshaghima@yahoo.com

Mosquitoes of *Anopheles superpictus* are one of the main malaria vectors in Iran and present in most parts of the country. This taxa play different rules in malaria transmission in different areas of its geographical distribution. This study has been conducted to investigate rate of genetic variation between different populations of *An. Superpictus* in Baluchistan, the most important malarious region in Iran. A portion of about 1512 bp long of mitochondrial DNA cytochrome oxidase subunits I and II were amplified and were assayed by either RFLP or direct sequencing. Analysis RFLP of COI-II and sequences of 750 bp of 3′ end of COI gene showed that there are two main groups within specimens. Rate of sequence variations were up to 5 percent which is far exceeding than inter-population or -species variation. It is suggested that presumably this species is a group species. The results of this study which is the first molecular study on *An. superpictus*, needs to be confirmed by further molecular, cytological, and morphological studies and checked with available epidemiological data to reveal the relationship between these haplotypes and malaria transmission in each locality.

Micromalthus debilis **LeConte and its varied symbionts**

MA Perotti, DK Young, HR Braig
[1]School of Biological Sciences, University of Wales, Bangor, Gwynedd, LL57 2UW, UK; bssc13@bangor.ac.uk

The wood-boring telephone pole beetle, *Micromalthus debilis*, is the only member of the primitive family Micromalthidae. It has fascinated entomologists for years because of its unique life history features such as haplodiploidy, parthenogenesis, paedogenesis, and matriphagy. Many aspects of its biology still remain a mystery due to complications in rearing and manipulating the fragile individuals and broods. In spite of the scarce experimental data available, speculations on the evolutionary biology of this insect have been plentiful; for example, obligate matriphagy by males has been linked to the presence of a non-functional nutritional endosymbiont suggesting that *Micromalthus* is a case of Hamilton's hypothesis about the evolution of haplodiploidy, and the high cost of producing males has created a selective advantage for cyclic thelytoky. Using microscopical and molecular tools we are screening the symbiotic load of the different larvae and adults of *Micromalthus*. Several symbionts have been identified so far, including renowned reproductive parasites. We discuss the life history traits and evolutionary biology of this beetle in relation with our results and the comprehensive early literature.

Rapid cold hardening increases aphid survival at low temperatures.

SJ Powell, JS Bale
School of Biosciences, University of Birmingham, Edgbaston, Birmingham, UK, B15 2TT; SJP822@Bham.ac.uk

Most studies on insect cold hardiness have focused on seasonal adaptations occurring within the overwintering stage of an insect's life cycle, triggered by decreasing temperature and photoperiod from summer through autumn to winter. Due to their short generation times, an aphid that enters winter is unlikely to be the same individual that survives until spring. For this reason, although aphids are able to cold harden when reared at lower temperatures (10° and 5°C), the ability to rapidly cold harden may be relatively more important than in other longer-lived overwintering insects, where seasonally-induced cold hardening is the dominant response. This study assesses the effects of sub-zero temperatures on the mortality of nymphs and adult *S. avenae*, provides evidence of rapid cold hardening in *S. avenae* and investigates the ecological costs of rapid cold hardening in terms of effects on development, longevity and fecundity. The hypothesis that rapid cold hardening can be induced during the cooling phase of natural diurnal temperature cycles is supported. Rapid cold hardening increases survival and extends the lower lethal temperature, allowing aphids to acquire maximum cold hardiness when it is most needed.

Using geometric morphometrics to investigate wing dimorphism in males and females of hymenoptera – a case study based on the genus *Tachysphex* (Sphecidae: Larrinae)

E Pretorius
BMW building, Room 6.27. Faculty of Medical Sciences, PO Box 2034, University of Pretoria, Pretoria, 0001 South Africa; resia.pretorius@up.ac.za

Traditional morphometrics are currently complimented by an additional statistical method, namely geometric morphometrics which is based on the quantification of shape using *x,y* coordinates. It is characterized by the obtaining of an exact geometric description of the morphology, and the ease to visually determine which landmarks are responsible for differences/similarities. The amount of variation between the forewings of males and females of the genus *Tachyshpex* (Hymenoptera) is investigated here. The research investigates the extent of morphological similarities/differences between males and females of the same species, in order to make recommendations regarding inclusion of both sexes in a systematic or geometric morphometrics study. Mantel statistics revealed a good correlation between the male and female dataset, and although visual analysis of the RWA plots of the two sexes indicated significant correlations between sexes of the same species, differences in the position of the species clusters suggests that sexual dimorphism in wings are present. Results from the thin-plate spline analysis of the mean shape of the male and female dataset revealed which landmarks are responsible for the differences. It is concluded that, in an analysis of members of a genus, only one of the sexes be used in the analysis, as small-scale differences may influence the results.

Glue protein in *Drosophila*: protein with an obscure function?

SR Ramesh
Drosophila Stock Centre, Department of Studies in Zoology, University of Mysore, Manasagangotri, MYSORE – 570 006, India; srramesh2000@yahoo.com

Perusal of literature from the first description of larval salivary gland secretory protein (Fraenkel & Brookes, 1953) in *Drosophila* namely "Glue Protein", to the recently published article suggests that the glue 'helps' pupa to 'fix' to a substratum. Several lines of genetic and biochemical investigations on this tissue specific and stage specific protein in different species/subspecies of *Drosophila nasuta* subgroup has revealed that (a) abundant glycosylated protein is synthesized (b) most protein fractions are synthesized by co-dominant X-chromosomal gene/s (c) SDS-PAGE mobility differences of major glue fractions probably reflect differences in amino acid composition (d) there is exuberant SDS-PAGE pattern polymorphism (e) there is heteroselection of X-chromosomal glue gene/s in females in the natural populations of *D. nasuta nasuta* and *D. sulfurigaster neonasuta*. Morphometric, quantitative and behavioural studies involving several *Drosophila* species revealed absence of correlation between larval/pupal/gland size and the quantity of secretions. Species producing abundant glue prefer to pupate in the medium, those producing lesser quantities pupate on solid surface, while those producing negligible quantities, pupate in cotton plugs. These results suggest that the larval salivary gland secretions in *Drosophila* have other functions, in addition/rather than to help the pupa to 'fix' to a solid surface.

The evolution of sexually-selected traits in the sand cricket, *Gryllus firmus*

DA Roff
Department of Biology, University of California, Riverside, California, 92521, USA; Derek.roff@ucr.edu

Sexually-selected traits typically consist of components of morphology, physiology and behavior. This is particularly evident in Orthoptera where males call to attract females. Male call song is determined by the morphology of the sound-generating structure, physiological costs of calling and female behavior. In this talk I explore the evolution of these components in the cricket, *Gryllus firmus.* I discuss the genetic basis of the morphological components that generate the song, the song components themselves and the underlying physiology. I show that female choice is determined by both presence/absence of song and by song components. Because of the physiological costs of calling, macropterous males call substantially less than macropterous males and attract fewer females. Thus sexual selection can act not only on the components of the traits involved in female attraction but also on traits necessary for dispersal and hence can potentially have far-reaching affects on fitness. A common garden experiment using three geographically separate populations shows that the components underlying female choice vary among populations. Further, comparison of female choice in a population maintained in the lab for twenty years shows that this choice is stable over time, suggesting that it is maintained due to pleiotropy and not linkage disequilibrium.

The evolution of genetic architecture in response to environmental change

DA Roff
Department of Biology, University of California, Riverside, California, 92521, USA; Derek.roff@ucr.edu

Environments are highly variable in both space and time. Insects, being ectothermic are particularly sensitive to changes in their thermal environment. Evolutionary response to changes in the thermal environment are contingent on the presence of available additive genetic variation and the direct effect of the environment on the expression of this variation. I discuss two methods of investigating these factors: the experimental manipulation of temperature and the analysis, using a common garden experiment, of genetic variation along clinal gradients. For the experimental work I describe work with the cricket *Gryllus firmus*, showing that changes in temperature can have highly significant effects on phenotypic expression but relatively little on the genetic variance-covariance matrix. However, there are differences between wing morphs suggesting that these morphs show differential canalization responses to temperature change. For the work on geographic variation I describe common garden experiments conducted on two species of grasshopper (*Melanoplus* spp). These experiments show that the clinal variation in phenotypic traits is matched by clinal variation in genetic variation and that the differences among populations is concordant with previous phylogenetic analysis.

Reinvestigation of the mechanism of the female–biased sex ratio in *Wolbachia*–infected *Ostrinia furnacalis* (Lepidoptera: Crambidae)

H Sakamoto, H Hoshizaki, D Kageyama, S Tatsuki Y Ishikawa
Department of Agricultural and Environmental Biology, Graduate School of Agricultural and Life Sciences, The University of Tokyo, Yayoi, Tokyo 113–8657, Japan; hirowol@yahoo.co.jp

Wolbachia-infected females of *Ostrinia furnacalis* and *O. scapulalis* produce all-female offspring. The all-female production was interpreted as feminization of genetic males, since the antibiotic elimination of *Wolbachia* resulted in all-male offspring. However, in *O. scapulalis*, observation of the sex chromatin suggested that male-killing is the cause of the all-female production and that female-specific death is the cause of the all-male production after *Wolbachia* elimination. In the present study, we observed chromosomes of infected and cured insects of *O. furnacalis* to reinvestigate mechanism of the all-female production in this species. Infected female adults were found to be genetic females based on the presence of the female-specific sex chromatin. Both genetic males and females were included in the hatched larvae in the broods derived from infected females. Likewise, both genetic males and females were found in the hatched larvae in most broods derived from cured females. In contrast, the last instar larvae derived from infected females were in the all-female condition, and those derived from cured females were in the all-male condition. These results suggested the occurrence of opposite sex specific lethality in *Wolbachia*-infected and cured females of *O. furnacalis*, as suggested in *O. scapulalis*.

Paropsis atomaria (Olivier) (Coleoptera: Chrysomelidae): The significance of genetic and ecological diversity in a wide-ranging insect species

MK Schutze
School of Natural Resource Sciences, Queensland University of Technology, GPO Box 2434, Brisbane, Qld, Australia, 4001

The *Paropsis atomaria* complex currently consists of three described species, *P. atomaria*, *P. deboeri* and *P. elytrura*. While the latter two species have restricted distributions (to Tasmania and South-west Western Australia, respectively), *P .atomaria* is widely distributed in temperate, sub-tropical and tropical eastern Australia. The species are all *Eucalyptus* herbivores and are morphologically and behaviourally similar. This paper reports on a detailed investigation of both inter- and intra-specific relationships within the complex. Using molecular, morphological and ecological approaches the specific status of the three named taxa, as well as population level differentiation within the widely distributed *P. atomaria,* is being investigated. Special attention is paid to *P. atomaria* as it is an important forestry pest and there is potential that elucidation of population characteristics may reveal genetically distinct populations, possibly cryptic species, within the taxon. Assessment of the mitochondrial genome (COI, 550 b.p.) revealed approximately 9% differentiation between mainland *P. atomaria* and *P. deboeri*, whilst demonstrating a maximum of approximately 1.5% differentiation within *P. atomaria.* This supports current morphological classification. Such a multi-disciplinary, holistic approach will ultimately provide a robust foundation for the understanding of species boundaries and population dynamics in this economically important complex.

Adaptation to environmental gradients.

CM Sgrò, MW Blows
"Centre for Environmental Stress and Adaptation Research, La Trobe University, Melbourne 3083, Victoria, Australia; c.sgro@latrobe.edu.au"

Latitudinal clines are widespread and provide a natural framework within which to examine natural selection. Repeated clines in different geographic areas or in related taxa strongly implicate the occurrence of natural selection. Clinal variation at the phenotypic level therefore provides an opportunity to examine the way in which genetic variation may also be influenced by natural selection. Despite the widespread occurrence of latitudinal clines, there are few empirical data that address the question of how quantitative genetic variation varies along such clines. We have combined comparisons of clinal populations of *Drosophila serrata* collected from the eastern coast of Australia with laboratory natural selection experiments to examine the genetic basis of adaptation to environmental gradients. We show that clinal selection under natural conditions does result in changes in both the additive and nonadditive genetic variances. Furthermore, we show that adaptation to clinal environments may involve a number of distinct genetic responses along the length of the cline, the complexity of which may not be fully revealed by focussing primarily on populations at the ends of the cline.

Metabolism of the sub-Antarctic caterpillar *Pringleophaga marioni* during cooling, freezing and thawing

BJ Sinclair, CJ Klok, SL Chown
Spatial, Physiological and Conservation Ecology, Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa, bjs@sun.ac.za

Although general models of the processes involved in insect survival of freezing exist, there have been few studies directly investigating physiological processes during cooling, freezing and thawing, without which those models remain hypothetical. Here we use open-flow respirometry to investigate metabolism of the freeze-tolerant sub-Antarctic caterpillar *Pringleophaga marioni* Viette (Lepidoptera: Tineidae) during cooling, freezing and thawing, and to compare animals exposed to non-lethal (-5.8 °C), and lethal (-6.0 °C, after which caterpillars are moribund for several days; and -18 °C, after which caterpillars are completely unresponsive) freezing stress. We found a large decrease in metabolic rate (that is not associated with freezing) at -0.6 ± 0.1 °C, and calculated a Q_{10} of 2.14×10^3 at this breakpoint. This breakpoint is coincident with the critical thermal minimum, and is hypothesised to be a metabolic manifestation of the latter. Caterpillars froze at -4.6 ± 0.1 °C, and had non-zero metabolic rates when frozen. Post-thaw, metabolic rates were lower than pre-freezing measurements. Post-thaw metabolic rates did not differ between temperatures that did and did not kill the caterpillars, which suggests that mortality may be a result of a breakdown in processes at the organismal, rather than cellular, level of organization.

Evolutionary implications of infection with parthenogenesis inducing *Wolbachia*

R Stouthamer
Department of Entomology, University of California, Riverside, CA 92521, USA

The presence of Parthenogenesis Inducing (PI) *Wolbachia* infected individuals can have a strong impact on both the infected individuals as well as on the uninfected individuals present in a population. Two situations exist, the infection remains at some equilibrium or the infection goes to fixation. In this presentation I will present a model showing that an equilibrium infection frequency can only exist at a low level of infection if there are some factors present in the population that counteract the *Wolbachia* by modifying its expression /transmission (suppressor), or when other genetic elements are present that exploit the female biased sex ratio caused by the infection. If populations have gone to fixation for the infection with PI *Wolbachia* this generally is accompanied by a change in the females mating behavior and/or fertilization behavior. These changes are such that females from infected lines are unable to successfully mate and/or fertilize their eggs, whereas males derived from these same infected lines (through antibiotic treatment) are still functional and capable of fathering offspring.

Does environmental stress increase genetic structure in the springtail *Orchesella cincta*?

MJTN Timmermans, J Ellers, NM Van Straalen
De Boelelaan 1085, 1081 HV Amsterdam, The Netherlands; timmerm@bio.vu.nl

Environmental stress can alter the genetic composition of natural populations by directional selection towards tolerant genotypes, by causing bottlenecks and by changing gene flow to and from stressed locations. Especially when gene flow is low, environmental stress is expected to increase levels of genetic differentiation among populations. We examined the effect of environmental pollution on population genetic structure for the soil dwelling species *Orchesella cincta* by comparing Isolation by Distance relationships. First, population genetic structure of sixteen NW European populations was estimated using six polymorphic microsatellite loci. A significant Isolation By Distance relationship was revealed, indicating gene flow is relatively high in this small soil arthropod species. Secondly, comparisons between stressed and pristine populations versus pristine populations revealed no differences in Isolation by Distance relationships. Our results indicate environmental pollution does not play a significant role in shaping population genetic structures within this species, most likely due to its migration capacity. Gene flow might, by filling up reduced genetic variability in stressed populations, be an evolutionary force maintaining versatility of stressed populations.

"Effects of eugregarine parasites on adult longevity in the polymorphic damselfly *Mnais costalis* Selys"

Y Tsubaki
"Biodiversity Conservation Research Group, National Institute for Environmental Studies, Tsukuba, 305-8506 Japan; tsubaki@nies.go.jp"

Males of *M. costalis* show a genetic polymorphism linked to mate-securing strategies, typically existing as orange-winged territorial fighters and clear-winged nonterritorial sneaks (the former are larger in size) (Tsubaki 2003). Orange-winged males have a higher daily mating rate, however, their reproductive life span and longevity is less than that of clear winged males. As a result, the estimated lifetime reproductive success is the same (Tsubaki *et al.*, 1997). In this paper I will compare the survival cost of eugregarine infection for the two morphs looking at the relationship between the abundance of mid-gut parasites and the survival of field-collected males in captivity. Orange-winged males suffered higher parasite infection and showed shorter longevity than clear-winged males when they were fed at lower levels than the natural feeding rate, or when they were deprived of food. In contrast, morph longevity did not differ when they were fed until satiation. The survival of damselflies was negatively correlated with the parasite abundance except when damselflies were fed until satiation. The results suggest that the abundance of eugregarine parasites exerts a substantial cost, which is associated with the maintenance of alternative mating strategies, together with the higher developmental cost and energy expenditure of the fighter morph.

An evolutionary view of the sex communication in *Melittobia* spp.

FL Cônsoli, HJ Williams, J Gonzalez, RW Matthews, SB Vinson
Department of Entomology, Texas A&M University, College Station, TX, 77843-2475, USA; f-consoli@tamu.edu; bvinson@tamu.edu

Melittobia are ectoparasitoids of late larval and pupal stages of several species of solitary bees and wasps. Females locate their hosts on which they will lay their eggs, and will represent the only nutritional resource to the developing larvae. Sex dimorphism is remarkable and males will fight to death to eliminate competing males as they mate emerging females. Males remain in the confines of the host's nest they developed in, while females may disperse to locate new hosts. Mating occurs after an elaborate courtship behavior, in which a male produced sex pheromone is involved, and is supposed to play an important role in mate recognition. We will describe the differences in the male pheromone of 4 species of *Melittobia* and evaluate the attractiveness of females to interspecific males, and discuss the role of the male sex pheromone and the cuticular hydrocarbon composition of these 4 species in sex mate recognition. We will discuss the evolutionary process involved in the chemical communication of this parasitoid and provide supportive molecular data.

The sociobiology of plant defense

AE Weis
Department of Ecology and Evolutionary Biology, University of California-Irvine, Irvine, CA 92697-2525, USA

"Social context" can inflate or diminish the evolutionary success of a resistance gene by making genetic variance in fitness density/frequency-dependent. Three models illustrate. First, a plant growth model shows that intraspecific competition increases the benefit of resistance when attack levels are high (resistant plants usurp resources that damaged susceptible plants need for recovery), but also increases the costs when attack is absent (undamaged susceptible plants outgrow resistant ones). Next, a game theory model shows that the fitness benefit of resistance can vary through the interaction of enemy behavior with local genotype frequency: susceptible genotypes can gain associational resistance when at low frequency if enemies can move freely to more palatable patches; however, if enemies are restricted to single patches, the susceptibles are eventually found. Finally, plants with high allocation to resistance flower late, causing assortative mating for resistance under low herbivory. Heavy attack retards susceptibles, bringing them into flowering synchrony with resistants. A population genetic model shows that assortative mating inflates genetic variance during zero-herbivory periods when costs exceed benefits, but not during high herbivory periods when benefits exceed costs. This causes asymmetric selection responses that prevent fixation of resistance even if average benefit exceeds average cost.

The role of the hedgehog pathway in polyembryonic development

MA White, LS Corley
P.O. Box 646382, Department of Entomology, Washington State University, Pullman, WA 99164-6382 USA; mwhite10@wsu.edu

Copidosoma floridanum is a polyembryonic parasitoid wasp that produces over 1000 individuals from a single egg. This clonal proliferative process is remarkable for a number of reasons but primarily because this insect system has evolved clonal proliferation as an adaptive strategy; therefore, understanding how cellular proliferation can occur without causing disease in this organism will increase our understanding of how the cell cycle is regulated in animals and how it might be possible to mimic this natural system. The Hedgehog (HH) signal transduction cascade is a candidate gene pathway that may be regulating proliferation within the dividing cells. Among metazoan taxa, one function of HH is to regulate cellular proliferation during development. Within *Drosophila,* for instance, HH has been shown to control the proliferation and differentiation of somatic stem cells and progeny within the ovary. To determine whether HH is implicated in polyembryonic proliferation in *C. floridanum*, we cloned the C. floridanum HH gene. Ultimately, we are interested in determining the role the *C. floridanum* HH signal transduction pathway has in polyembryonic proliferation. We predict that in areas of active cellular proliferation, high levels of HH will be translated, while in areas with no proliferation, HH expression will be absent.

The genetic basis of divergent gene expression in ***Drosophila***

PJ Wittkopp, BK Haerum, AG Clark
Department of Molecular Biology and Genetics, 227 Biotechnology Building, Cornell University, Ithaca, NY 14853 USA; pw72@cornell.edu

Differences in gene expression play a central role in evolution. Both *cis*- and *trans*-regulatory changes contribute to divergent gene expression, but their respective contributions remain largely unknown. Using closely related *Drosophila* species, we examined *cis*- and *trans*-regulatory changes underlying interspecific expression differences. Functional *cis*-regulatory changes were detected by comparing the relative abundance of *D. melanogaster* and *D. simulans* transcripts in F_1 hybrids, whereas differences in *trans*-regulatory activity were inferred by comparing the ratio of allelic expression in hybrids to the ratio of gene expression between species. We found that interspecific expression differences were almost always accompanied by changes in *cis*-regulatory function. In addition, *trans*-regulatory divergence affected approximately half of the genes we examined. These data contrast with recent studies of intraspecific gene expression, which found that expression variation was caused primarily by differences in *trans*-regulation. Distinct patterns of *cis*- and *trans*-regulatory changes appear to underlie expression differences within and between species.

Phenotype matching in wild parsnips and parsnip webworms: costs and consequences.

AR Zangerl, MR Berenbaum
Department of Entomology, University of Illinois at Urbana-Champaign, 320 Morrill Hall, 505 S. Goodwin, Urbana, IL 61801, USA; azangerl@life.uiuc.edu

The coevolutionary consequences of present-day interactions between plants and their insect herbivores may vary among populations as envisioned in the Geographic Mosaic Model of Coevolution. The interaction between wild parsnip, *Pastinaca sativa*, and its principal herbivore, the parsnip webworm (*Depressaria pastinacella*), is mediated by the amounts of furanocoumarins produced in the plant and the ability of the insect to detoxify them. Within 20 midwestern U.S. populations, trait frequencies in parsnips frequently were matched by trait frequencies in webworms. Exceptions were found in populations of parsnips with high xanthotoxin chemotypes, which are difficult for webworms to utilize, and in regions where an alternative host, *Heracleum lanatum*, which has a different furanocoumarin profile from wild parsnip, is abundant. The maintenance of more susceptible genotypes of wild parsnip in all populations is presumably due to the high cost of furanocoumarin production, while mismatching in alternate host populations is likely due to the cost of adaptation by webworms.

Anisotropic index of refraction of the iridescent scales of *Morpho* butterflies

S Berthier
Laboratoire d'Optique des Solides, Université Pierre et Marie Curie, case 80, 140rue de Lourmel, F-75015 Paris France; berthier@ccr.jussieu.fr

The ground scales of the blue iridescent *Morpho* butterflies are responsible of the coloration of the wings. Such a scale has been modelized as a 2dimensions photonic crystal with two very different periodicities: a nanoscopic vertical one in each ridge (typically 100 nm) leading to interferential effects, and a microscopic horizontal one, the ridges themself (~1 µm apart) giving a strong diffraction effect. We have modelized the actual structure of the scale as a graded grating, each ridge being equivalent to a multilayered mirror of alternatively high index films (cuticle material) and low index film (air with low fraction of cuticle material). In an effective medium framework, these two films are then assimilated to continuous films characterized by their effective refraction index. These index are determined by fitting the hemispherical reflectivity. Knowing the composition of each film, via electron microscopy, one can then deduced the cuticular material index. The cuticular material is equivalent to a uniaxial crystal, with the extraordinary axis parallel to the ridge. The two refractive index curves intersect in the 450-500 nm range, *i.e.* in the blue part of the spectra. The calculated value is in good agreement with the values usually found by liquid index technique.

The effects of dopamine receptor agonist and antagonists on the secretory rate of cockroach (*Periplaneta americana*) salivary glands

S Marg, B Walz, W Blenau
Universität Potsdam, Institut Für Biochemie Und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany; blenau@rz.uni-potsdam.de

The acinar salivary glands of the cockroach, *Periplaneta americana*, are innervated by dopaminergic and serotonergic nerve fibers. Serotonin stimulates the secretion of a protein-rich saliva, whereas dopamine causes the production of protein-free saliva. This suggests that dopamine acts selectively on ion-transporting cells (peripheral cells within the acini and duct cells), and serotonin acts on the protein-producing central cells of the acini. We investigated the pharmacology of the dopamine-induced secretory response of the salivary gland of *P. americana* using several dopamine receptor agonist and antagonists. The effects of dopamine could be mimicked by the non-selective dopamine receptor agonist 6,7-ADTN but not by the vertebrate D1 receptor-selective agonist SKF 38393. R(+)-Lisuride induced a secretory response but with a slower onset and a lower maximal response compared to dopamine-induced secretion. However, lisuride-stimulated glands continued secreting saliva even after lisuride-washout. This indicates that lisuride might be a partial agonist with very high affinity but low efficacy. Saliva secreted after stimulation with ADTN or lisuride had no measurable protein content arguing against serotonin receptors being activated by these drugs. Dopamine-induced secretions could be blocked by the vertebrate dopamine receptor antagonists *cis*(Z)-flupentixol, chlorpromazine and (+)-butaclamol with a similar potency.

Dynamics of biogenic amines in the brain of bee under stress conditions

YL Chen, YS Hung, EC Yang
Dept. of Entomology, National Chung Hsing University, Taichung, Taiwan; lolita-chen@umail.hinet.net

Stress treatments, CO_2 anesthesia, chilling anesthesia and vertical spin, were applied to examine whether the honeybee workers express stress responses in foraging behavior and to measure biogenic amines level changes in the stressed bee brains. A longer time interval between back and forth the feeding place was found when bees were stress-treated, suggesting that the worker foraging behavior was affected by the stress treatments. Further analysis to the stressed bee brains found that the dopamine (DA) and octopamine (OA) levels significantly decreased after chilling anesthesia but only DA was significantly decreased if the bees were anesthetized by CO_2. Similarly, the vertical spin with the velocity up to 50 and 60 rpm for 90 s, the DA and OA levels also significantly decreased. This result shows an opposite trends from the blood levels of OA and DA as reported previously, while none of these stress treatments induced changes of the serotonin (5-HT) levels neither in the blood level nor brain level, suggesting both DA and OA are the crucial compounds for stress responses in foraging behavior.

Neuroendocrine regulation of the termination of adult reproductive diapause in two species of nymphalid butterflies

K Muranaka, A Yamanaka, RM Shahjahan, K Endo
Institute Of Biological Science, Faculty Of Science, Yamaguchi University, Yamaguchi 753-8512, Japan; endo@yamaguchi-u.ac.jp

The Asian comma butterfly, *Polygonia c-aureum*, exhibits seasonal dimorphism (summer and autumn morphs) whose development is determined by photoperiod and temperature during the larval stages in a close relation to the determination of adult reproductive diapause. The physiological mechanism underlying the photoperiodic control of seasonal morph development involves a cerebral factor, named summer-morph-producing hormone (SMPH). A neuropeptide showing the SMPH-activity can be extracted with 2% NaCl and quantified by *Polygonia* pupal assay. Autumn-morph females of *P. c-aureum* and females of univoltine butterfly, *Nymphalis xanthomelas japonica*, enter adult reproductive diapause. Diapausing female adults of these two butterfly species started ovarian maturation, a termination sign of diapause, when they were treated with juvenile hormone-I (JH-I) or 2% NaCl extracts of adult brain-suboesophageal ganglion (Br-SG) complexes. Ovarian maturation was also induced by JH-I in decapitated females and isolated female abdomens of these two butterfly species. Neuroendocrine factors stimulating ovarian maturation in diapause female adults of the same species may exists in adult Br-SG complexes. Activity of the factor extracted from the adult Br-SG complexes with 2% NaCl can be assayed using female adults of the same butterfly species.

Photoperiodic regulation of the maintenance and Termination of adult reproductive diapause in the Asian comma butterfly, *Polygonia c-aureum* L.

K Fujita, A Yamanaka, ATMF Islam, K Endo
Institute Of Biological Science, Faculty Of Science, Yamaguchi University, Yamaguchi 753-8512, Japan; endo@yamaguchi-u.ac.jp

The Asian comma butterfly, *Polygonia c-aureum* L., exhibits seasonal polymorphism and reproductive diapause, which are controlled by photoperiod and temperature imposed during the larval (the 2nd to 5th instar) and the larval-pupal (the 2nd instar to the middle of pupal) stages, respectively (Endo et al. 1992). Larvae raised up from the egg stage under long-day conditions at 20°C develop into summer morph adults, females of which produce eggs within four days after adult emergence. Under short-day conditions at 20°C larvae develop into autumn-morph adults, females of which do not start ovarian maturation and enter reproductive diapause after adult emergence. When subjected successively to short-day conditions at 20°C, autumn-morph female adults did not start ovarian maturation more than three months after emergence. However, they were found to start ovarian maturation within 10 days and produce eggs within 15 days when they were transferred to a long-day conditions. It is concluded that adults of *P. c-aureum* count the numbers of long and short days after adult emergence, on which the maintenance and termination of their reproductive diapause may be regulated to start ovarian maturation at an adequate season.

Synaptic circuitry in the mushroom bodies of the honeybee *Apis mellifera*

O Ganeshina, D Müller, J Rybak, R Brandt, U Schröter, R Menzel
Institute of Neurobiology, Free University of Berlin, Germany and VTHRC, University of Queensland, Brisbane, QLD 4072, Australia; o.ganeshina@mailbox.uq.edu.au

Insect mushroom bodies (MBs) are brain centers, involved in the control of complex behavior. We studied synaptic connections within the MB lip region of the honeybee *Apis mellifera* using electron microscopy combined with double labeling of the MB sensory and inhibitory input neurons. A medial antenno-cerebral tract neuron (m-ACTn) was with dextran-conjugated neurobiotin (Micro-Ruby), and GABA-ergic inhibitory neurons were labeled using immunocytochemistry. Three-dimensional reconstruction of labeled profiles showed that the m-ACTn and GABA-immunoreactive neurons (GABA-irns) had extensive contact area within the neuropil. Output synapses from the m-ACTn and GABA-irns into putative intrinsic mushroom body neurons (Kenyon cells) were revealed. GABA-irns also exhibited occasional output synapses into the m-ACTn. Our results indicate the presence of both pre- and post-synaptic inhibition within the MB calyces. The small number of inhibitory synapses on the m-ACTn may reflect a low level of ACTn inhibition within the MBs; alternatively, the level of presynaptic inhibition may vary among different subpopulations of the ACTns.

A bug rambles in the outbound trip: the navigational strategy in the *Parastrachia japonensis* (Heteroptera: Cydnidae)

M Hironaka, S Tojo, H Horiguchi, T Hariyama
Department of Biology, Faculty of Medicine, Hamamatsu University School of Medicine, Handayama 1-20-1, Hamamatsu 431-3192, Japan;
kd0334@hama-med.ac.jp

A female of subsocial bug, *Parastrachia japonensis* (Heteroptera: Cydnidae) transports drupes of a host tree to a nymph-containing burrow on the ground by the host tree. Because its burrow usually located up to 5m away from the host tree, the bug should take the round trip between its burrow and the area where the drupes could be obtained. We compared the outbound trip with the homing one and there was much difference. In the first outbound trip, the bug oriented randomly and searched tortuously, however, it failed many times to obtain a drupe. When the bug had encountered one, it always took the shortest route back to the burrow. After the successful trip, the bug oriented toward the position where it had obtained the drupe in the previous navigational trip using the path integration. However, its outbound trip was slower and unsteadier than the homing one. The burrow is a limited goal for the homing bug, whereas the drupes as goals for the foraging bug distribute over the ground with several patches. The behavioural differences of the outbound trip from the homing one are assumed that the bug changes the navigational strategy adjusting the spatial configurations of their goals.

Partial purification of *Bombyx* cerebral peptide showing activity of summer-morph-producing hormone (SMPH) in the Asian comma butterfly, *Polygonia c-aureum* L.

M Inoue, A Yamanaka, K Taniguchi, ATMF Islam, K Endo
Institute Of Biologibal Science, Faculty of Science, Yamaguchi University, Yamaguchi 753-8512, Japan; endo@yamaguchi-u.ac.jp

Asian comma butterfly, *Polygonia c-aureum*, exhibits seasonal (summer and autumn) morphs. Physiological mechanism underlying the photoperiodic control of seasonal morph development involves a cerebral factor, named summer-morph-producing hormone (SMPH). The cerebral factor is a peptide which can be extracted from brains of *Polygonia* long-day pupae with 2% NaCl and purified partially by a gel-filtration and a reverse-phased HPLC on *Polygonia* pupal assay for the SMPH. Besides, a cerebral peptide showing SMPH-activity in *P. c-aureum* was found to exist in brain-suboesophageal ganglion (Br-SG) complexes of the silkmoth, *Bombyx mori.* The peptide could be extracted and purified partially by the same manner as above (Tanaka et al., 1997). Here, we tried to extract the SMPH-active peptide from Br-SG complexes of *B. mori* adults and were purified partially by a gel-filtration with Superose-12 column and 6 steps of reverse-phased HPLC with C-8, C-4 and C-18 ODS-column. We succeeded to obtain highly purified SMPH-active peptide as a single peak fraction in absorbance at 220 nm.

Immunoreactivity of glutamic acid decarboxylase (GAD) isoforms in the central nervous system of the barn spider, *Araneus cavaticus*

MJ Moon, EK Tillinghast, CS Kang
Department of Biological Sciences, Hoseo University, Asan 336-795, Korea; cskang@office.hoseo.ac.kr

The γ-aminobutyric acid (GABA) has long been considered an inhibitory neurotransmitter in the central nervous system (CNS) of both vertebrates and arthropods. The glutamic acid decarboxylase (GAD) catalyzes the conversion of L-glutamate to GABA. As the GAD has a restricted tissue distribution, it is highly expressed in the cytoplasm of GABAergic neurons in the CNS. However it is also present in other non-neuronal tissues such as testis, oviduct and ovary. Recently, there were reports that a GABA-like immunocytochemical reactivity and a ninhyin-positive GABA derivative, GABamide, exists in the visual ganglia and in the water-soluble fraction of the spider web respectively. So, this experiment initiated to identify exact distribution of the GAD isoform immunoreactivity in the CNS of the spider to reveal the ecophysiological significance of GABA for spider's behavior.

Cloning of biogenic amine receptor fragments from *Periplaneta* and *Schistocerca*

C Krach, A Baumann, W Blenau
Universität Potsdam, Institut für Biochemie und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany;
christian.krach@gmx.de;

Biogenic amines regulate and modulate many physiological and behavioral processes in insects. The identification of biogenic amine receptors is decisive for an understanding of the cellular pathways regulated by the amines. Biogenic amine receptor genes encode membrane proteins that primarily belong to the superfamily of G protein-coupled receptors (GPCRs). GPCRs share the common motif of seven transmembrane domains (TM). We endeavoured to isolate members of this gene family from two hemimetabolous insects, the American cockroach, *Periplaneta americana*, and the desert locust, *Schistocerca gregaria*. Both species are important model organisms for neurobiological and physiological research. Degenerate primers were designed corresponding to highly conserved sequences in TM 6 and 7 of already cloned insect receptors. Using a *P. americana* brain cDNA library and *S. gregaria* genomic DNA as templates, four and three different PCR fragments were amplified, respectively. BLAST similarity searches to Genbank showed that the cloned fragments are derived from different biogenic amine receptor genes of both species.

Antagonists of $5HT_3$-like receptors of invertebrates as pesticides

CY Liao, S Saubern, J Ridsdill-Smith, O Edwards, SC Trowell
CSIRO Entomology, GPO Box 1700 ACT 2601, Australia; Chunyan.Liao@csiro.au

Serotonin (5HT) modulates pharyngeal pumping in nematodes. This paper concerns novel pesticides acting on $5HT_3$-like receptors in both nematodes and insects. Two selective and structurally unrelated antagonists of the vertebrate $5\text{-}HT_3$ receptor, MDL-72222 (tropanyl dichlorobenzoate) and ondansetron, were tested for their effects on feeding and survival of nematodes and insects. When applied to the nematode *Caenorhabditis elegans*, MDL-72222 stops pharyngeal pumping. MDL-72222 also causes dose-and time-dependent mortality of free-living and parasitic nematodes. The IC_{50} of MDL-72222 for blocking pharyngeal pumping of the nematode *C. elegans* was 10 M. The LD_{50} of MDL-72222 for the murine hookworm *Heligmosomoides polygyrus* was 19 M (3 days) and 5 M (5 days). Statistically significant mortality was also observed against the peach-potato aphid, *Myzus persicae*. MDL-72222 had little or no effect on growth rate of the caterpillar, *Helicoverpa armigera*. Ondansetron had qualitatively similar effects to MDL-72222 but at higher concentrations. Chemical analogues of MDL-72222 were synthesised and tested against *C. elegans* and *H. polygyrus*. One showed slightly higher potency against nematodes than MDL72222. We also report development of a 96-well-plate based assay for detecting compounds which affect pharyngeal pumping of nematodes. Patents pending.

Does the neuroanatomy of visual neurons in hoverfly match visual ecology?

TJ Rainsford, IM Moyer, M Browning, DC O'Carroll
Disipline of Physiology, The University of Adelaide, SA, 5005 , Australia; tamath.rainsford@adelaide.edu.au

Wide-field (tangential) neurons of the fly lobula plate collate information about motion. One class of such neurons is the 'horizontal system' or HS cells. These respond with graded, direction-selective responses to wide-field motion associated with yaw during flight. In several families of Cyclorraphan flies (Calliphoridae, Muscidae and Drosophilidae) there are believed to be 3 HS cells in each optic lobe. These cells divide the visual world into 'north' (HSN), 'equatorial' (HSE) and 'south' (HSS) regions. Previous work suggests that the number and morphology of HS neurons is variable amongst other species of dipteran flies in a manner that consistent with visual ecology. However, there is little supporting evidence for functional differences amongst fly species from electrophysiology. The hoverfly, *Eristalis*, is emerging as a physiological model for the study of such motion detecting neuron, and exhibits spectacular aerial performance compared with other Cyclorraphan species. We have commenced electrophysiological recordings with detailed anatomical investigation of these neurons using intracellular injection with fluorescent probes (Lucifer yellow, Alexa dyes) and confocal microscopy. Our initial data suggest that *Eristalis* has additional HS neurons, dividing the world into smaller segments than in the other Cyclorraphan species studied to date.

Characterization of small motion detection neurons of *Eristalis tenax*

K Nordström, DC O'Carroll

Discipline of Physiology, The University of Adelaide, SA 5005, Australia; Karin.Nordstrom@adelaide.edu.au

The hoverfly *Eristalis tenax* exhibits typical syrphid behaviour, with stationary hovering followed by rapid pursuit of conspecifics. Male and (possibly) female flies depend on detection of small rapidly moving targets to find mates and defend their territory. Neurons specialized for detecting small targets against cluttered backgrounds can be found in the lobula complex (3rd optic ganglion) of the fly brain. We are characterizing the morphology and physiology of a range of lobula small target motion detecting (STMD) neurons using dye-fills and electrophysiological techniques. We define STMDs as neurons that give a powerful response to a small object (1-2 degrees square) moving across a bright or cluttered background, but weaker responses to larger size targets. We find a number of classes of STMDs with unique properties in both sexes. These include neurons with small excitatory receptive fields surrounded by distinctly shaped inhibitory areas, and wide-field STMDs that may be used for mate detection. STMDs generally give spiking responses, and have variable degrees of spontaneous spike activity, including neurons that are 'silent' until stimulated by a target. A prominent feature of some STMDs is the robustness of their responses in the presence of background motion.

Comparisons of the image-step response in flies & humans

K Nordström, L Swan, S Mayrhofer, DC O'Carroll
Discipline of Physiology, The University of Adelaide, SA 5005, Australia; Karin.Nordstrom@adelaide.edu.au

Neurons specialized for detecting motion patterns are located in the fly lobula complex (3rd optic ganglion). HS (horizontal system) cells give graded direction-selective responses to the stereotypical wide-field motion generated during flight. It has long been known that identical cellular responses can be generated by apparent motion, e.g. by a stationary image that jumps in the preferred direction. HS cells give a strong, sustained response over a few milliseconds to stimuli of this kind, where an adapting image appears and then steps a few degrees in either direction (anti-preferred direction gives an inhibitory response). The amplitude of the response depends on factors such as the contrast and duration of the adapting stimulus. Human subjects do not seem to perceive the image-step stimulus as continuous motion, despite the fact that many other visual motion illusions have been shown to be similar in fly wide-field cells and human perception. By comparing fly electrophysiological data with human psychophysics we are analysing the cause of these different responses.

Pattern noise in insect motion detector responses to natural scenes

TJ Rainsford, S Rajesh, AD Straw, DC O'Carroll
"Disipline of Physiology, The University of Adelaide, SA, 5005, Australia; tamath.rainsford@adelaide.edu.au"

We are using the Hoverfly *Eristalis* as a physiological model for studying visual motion analysis in natural scenes. Natural images have predictable statistics, and biological systems may be optimized to take advantage of this predictability. In insect vision, outputs of local motion detectors are collated by a system of tangential neurons tuned to very specific types of complex motion. We utilized intracellular recordings from tangential (HS) neurons stimulated by natural panoramic images in an open-loop yaw simulator. Differences in the local structure of natural images result in variations in the correlated response of the local detectors. We investigated this 'pattern noise' through experiments, in which we present images at various initial positions and versions of the same images modified to disrupt vertical contours. By aligning responses in time across several initial positions, pattern noise is largely removed from the mean, but contributes to standard deviation. We propose a computational model with additional nonlinearity (saturation, motion adaptation) based on this principle and taking account of the receptive field shape of the tangential neurons. Such a model can provide a robust indication of the angular velocity of optical flow, with widespread applications in artificial vision systems.

Radar observations reveal the efficacy of path integration mechanisms in flying bees

AD Smith, JL Osborne, NL Carreck, DR Reynolds, JR Riley
N.R.I., University of Greenwich, Chatham, Kent ME4 4TB, UK; D.Reynolds@gre.ac.uk

We have used harmonic radar to record the complete flight paths of individual foraging honeybees that had been trained to a feeder 200 m from their hive. When the feeder was removed, hive-departing bees maintained accurate flights (often in strong gusty cross-winds) to where the feeder had been, and then searched over a progressively larger area centred on this position, before eventually returning to the hive. In spite of the extensive searching phase, the final approach to the hive was often impressively accurate, demonstrating that the bees' combination of path integration and wind compensation was remarkably robust. Over the relatively short distances and open landscape of the present experiment, changing the position of a prominent landmark adjacent to the hive-feeder axis produced no discernible effect on either the outward or return 'vector' flights. This indicated that the bees were relying entirely on path integration, and flying in an 'automatic pilot mode' seen in bees that have been artificially displaced.

Turn alternation in the pill bug on a servosphere

M Sakuma, M Hirai, T Ono
Lab. Insect Physiology, Grad.School.Agric, Kyoto Univ., Kyoto 606-8502, Japan; sakuma@kais.kyoto-u.ac.jp

In a maze consisting of a series of T-branched trenches meeting at right angles, a pill bug, *Armadillidium vulgare*, generally chooses branches in an alternative way: once it has turned right at a branching point, it will turn left at the next. The *turn alternation* response, which has been considered to be due to short-term memory regarding the turn-direction or compensatory leg-movement after the previous turn, was re-investigated in a T-maze as well as on a *servosphere* locomotion compensator. Because of the intense thigmotaxis, the animals were contacting and following either the right or left wall of the trench to a branching zone, where they move away from the wall and strayed into the zone. Since most of the animals made a slight turn towards the contacting side at leaving the wall, they hit the facing wall with the contralateral appendages then started wall-following with the other side of the body. This behavioral context, being reproduced on a servosphere with control of tactile cues, cause a pill bug to make alternating turns in a T-maze.

Suboesophageal neck motoneurons in the honeybee, *Apis mellifera*

U Schröter, MR Ibbotson, MV Srinivasan
RSBS, Australian National University, Canberra, ACT 2601, Australia; schroeter@rsbs.anu.edu.au

We are interested in how the visual input during flight and other locomotion is translated into corrective movements of the head, body and abdomen in the honeybee. We studied the morphology of neck motoneurons (NMs) that run in nerve IK1 and innervate neck muscles 44 and 51. Muscle 44 is a direct neck muscle, which serves to pull the head downwards, muscle 51 is an indirect muscle of undetermined function. Recordings from IK1 have shown that these NMs are motion-sensitive. With dye-application into muscle 44 we labeled several NMs in the suboesophageal ganglion, where they innervate the dorsal neuropil, an area that is also innervated by motion-sensitive descending interneurons. A group of NMs that look very similar was stained via dye-application into muscle 51: two NMs with a median cell body and two NMs with a lateral cell body. To find out, whether muscles 44 and 51 are innervated by the same or different NMs, we investigated the number of neurons that run in nerve IK1. In cross sections of IK1 we found eight axon profiles larger than 10 µm. The data suggest that muscles 44 and 51 are innervated by different, but similar NMs.

Processing of mosquito signaling peptides by ACE: a functional genomics approach.

JA Smith, S Burnham, A Lee, RE Isaac, AD Shirras
Department of Biological Sciences, Lancaster University, UK, LA1 4YQ; j.a.smith@lancaster.ac.uk

Neuropeptides are important regulators of many aspects of physiology and development. Hydrolysis by extracellular peptidases can result in activation; alteration of biological activity; or inactivation. Mammalian angiotensin-converting enzyme (ACE) is one of the best known metallo-enzyme peptidases. ACE homologues have been in found in all insect species studied so far. Two *Drosophila melanogaster* ACE genes (*Ance* and *Acer*) are known to code for proteins with peptidase activity. The expression pattern and mutant phenotypes of these genes suggest important roles for these enzymes at different stages of development. ACE activity has been shown to rise after a blood meal in the mosquito *Anopheles stephensi* where it may play a role in control of host blood pressure, in regulating peptide activity after a blood meal or as a means of compromising host defense mechanisms. We have identified 9 ACE-like genes in the mosquito *Anopheles gambiae*. We aim to identify full length cDNA clones for these AnoACE genes and express the AnoACE proteins in the yeast *Pichia pastoris*, in order to investigate functional conservation of this group of enzymes in insects, to understand the physiological role of *A. gambiae* ACE, to and to identify selective inhibitors of ACE with potential for vector control.

Comparative genomics of *Drosophila* odorant receptors

NE Tunstall, CG Warr
School of Biological Sciences, Monash University, Clayton VIC 3800, Australia; coral.warr@sci.monash.edu.au

The odorant receptors (Ors) of *Drosophila melanogaster* are a highly divergent family of 62 seven trans-membrane domain proteins, presumed to be G-protein coupled receptors, that exhibit no primary sequence similarity to odorant receptors from nematodes, vertebrates, or to any other family of GPCRs. In several families of GPCRs conserved regions in intracellular loops 2 and 3 and the C terminus interact with G proteins. However in the diverse *D. melanogaster Or* family (average level of identity ~20%), such conserved regions are difficult to identify. We are therefore using a comparative genomics approach to identify domains in *Drosophila* Ors that may interact with downstream signalling components. We have isolated orthologues of nine different *Or* genes from other members of the *melanogaster* subfamily. Individual sequence identity among the species ranges from 60-98% at the amino acid level. The number of exons and introns and the position of introns are conserved in all species, however intron sizes vary. This data has helped us identify potential functional regions, which will be described. We have also used this data to undertake analysis of the evolutionary dynamics and patterns of selective pressure on these genes, and these results will be presented.

Are innate colour preferences adaptive for young forager bees?

AM Wertlen, N Hempel de Ibarra, A Cocucci, W Kreisch, M Ristow
Free University Berlin, Institut of Biology, Neurobiology, Königin-Luise-Straße 28/30, 14195 Berlin, Germany, AMWertlen@gmx.net

Bees show high flexibility in colour learning. However, testing of colour-deprived bees revealed an inherited colour memory. Unexperienced foragers exhibit colour preferences toward targets appearing to humans blue or violet. They are suppressed by colour experience acquired during nectar foraging but may interact with decision making in a novel context. We focused on the question whether such colour preferences might be adaptive for young bee foragers by studying the distribution of bee-subjective colour cues and nectar properties in natural grassland habitats. We hypothesised blue-violet flowers to be either highly rewarding or most abundant. The flower colours of 10-15 bee-pollinated and key plants were measured in each of several natural patches. Bee-subjective spectral parameters were determined using the RNL model of honeybee colour vision. Simultaneously we recorded insect visitation, nectar properties and floral abundances. Flower colours were widely distributed in the perceptual colour space representing different colour hues to bees. High abundance and reward were characterised for blue-violet flowers but also for several other colours. The flowers with highest colour contrast, possibly facilitating the identification as floral object, were not exclusively blue-violet. We suggest that innate colour preferences found in higher bees might be related to physiological or phylogenetical constraints.

Photoperiodic and thermal regulation of pupal beige/black polyphenism in the small copper butterfly, *lycaena phlaeas* Daimio Seitz

Y Usui, A Yamanaka, ATMF Islam and K Endo
Institute Of Biological Science, Faculty Of Science, Yamaguchi University, Yamaguchi 753-8512, Japan; endo@yamaguchi-u.ac.jp

The small copper butterfly, *Lycaena phlaeas* Daimio Seitz, has pupal beige/black polymorphism which was controlled by photoperiod and temperature imposed during the larval stages in an apparent association with the development of adult (spring and summer) morphs. Under long-day conditions at 23°C larvae developed into beige-type pupae and into red-winged adults, whereas under short-day conditions larvae developed into black-type pupae and into brown-winged adults. When young pharate pupae obtained under long-day conditions at 24°C were subjected to 4°C for 5 days, they develop into TB-pupae, head-thoraxes and abdomens of which were judged as to be black and intermediate types, respectively. Adults developed from the TB-pupae were found to have reddish wings as compared to the unchilled (control) ones. The results indicate that the physiological mechanism underlying the photoperiodic control of seasonal morph development may play a significant role in the determination of pupal beige/black polyphenism in *L. phlaeas daimio*. Furthermore, melanization of the pupal cuticle may occur in a close relation to the determination of the color of adult wings.

Spectral sensitivity & color preference of the oriental fruit fly, *Bactrocera dorsalis* (Diptera: Tephritide)

WY Wu, YP Chen, EC Yang
Dept. of Entomology, National Chung Hsing University, Taichung, Taiwan; d9236001@mail.nchu.edu.tw

Several species of fruit flies (Tephritidae) are the destructive agricultural pests widespread around the world, and the oriental fruit fly, *Bactrocera dorsalis*, is the critical one in Pacific Rim. Numerous "yellow traps" are applied to control this pest; however the crucial attractive cues have still not been fully investigated. In this study, the spectral sensitivities of the photoreceptors in the compound eyes of *B. dorsalis* were measured intracellularly. Five spectral types of photoreceptors with the peak sensitive wavelength at 370, 380, 490, 510 nm, and one with dual peak at 350 and 490 nm respectively were recorded, indicating the visual spectrum of the fly mainly distributes over the UV (300 ~ 400 nm) and blue-green (400 ~ 550 nm) ranges. In addition, the color preference of the fly was tested by the attractive effects of color papers with different reflectance spectra. It showed the color papers with reflectance spectra rising from 490 nm are more attractive than those rising from 560 nm, indicating that the visual stimuli with spectrum covering the range of 490 ~ 560 nm has a positive effect to attract the oriental fruit fly.

Neuroendocrine regulation of the orange coloration of diapause pupae in the swallowtail butterfly, *Papilio xuthus* L. (Lepidoptera: Papilionidae)

A Yamanaka, H Imai, M Adachi, ATMF Islam, K Endo
Yamaguchi University, Yoshida 1677-1, Yamaguchi, 753-8512, Japan; yamanaka@yamaguchi-u.ac.jp

Diapause pupae of *Papilio xuthus* show color polymorphism, represented by diapause-green, orange, and brownish orange types that are each associated with specific pupation sites. We investigated the role of the site of pupation on the induction of the development of orange types (or brownish-orange types), and the neuroendocrine mechanism underlying the control of color polymorphism in short-day pupae. All short-day larvae of the wandering stage developed into orange or brownish-orange type pupae when they were placed in rough-surfaced containers after gut-purge. Utilizing a pharate pupal ligation between the thorax and abdomen, the neuroendocrine mechanism underlying the control of color polymorphism was shown to involve a head-thorax factor (Orange-Pupa-Inducing Factor: OPIF) that induced orange types in short-day pupae. OPIF was bioassayed using the ligatured abdomens of short-day pharate pupae and extracted with a 2% NaCl solution from 5th-instar larval ganglia complexes following the mesothoracic complex ($TG_{2,3}$-AG_{1-7}), but it could not be extracted with either an acetone or 80% ethanol solution. OPIF may not exist in the brains of day 0 pupae or in brain-subesophageal ganglion and prothoracic ganglion complexes of 5th-instar larvae. The action of OPIF on short-day pharate pupae is considered dose-dependent.

Patterns of chromatic information processing in the lobula of honeybee

EC Yang, CC Lin, YS Hung
Dept. of Entomology, National Chung Hsing University, Taichung, Taiwan; ecyang@nchu.edu.tw

The honeybee, *Apis mellifera* L., is one of the few living creatures that have their colour vision proven through behavioural tests. Previous studies on a honeybee's colour vision emphasized the relationship between the spectral sensitivities of photoreceptors and colour discrimination behaviour, and the knowledge regarding neural mechanisms of colour vision is rather limited. We surveyed the patterns of chromatic information processing of visual neurons in the lobula of the honeybee, using intracellular recording and three light emitting diodes, whose emitting spectra approximately match the spectral sensitivity peaks of the honeybee, as the light stimuli source. The recorded visual neurons can be divided into a non-colour opponent cells group and a colour opponent cells group. In non-colour opponent cells group, in which six response patterns of broad-band neurons and four response patterns of narrow-band neurons were recorded. In colour opponent cells group, the principal neural mechanism of colour vision, eight response patterns of colour opponent cells were recorded. Thus, together with previous studies, the visual system of the honeybee might possess 26 types of colour-coding neurons, including 12 types of colour opponent neurons. Besides, some recorded neurons with tonic post-stimulus responses were observed, suggesting spectro-temporal opponency may be part of the colour-coding mechanisms.

Colourful orb-weaving spiders, *Nephila pilipes*, through a bee's eyes

EC Yang, IM Tso, CW Lin
Department of Entomology, National Chung Hsing University, Taichung, Taiwan; ecyang@nchu.edu.tw

Many orb-weaving spiders in the tropics forage in open sites during the day and some of them have both bright and dark colorations. The conspicuous UV reflective colour markings of these spiders have been reported to be attractive to visually oriented prey and thus could increase the spiders' foraging success. Using a combination of field and laboratory studies, we examine whether or not the body coloration of orb-weaving spiders exhibit optical properties that are attractive to insect prey from the viewpoints of insect visual physiology. We compared the prey interception rates and colour contrasts of the typical and melanic morph of giant wood spider *Nephila pilipes*. Results of the field study showed that the typical morph *N. pilipes* caught significantly more insects than the melanics. Colour contrasts calculated from spectral reflectances of the background and body surface of spiders showed that the brightly-coloured body parts of typical morph exhibited rather high values, but those of the dark body parts were below the discrimination threshold. The differential colour contrasts of body parts generated a visual signal unlike that of a spider but certain form of food resources. On the other hand, the melanic morphs did not have bright coloration and the colour contrasts of every parts of body were significantly higher than the threshold, making the contour of spiders quite clear to bees.

Fine structural analysis of the silk apparatus in the spider, *Paracoelotes spinitarsis* (Araneae: Amaurobiidae)

MJ Moon, CS Kang, SM Yoe
Department of Biological Sciences, Hoseo University, Asan 336-795, Korea; smyoe@dankook.ac.kr

The silk of spider is used to form various structures such as aglines, retreats, webs, snares, and cocoons. Since the interactions between spider and environment are silk-mediated, the silk apparatus and its silk glands deserve treatment from morphological and ecological point of view. The silk apparatus of this spider, *Paracoelotes spinitarsis* is composed of internal silk glands and external spinnerets. Among the three pairs of spinnerets, the posterior pairs are highly elongated along the body axis. In order to understand the properties and the evolutionary origins of these silk constructs, we analysed here the morphological characteristics of the silk spinning apparatus and its ecological significance in this spider. Through the fine structural analysis using light and electron microscopes, the silk glands of the adult female spider were composed of four types of silk glands (ampullates, tubuliforms, aciniforms and pyriforms) which connected with typical spinning tubes of each spinneret. It has been also revealed that the tubuliform glands were only observed in female spiders, however the flagelliform and aggregate glands which had the function of adhesive thread production in orb-web spiders were not observed at both sexes of this spider.

Corazonin receptor signaling in ecdysis initiation.

ME Adams, Y-J Kim, I Spalovska-Valachova, I Zitnanova, K –H Cho, D Zitnan,
Dept. of Entomology, University of California, Riverside, CA, USA; Institute of Zoology, Slovak Academy of Sciences, Bratislava, Slovakia.

Corazonin is a highly conserved neuropeptide hormone in widely divergent insects, yet is associated with no common function. Following discovery of the corazonin receptor in *Drosophila*, we identified its ortholog in *Manduca sexta*. Corazonin receptor cDNA in *Manduca* encodes a protein of 436 amino acids (MasCRZR) with seven putative transmembrane domains and shares common ancestry with its *Drosophila* counterpart. MasCRZR exhibits high sensitivity and selectivity for corazonin when expressed in *Xenopus* oocytes (EC_{50} ~200 pM) or Chinese hamster ovary (CHO) cells (EC_{50} ~75 pM). Northern blot analysis locates its expression in peripheral endocrine Inka cells and in the CNS. Injection of corazonin into pharate larvae elicits release of pre-ecdysis and ecdysis triggering hormones (PETH and ETH) from Inka cells, followed by precocious pre-ecdysis and ecdysis behaviors. Corazonin (25-100 pM) also induces PETH and ETH secretion from isolated Inka cells *in vitro* and circulates in the hemolymph (20-80 pM) just prior to natural pre-ecdysis onset. Early and late phases of peptide release from Inka cells, controlled by corazonin and eclosion hormone, respectively, appear to regulate sequential steps in the ecdysis behavioral sequence.

PTTH signal transduction in the prothoracic gland: a tangled web with one purpose?

R. Rybczynski
"Dept. of Biology, UNC at Chapel Hill, Chapel Hill, NC, 27599, USA, rybczy@bio.unc.edu"

Molting and metamorphosis in insects is controlled by several hormones, with 20-hydroxyecdyone (molting hormone) playing an overarching role. Prothoracicotropic hormone (PTTH), the best-understood regulator of ecdysteroidogenesis, stimulates ecdysteroid synthesis by the prothoracic glands. Work in the 1980s and 1990s revealed that PTTH activated a signal transduction cascade that included Ca^{2+}- influx, cAMP generation, phosphorylation of the ribosomal protein S6 and protein translation. In this talk, I will review more recent work, from our group and others, indicating that the PTTH signal transduction cascade is surprisingly complex. We now know that additional kinases are activated, including an extracellular signal-regulated kinase (ERK), a protein kinase C, and one or more unidentified tyrosine kinases. Ongoing studies also suggest PTTH-stimulated Ca^{2+}- influx is complexly regulated, with increases in cytoplasmic free Ca^{2+} coming from at least three sources, and that phospholipase C activation is among the earliest intracellular events triggered by PTTH. The composite data suggest that (1) PTTH regulates more processes in the prothoracic gland than ecdysteroid synthesis; (2) the study of phosphorylated proteins offers an avenue to identify these additional functions of PTTH; and (3) the control of ecdysteroid synthesis is subject to a Pandora's box of developmentally varying checks and balances.

Dielectric waveguide antenna theory helps explain insect detection of enantiomers

T.M. Dykstra
Dykstra Laboratories, Inc., 3499 NW 97th Blvd., Suite 6, Gainesville, FL 32606 USA

Many decades ago, a debate arose as to how insects detected semiochemicals. One group maintained that detection was accomplished by electromagnetic energy emanating from the semiochemical, while the other group maintained that the molecule fit into a receptor in order for it to be detected. The latter group's theory is termed the "lock and key model". It is the predominant theory today. The former group's theory was termed the "vibrational theory of odor" by Robert Wright in the 1950's. In the 1960's, Philip Callahan offered a mechanism for this detection whereby the insect sensillae act as dielectric antennae. Behavioral and electrophysiological tests involving the detection of enantiomers could not be easily explained by either theory. Some insects could differentiate between enantiomers while others could not. A more thorough knowledge of antenna theory reveals that enantiomer detection can be explained by the dielectric antenna model. Additionally, replicas of insect sensillae can be artificially reproduced by conventional lasers to make efficient infrared detectors.

"Insects as Flying Machines"

C P Ellington
Dept. of Zoology, Univ. of Cambridge, Downing Street, Cambridge CB2 3EJ, UK. c.ellington@zoo.cam.ac.uk

Insects are small flying machines with an apparent disregard of good aerodynamic practice. Instead of producing lift with their wings, some butterflies rely on drag for slow flight. Tiny insects were predicted to 'swim' through the air using drag, but they rely more on lift. Hovering dragonflies and hoverflies flap their wings in a plane inclined to the horizontal. They use dynamic stall on the downstroke to support their weight, and their lift-to-drag ratio is necessarily less than 2. Most hovering insects flap their wings in a horizontal plane, using lift on both the downstroke and upstroke to support their weight. A leading-edge vortex created by dynamic stall enhances lift production. Because of flow separation at the leading edge, the resultant aerodynamic force is approximately normal to the wing surface, and the lift-to-drag ratio is again typically less than 2. The lift-to-drag ratios for all high-force mechanisms employed by insects are appallingly low by conventional standards, and would entail a high power consumption for fixed and rotary wing designs. For small man-made flying machines to exploit these mechanisms, a flapping motion is essential to ensure that weight is supported by the resultant aerodynamic force and not just the lift.

Controlling flapping flight: lessons from locusts, dragonflies and *Aedes* mosquitoes.

G K Taylor
Zoology Department, South Parks Road, Oxford, OX1 3PS, UK, graham.taylor@zoo.ox.ac.uk

"To a flying insect, unsteadiness is everything. With wings flapping tens or hundreds of times every second, the airflow changes continually, but despite – or perhaps because of – this complexity, insects are able to control manoeuvres with greater finesse than even the highest performance fighter aircraft. By adopting and adapting techniques used by engineers to analyse aircraft stability and control, it is possible to predict an insect's response characteristics to accidental disturbances and deliberate control inputs. By analysing the insect's natural modes of motion, we can then make quantitative predictions about the operating bandwidth of the nervous system and even the preferred directions and temporal resolution of its sensors. Besides yielding integrative physiological insight, analysing the insect as a miniature flying machine is instructive for the engineer seeking to mimic aspects of insect flight. In this talk I will illustrate some of the lessons we can learn from behaviours as diverse as the cruising flight of locusts, the take-off manoeuvres of dragonflies, and the mating flights of *Aedes* mosquitoes. Finally, I will show how an understanding of flight control can even contribute to pest control, by helping us select the most successful male mosquitoes for use with the sterile insect technique.
"

What drives adaptive gain control in insect motion detection?

D.C. O'Carroll, T.J. Rainsford,
Discipline of Physiology & Centre for Biomedical Engineering, University of Adelaide, S.A. 5005, Australia. E-mail <david.ocarroll@adelaide.edu.au>

"The phenomenon of motion adaptation is widespread among animals, having been demonstrated in species as diverse as humans, wallabies and flies. Motion adaptation appears to have evolved to maximize efficiency of visual coding in neurons with limited signaling range. Recent work highlights controversy over the site and mechanism of adaptation. Hypotheses range from simple gain control in 'early' vision (contrast normalization), to adaptive feedback that alters the delay mechanisms within local motion detectors. We have shown that adaptation does not alter the velocity tuning of motion detectors, but instead induces large reductions in contrast gain. Using moving natural scenes and a probe-adapt-probe protocol, we show here that gain reduction is driven by a mechanism with broad velocity tuning. While the tuning of adaptation resembles that of motion detectors themselves (favoring a feedback hypothesis), its broadness suggests extremely high gain in the feedback pathway and permits powerful adaptation to stimuli that drive motion detectors weakly. This mechanism may optimize coding of image velocity independent of the contrast variations between different natural scenes. Our work suggests easily implemented elaborations to existing motion detector models that could impart similar robustness to artificial motion detectors based on the same principle.
"

"Frictional properties of contacting surfaces in the hemelytra-hindwing locking mechanism in the bug *Coreus marginatus* (Heteroptera, Coreidae)"

P.J. Perez Goodwyn, S. N. Gorb.
"Evolutionary Biomaterials Group, Abt. Arzt. Max-Planck-Institut fuer Metallforschung.   Heisenbergstr. 3. D-70569 Stuttgart, GERMANY. Perez-Goodwyn@mf.mpg.de "

The structure and function of the hemelytra-to-hindwing locking mechanism of the bug *Coreus marginatus* were analysed. The system consists of a cuticular protrusion in the ventral side of the hemelytra, which locks the subcostal border of the hindwing in flight. The speed and distance slid by both surfaces against one another during flight were assessed using a combination of high-speed video recordings and a 2D geometrical model. The friction coefficient between sliding surfaces was assessed using a micromanipulator, coupled with force transducers. This was done under three experimental conditions: freshly dissected, air dried and rehydrated ethanol preserved samples. The results showed a high speed of sliding, approximately 0.18 $m \cdot s^{-1}$, with a relatively low friction coefficient (0.2 µ). The surface morphology of this mechanism, namely outgrowths of one part having rounded edges, and completely flat surface on the counterpart, effectively aids in the reduction of friction at the microscopical level. The structure is effective even dry, and after being preserved in ethanol, suggesting that no cuticle secreted lubrication substance is responsible for its effectiveness. The ultrastructure presumably confers mechanical stability to the system under the high load it is subjected to in flight.

Potential Northern Distribution of *Anoplophora glabripennis* (Motschulsky) in North America

D.B. Roden, R.A. Haack, M.A Keena and D.W. McKenney
"Natural Resources Canada, 1219 Queen Street East, Sault Ste. Marie, Ontario, Canada droden@nrcan.gc.ca"

The Asian long-horned beetle (alb), *Anoplophora glabripennis*, is a cerambycid endemic to China and the Korean peninsula that was recently introduced into North America. As a result, it now infests the urban forests of Long Island, Chicago, New Jersey and Toronto. Most North American insects from this family are usually consider beneficial because they hasten the breakdown of dead trees. However, members of the genus *Anoplophora* infest healthy hardwood trees. The preferred tree species in China are *Salix* and *Populus* whereas in North America *Acer* species are most commonly attacked. The supercooling point of insects has been used to predict the potential northern distribution of insects susceptible to freezing. These measurements have given a reasonably accurate prediction of the northern distribution of the gypsy moth and the smaller European elm bark beetle in North America. While there is no assurance this is an accurate assumption because of insect physiological and behaviorally adaptations, it does provides a useful tool for estimating the potential northern distribution of newly introduced species unless that species is freeze-tolerant. In our study, we investigated the supercooling point of alb larvae, its potential impact on distribution in North America and how this compares to a native cerambycid.

"Antioxidant and detoxifying enzyme activities in two strains of *Oncopeltus fasciatus* (Heteroptera: Lygaeidae) exposed to cadmium: I. Acute exposure."

"A Cervera, A C Maymó, R Martínez-Pardo, M D Garcerá"
"Departamento de Biología Funcional y Antropología Física, Universitat de València, Dr. Moliner 50, 46100 Burjassot, Valencia, Spain.
amelia.cervera@uv.es "

"Catalase (CAT), general esterase (EST), glutathione reductase (GR), glutathione S-transferase (GST), peroxidase activity of glutathione S-transferase (GSTpx), and superoxide dismutase activity (SOD) were determined in adult *O. fasciatus* exposed to Cd in drinking water for five days. Two different strains were studied: OS, a laboratory-reared strain, and OCdR, a strain subjected to Cd selection. In order to distinguish between genetic and physiological effects, two generations of OCdR were used in the experiments. OCdR F_{49} was born from 50 mg Cd/ml selected parents, but was not exposed to Cd itself, while OCdR F_{50} was exposed to 50 mg Cd/ml from egg eclosion to the moment of the experiment. Median lethal mortalities (LC_{50}) of adults after 5 day-exposure were 360 mg Cd/liter for OS, 412 mg Cd/l for OCdR F_{49}, and 455 mg Cd/litre for OCdR F_{50}. Survivors from toxicity bioassays exposed to 0, 100 and 200 mg Cd/litre were used for enzyme assays. CAT activity was significantly enhanced in Cd-treated insects of all strains, when compared to control insects of the same group. EST, GR and GST activities where only significantly enhanced in insects exposed to the highest Cd concentration, while GSTpx and SOD activities were not affected by Cd treatment. On the other hand, no differences in basal levels of enzyme activities were observed among strains.
"

The visual ecology of hawkmoths

A Balkenius, A Kelber
Vision Group, Department of Cell and Organism Biology, Lund University, Sweden; anna.balkenius@cob.lu.se

The diurnal *Macroglossum stellatarum* and the nocturnal *Deilephila elpenor* are active in amatically different light intensities but both have colour vision. *D. elpenor* can discriminate colours in light intensities a million times weaker than the light intensities normal for *M. stellatarum*. Both species have colour constancy, which allows them to discriminate colours irrespectively of the spectrum of the illumination. This ability is explained by chromatic receptor adaptation according to the von Kries coefficient law. *M. stellatarum* learns the size, patterns and brightness of flowers. Both species learn the spatial location of rewarding stimuli, when they are difficult to distinguish by colour alone. Nocturnal sphingids mostly use odour to localize nectar flowers. However, in the day-active *M. stellatarum*, vision has become the dominating modality. When faced with a colour and an odour stimulus, naive *M. stellatarum* select the colour. The behaviour of flower-naive *D. elpenor* is the opposite. We are currently investigating the role of multi-modal interaction in learning experiments with both species.

Technical perfection in the sensory periphery: spider mechanoreception

F G Barth
Institute for Zoology, University of Vienna, Althanstr.14, A-1090 Vienna, Austria; frieich.g.barth@univie.ac.at

Despite the small size of their brain arthropods show complex and highly refined behavior. One of the foundations making this possible is the refinement and filter action of their sensory periphery. Spider mechanoreceptors exemplify this nicely. Being interfaces between environment and behavior they not only reflect details of the physical properties of the adequate stimulus but also characteristics of species-specific behavior. This will be illustrated taking two different types of sensory hairs as examples. (i) *Trichobothria* are *medium flow sensors* of outstanding sensitivity which is largely due to an intriguingly well "designed" interaction between the moving air and the hair. Using fluid mechanics this interaction can be modelled quantitatively and the hair´s mechanical and nervous responses related to prey catching behavior. (ii) *Tactile hairs* follow mechanical principles different from those of a medium flow sensor as seen from their morphology and mechanical properties and revealed by finite element analysis and micromechanical measurements. Bringing together neurobiology and engineering not only deepens our understanding of sensory systems but also helps in developing new, biology-inspired technical sensors.

Molecular and pharmacological characterization of *Drosophila* octopamine receptors

A Baumann, S Balfanz, S Frings
"Forschungszentrum Jülich, IBI-1, Postfach 1913, D-52425 Juelich, Germany; a.baumann@fz-juelich.de"

In invertebrates, the biogenic amine octopamine regulates physiological functions including locomotion, neuronal development, circadian rhythm, as well as learning and memory. Pharmacological investigations indicate that octopamine mediates these effects by activation of several G protein-coupled receptor types.
We have cloned two genes from *Drosophila melanogaster* that encode three functional octopamine receptors. The first gene (Dm*oa*1) codes for two polypeptides which are generated by alternative splicing. The proteins share identical N-terminal halves but differ in the C-terminal half. When stimulated with nanomolar concentrations of octopamine, both splice variants induce Ca^{2+} release from internal stores. At high concentrations of octopamine (${}^{3}10^{-6}$ M) the receptors also cause cAMP production. The second gene (Dm*oa*2) encodes a single polypeptide that specifically causes a rise of intracellular cAMP. The EC_{50} value is ~5×10^{-8} M octopamine. Tyramine activates all three receptors but at ^{3}100 fold higher concentrations. The biogenic amines dopamine and serotonin are non-effective at all. Developmental expression of Dm*oa* genes was assessed by RT-PCR. Overlapping but not identical expression patterns were observed for the individual transcripts. Since native octopamine receptors induce either cAMP production or Ca^{2+} release, the two genes may encode the complete set of octopamine receptors that are expressed in *Drosophila*.

The imaging properties of the dragonfly median ocellus

RP Berry, EJ Warrant, G Stange.
RSBS, The Australian National University, GPO Box 475, Canberra, ACT 2601, Australia

Current literature describes the ocelli of pterygote insects as average illumination detectors, which serve to provide attitude information for the maintenance of flight equilibrium. This view has arisen because of several prominent features of the ocelli, including; fields of view centred on the horizon, under-focussed optics and a high rate of convergence from photoreceptors to second-order neurons which output to regions of the nervous system involved in flight control. However, recent research has indicated that dragonfly ocelli possess unusual structural and optical properties that are inconsistent with this view of ocellar function. In particular, from hanging-op preparations of the dragonfly median ocellar lens it has been determined that the image formed by this lens lies close to the underlying retinal layer, that the resolution of the image is dependent upon the orientation of an object and that the image is split laterally into left and right halves. Preliminary investigations also indicate the presence of a gradient of refractive index in the median ocellar lens. The optical properties of this lens and their relevance to dragonfly behaviour will be discussed.

Stop and go with NO: nitric oxide and cyclic nucleotides regulate neuronal motility in an insect embryo

G Bicker, A Haase
School of Veterinary Medicine Hannover, Cell Biology, Bischofsholer Damm 15, D-30173 Hannover, Germany; gerd.bicker@tiho-hannover.de

The dynamic regulation of nitric oxide synthase (NOS) activity and cyclic GMP levels suggests a functional role in the development of nervous systems. Here, we report evidence for a key role of the NO/cGMP signalling cascade on migration of postmitotic neurons in the enteric nervous system of the embryonic grasshopper. During development, a population of enteric neurons migrates on the surface of the midgut. These midgut (MG) neurons exhibit nitric oxide-induced cGMP-immunoreactivity coinciding with the migratory phase. Using a histochemical marker for NOS, we identified potential sources of NO in subsets of the midgut cells below the migrating MG neurons. Inhibition of endogenous NOS, sGC, and protein kinase G (PKG) activity in whole embryo culture results in a significant retardation of MG neuron migration. This inhibition can be rescued by supplementing with protoporphyrin IX free acid an activator of sGC, and membrane-permeant cGMP, indicating that NO/cGMP signalling is crucial for MG neuron migration. Conversely, the stimulation of the cAMP/protein kinase A signalling cascade results in an inhibition of cell migration. Activation of either the cGMP or the cAMP cascade influences the cellular distribution of F-actin in neuronal somata in a complementary fashion. The cytochemical stainings and experimental manipulations of cyclic nucleotide levels provide clear evidence that NO/cGMP/PKG signalling is permissive for MG neuron migration whereas the cAMP/PKA cascade may be a negative regulator. Since NO/cGMP signaling is also involved in axonal extension of pioneer neurons, these investigations reveal an accessible insect model in which the role of the NO/cGMP/PKG signalling cascade on neuronal cell motility can be analyzed in a natural setting.

Excitation-secretion coupling in the salivary glands of *Periplaneta americana*

W Blenau, A Baumann, S Marg, C Krach, O Baumann, B Walz
"Universität Potsdam, Institut Für Biochemie Und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany; blenau@rz.uni-potsdam.de"

The acinar salivary glands of the cockroach, *Periplaneta americana*, are innervated by dopaminergic and serotonergic nerve fibers. Serotonin stimulates the secretion of protein-rich saliva, whereas dopamine causes the production of protein-free saliva. This suggests that dopamine acts selectively on ion-transporting peripheral cells within the acini and the duct cells, and serotonin acts on the protein-producing central cells of the acini. We investigated the pharmacology of the dopamine-induced secretory response by using several dopamine receptor agonists and antagonists. The effects of dopamine can be mimicked by the agonists 6,7-ADTN and R(+)-Lisuride. Dopamine-induced secretions could be blocked by *cis*(Z)-flupentixol, chlorpromazine, and (+)-butaclamol. We performed PCR experiments with degenerate primers in order to clone dopamine and serotonin receptor genes from *Periplaneta.* So far, we obtained four PCR fragments with their sequences being similar to the *Drosophila* serotonin 5-HT1A, the *Drosophila* dopamine DopR2, the honeybee Am*tyr*1, and a non-characterized *Drosophila* biogenic amine receptor-gene, respectively. In addition, we have cloned a cDNA fragment coding for nitric oxide synthase (NOS). Using RT-PCR and NADPH diaphorase staining we proved NOS expression in the salivary glands. Dopamine-induced secretion is reduced by the NO donors sodium nitroprusside and DEA-NONOate. The effects of both substances were dose-dependent and reversible.

Molecular and pharmacological characterization of honeybee biogenic amine receptors

W Blenau, Schlenstedt, L Grohmann, A. Baumann.
"Universität Potsdam, Institut Für Biochemie Und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany; Blenau@Rz.Uni-Potsdam.De"

Biogenic amines and their receptors are important regulators of physiological and behavioral functions in insects. So far we have cloned the cDNAs encoding a dopamine D1 receptor (AmDOP1), a tyramine receptor (AmTYR1), an octopamine receptor (AmOA1) and a putative serotonin receptor from the honeybee brain. In the honeybee, octopamine acts as a neuromodulator and is involved in learning and memory formation. The AmOA1 receptor is most closely related to octopamine receptors from *Drosophila melanogaster* and the pond snail, *Lymnea stagnalis*. Signaling properties of the cloned receptor were studied in transiently transfected HEK 293 cells. Nanomolar to micromolar concentrations of octopamine induced oscillating increases in the intracellular Ca^{2+} concentration. The Am*oa*1 gene is abundantly expressed in many somata of the honeybee brain, suggesting that this octopamine receptor is involved in the processing of sensory inputs, antennal motor outputs, and in higher-order brain functions. Recently, we have isolated the cDNA of a putative serotonin receptor from *Apis mellifera*. The deduced amino acid sequence of this honeybee receptor shows greatest sequence homology to 5-HT7 receptors from *Drosophila melanogaster* and *Aedes aegypti* as well as to 5-HT1A receptors from vertebrates. The functional properties of this receptor and its tissue distribution are currently under investigation.

Modulation of tyramine signaling by osmolality in the *Drosophila* malpighian tubule

EM Blumenthal
"Dept. of Biological Sciences, Marquette Univ., Box 1881, Milwaukee, WI 53201-1881, USA; edward.blumenthal@marquette.edu"

The biogenic amine tyramine acts as a diuretic agent in the Malpighian tubules of *Drosophila melanogaster*, boosting urine production by increasing the transepithelial chloride conductance. The effects of tyramine can be measured electrically as a depolarization of the transepithelial potential. The response of isolated tubules to tyramine can be modulated by changes in the osmolality of the peritubular bath; an increase in osmolality results in a decreased response to tyramine, while a decrease in osmolality results in an enhanced tyramine response. Because the tyraminergic pathway is likely to be constitutively activated *in vivo*, this modulation may allow for greater responsiveness of the tubule to changes in hemolymph osmolality. In response to a sustained osmotic challenge, the modulation of the tyramine response is not constant but adapts, such that the amplitude of the tyramine response returns towards the control value over the course of 5-10 minutes. Interestingly, in one strain of flies this adaptation does not occur. These flies are also salt-sensitive, dying on food containing 0.4M NaCl. Genetic studies are now underway to determine if both of these phenotypes are due to the same locus and to identify the affected gene. Supported by NIH R21DK60860 and Marquette University.

Rapid evolution of the butterfly eye through multiple independent duplications of the opsin gene family

AD Briscoe, M Sison-Mangus
University of California, Irvine, Dept. of Ecology and Evolutionary Biology, 321 Steinhaus Hall, Irvine, CA 92697, U.S.A.; abriscoe@uci.edu

Lycaena butterflies have four major spectral classes of visual pigments in the compound eye photoreceptors with lambda-max values of 360 nm, 437 nm, 500 nm and 568 nm, respectively (Bernard and Remington 1991). In this study, we characterized these visual pigments molecularly. A cDNA library from the eyes of two male *Lycaena rubidus* was constructed and screened for opsin transcripts using 3' and 5' RACE (rapid amplification of cDNA ends), cloning, and automated sequencing. An exhaustive screen yielded four distinct full-length opsin mRNAs with varying lengths of 1738, 1500, 1514, 1521 bp, and which encode opsins of 381, 377, 380 and 382 amino acids. Phylogenetic analysis indicates that these four opsins cluster within clades of UV-, blue- and long wavelength (LW)-sensitive insect opsins, and are most closely related to their nymphalid homologues. Unexpectedly, we found that *L. rubidus* expresses duplicated blue-sensitive opsin genes in the retina. This is the first report of a duplication of the blue-sensitive opsin gene within insects. Secondly, this result suggests that the 500 nm visual pigment has likely evolved from a blue-sensitive ancestral pigment. This therefore represents the most red-shifted blue-sensitive opsin known in insects. Finally, these data indicate that compound eyes (and by extrapolation, color vision) has evolved rapidly between butterflies families with both the lycaenids and papilionids expressing the products of novel, independent opsin gene duplications.

Air flow sensing: from physical ecology in the field to nanotech implementation

J Casas for the CICADA consortium
"Institut de Recherches sur la Biologie de l'Insecte – IRBI UMR CNRS 6035 – Université de Tours, 37200 Tours, France, casas@univ-tours.fr"

Air flow sensing mechanoreceptors on the cricket cerci are amongst the best known sensors in the animal kingdom, working at the limit of thermal noise. They enable crickets to perceive the slightest air movement generated by an approaching predator and to escape. This talk will review the advances of an EU project (IST - Future and Emerging Technologies) in bionics which aims at understanding the natural selection forces in the field and the biomechanical functioning of hairs as well as the integration into a hair canopy response. Our work aims furthermore at reproducing some of the findings at the micro/nanotechnological level as MEMS (micro-electro-mechanical systems) devices and to build a miniature cricket robot in which networks of living cells on silicon chips would be directly connected to the sensors. The talk will also highlight the unusual integrative approach this consortium has, from field ecology, material sciences & nanotechnology up to living computers, and will focus on the biological findings obtained so far. The Consortium is headed by J. Casas and his team, and is made of the teams of G. Krijnen (Micro- and Nanosensors- Twente), A. Offenhaüser (Surfaces and Interfaces - Jülich Forschungzentrum) and G. Jeronimidis (Material Sciences - Reading).

Neurotransmitter transporters in the cabbage looper moth (*Trichoplusia ni*)

BC Donly, H McLean, L Verellen, S Caveney
Southern Crop Protection and Food Research Centre, Agriculture and Agri-Food Canada, 1391 Sandford St., London, ON, Canada N5V 4T3;
donlyc@agr.gc.ca

In the nervous system, neurotransmitter signaling molecules are taken back up after release into the synapse by specialized transport proteins located in the membranes of neurons and glial elements bordering the synaptic space. These proteins belong to widely divergent families present throughout eukaryotes and extending even to prokaryotes. We have characterized a group of neurotransmitter transporters from a pest insect, the cabbage looper *Trichoplusia ni*. These include transporters for most of the principal transmitter molecules in the insect nervous system; glutamate, GABA, dopamine, serotonin, octopamine, and a transporter for the acetylcholine precursor and breakdown product, choline. Most of the cabbage looper transporters correspond clearly to orthologous proteins in other insects as well as in other animals. One exception is a transporter we have identified with high affinity for octopamine. Genes for this moth transporter, which may represent an evolutionary counterpart of the vertebrate norepinephrine transporter, are not found in the completed dipteran genomes of either the fruit fly or mosquito. We have therefore compared the distribution of this transporter with those of other monoamine transporters in insects to assess its prevalence and also its potential as an insect or order-selective target for pest control.

Allometry of insect flight performance: the case of hovering orchid bees

R Dudley
Dept. of Integrative Biology, UC-Berkeley, Berkeley, CA 94720 U.S.A.; wings@socrates.berkeley.edu

Limits to insect flight performance are difficult to evaluate because maximum capacity is both context-specific and difficult to identify unequivocally. Most generally, anatomical constraints on stroke amplitude and a systematic decline in wingbeat frequency with increasing body size suggest that the relative capacity for power production should increase in smaller insects. Use of low-density helium-oxygen mixtures and of a load-lifting method that imposes asymptotically increasing loads during ascent has permitted assessment of maximum performance in both hummingbirds and hymenopterans for the specific behavioural context of hovering flight. In orchid bees, load-lifting methods have been applied to twelve species with known phylogenetic relatedness to assess the allometry of force and power production within the subfamily. Vertical force production scales adversely with greater body mass even if flight muscle mass scales isometrically. These results are compared with existing theoretical estimates of the allometry of animal flight performance.

Molecular and pharmacological analysis of an octopamine receptor from American cockroach and fruit fly

LJ Bischof, EE Enan
"Vanderbilt University-School Of Medicine, Department of Biochemistry, 635 Light hall, Nashville, TN 37232, USA; essam.enan@vanderbilt.edu"

Octopamine regulates multiple physiological functions in invertebrates. The biological effects of octopamine and the pharmacology of octopamine receptors have been extensively studied in the American cockroach, *Periplaneta americana*. This study reports the cloning of the first octopamine receptor from *Periplaneta americana*. A cDNA encoding a putative 7 transmembrane receptor was isolated from the head of *Periplaneta americana*. The encoded protein contains 628 amino acids and has sequence similarity to other biogenic amine receptors. This protein was expressed in COS-7 cells for radioligand binding studies using the antagonist ^{3}H-yohimbine. Competitive binding comparing biogenic amines that could potentially function as endogenous ligands demonstrated this receptor had the highest affinity for octopamine (K_i=13.3 μM) followed by tyramine, dopamine, serotonin and histamine. Octopamine increased both cAMP levels (EC_{50}=1.62 μM) and intracellular concentrations of calcium through the receptor expressed in HEK-293 cells. Tyramine increased levels of both of these second messengers but only at significantly higher concentrations than octopamine. The cAMP increase by octopamine was independent of the increase in calcium. Competitive binding with antagonists revealed this receptor is similar to Lym oa_1 from *Lymnaea stagnalis*. The data indicate this cDNA is the first octopamine receptor cloned from *Periplaneta americana* and therefore has been named Pa oa_1.

Bio-inspired legged locomotion on land

RJ Full
Dept. Integrative Biology, University Of California At Berkeley, 94720, USA; rjfull@socrates.berkeley.edu

Running insects bounce from one tripod of legs to another. A single tripod functions as one leg in a human, two legs in a trotting dog or four legs in a trotting crab. All produce the same pattern of ground reaction forces that can be modelled by a mass atop a spring – much like a pogo stick. Remarkably, the relative stiffness of an insect's leg is similar to other runners that differ in skeletal type and posture. Dynamic testing of legs shows that they can be represented by a damped-spring. Insects run over rough terrain possessing obstacles three times their "hip" height without even decreasing their preferred speed. Dynamic models reveal that running insects can function as a passive, dynamic self-stabilizing system. Models respond to perturbations of the body by self-correcting without using sensory information from the environment. Tuned visco-elastic legs respond to perturbations *preflexively* – before reflexes. Perturbations of running insects reveal that recovery begins in less than 10 msec challenging the fastest known reflexes. New materials manufacturing techniques have resulted in bio-inspired tuned legs. The concepts of control discovered in insects have biologically inspired the fastest, most stable legged robots yet built.

The trans-membrane topology of an *Epiphyas postvittana* odourant receptor protein expressed using baculovirus in Sf9 cells

LN Gatehouse.
HortResearch, Palmerston North Research Centre, Tennentive, Private Bag 11030, Palmerston North, New Zealand; lgatehouse@hortresearch.co.nz

Odourant receptor molecules in insects are thought to be G-protein receptors and hence members of the seven transmembrane protein super family of genes, characterised by having seven transmembrane domains but little or no sequence homology. However, the known insect odourant receptors have a number of conserved amino acids, particularly within the last third of the proteins that allow the alignment of the sequences and the assignment to a family. The candidate odourant receptor was mined from an *Epiphyas postvittana* antennal EST library and the sequence was extended by 5′ RACE. The green fluorescent protein gfp5 gene was translationally fused onto the 3′ end to track where in the insect cell the candidate receptor protein was targeted. A bona fide receptor protein would be targeted to the cell membrane where it would insert itself leaving its 3′ end inside the cell. A series of deletions were planned where the gfp was fused progressively further towards the 5′ end of the receptor based on an *in silico* model of the transmembrane domains. The fate of the gfp was determined with fluorescent anti-gfp antibodies which will bind to the undisrupted cells only if the gfp is on the outside of the cell membrane.

Structure and properties of hairy attachment devices

SN Gorb
Evolutionary Biomaterials Group, Mpi For Metals Research, Heisenbergstr. 3, D-70569 Stuttgart, Germany; s.gorb@mf.mpg.de

Many animals bear leg attachment pads with an excellent ability to adhere to a smooth surface as well as to a variety of natural surfaces with rough profiles. There are two alternative designs of such systems: smooth and hairy. The smooth systems consist of soft deformable structures with a relatively smooth surface. Pads of geckos, flies, beetles, and spiders are covered by relatively long, deformable setae which, due to individual bending, increase the number of contacting points with the surface. Most recent data on hairy systems demonstrated their excellent adhesion and high defect tolerance of contact. The size of single points gets smaller and their density higher as the body mass increases. We provided the first experimental evidence of adhesion enhancement by division of contact area. A patterned surface, made out of polyvinylsiloxane (PVS), has significantly higher tenacity on a glass surface than a smooth sample made out of the same material. This effect is even more pronounced on curved substrata. An additional advantage of patterned surfaces is the reliability of contact on various surface profiles and the increased tolerance to defects of individual contacts.

Biomechanics of insect wing folding: a model for robotic applications

F Haas
"Staatliches Museum für Naturkunde Stuttgart, Rosenstein 1, D-70191 Stuttgart, Germany; haas.smns@naturkundemuseum-bw.de"

Insect hind wings are densely folded to fit two requirements. Firstly they need to have a minimum size to be flight worthy, too small wings are not usable as aerofoils. Secondly, they need to fit in a small casing, which is usually formed by stiff fore wings. These are, however, small to ensure mobility of the insect, which has to find crevices or is swiftly hunting. To meet these specifications, wings are folded in a taxon-specific manner, and so Dermaptera (earwigs) and Coleoptera (beetles) were examined to detect general principles as well as ‚customized' solutions. Additionally, wings were compared with other folded structures and computer simulations. Insect wings use a remote and distributed iving system with muscles exclusively located in the thorax proper, and resilin in the wing span. In Dermaptera, wings are unfolded with the cerci while folding is driven by elasticity, whereas in Coleoptera, wings unfold by the muscles, and fold by abdomen action. Folding lines divide the wing span into a system of stiff areas, which do not follow the veins and work as a lever system. Resilin is used to prevent material fatigue and fracture. Insect wings are smart structures with functionality built into their design.

Colour pattern recognition in bees

N Hempel de Ibarra
Neurobiology, Free University, Königin-Luise-Str. 28/30, 14195 Berlin, Germany; nhempel@neurobiologie.fu-berlin.de

Colours are meaningful signals to bees, used to optimise their choices during foraging. In flowers they are often arranged in more or less complex patterns increasing the display variability between species. Little is known about which spectral and spatial cues are available to bees in floral patterns and how bees perceive and learn them. Behavioural studies revealed that achromatic visual cues determine the detectability of coloured patterns. Stimuli with bright surroundings and dim centres are detected from a greater distance than those with dim surroundings and bright centres. A quantitative analysis of natural floral displays evinces that plants exploit this visual ability. Chromatic cues seem to be mainly involved in pattern recognition. Bees evince two evaluation strategies for the colour elements of a learned concentric pattern which are related either to the area occupied by a colour or to a colour's salience correlating with the strength of chromatic contrast. In the latter case bees ignore obvious spatial cues while discriminating patterns. This perceptual salience is based on the properties of the bee's visual system, rather than its experience in the field.

Is *Papilio* color vision tetrachromatic?

M Kinoshita, H Koshitaka, K. Arikawa
"Graduate School of Integrated Science, Yokohama City University, 22-2 Seto, Kanawaza-ku, Yokohama 246-0027, Japan; kinokom@yokohama-cu.ac.jp"

Papilio butterflies use color vision when searching for food. Their retina contains six types of spectral receptor; UV, violet, blue, green, red and broad-band. Do all of them contribute to color vision? To answer this question, we measured the discrimination ability of wavelength difference ($\Delta\lambda$ function) of foraging *Papilio.*
We trained female butterflies to take nectar on a certain wavelength of monochromatic light projected on a transparent screen from below. After 10 days of training we presented two monochromatic lights on the screen at the same time to the butterflies, one at the training wavelength and another at 0~10nm away from the training wavelength. We then let the butterflies select one of the lights by extending the proboscis towards it. It appeared that the butterflies are able to discriminate 5nm difference over the wavelength range from 400 to 600nm. In this range, there are high resolution regions at 430, 500 and 560nm. The behaviorally-determined $\Delta\lambda$ function well fitted to the predicted function with the assumption that UV, blue, green, and red receptors contribute to the behavioral task. Consequently we conclude that the *Papilio* butterfly has a tetrachromatic color vision system.

The aminergic control of reproductive tissues in the female locust, *Locusta migratoria***.**

AB Lange, I Orchard
"University Of Toronto At Mississauga, Mississauga, ON, Canada, L5L 1C6; alange@utm.utoronto.ca"

Successful fertilization of eggs in the female locust, *Locusta migratoria*, relies upon the coordination of spermathecal muscle movements with those of the oviducts during oviposition. We have examined the neurochemicals involved in the control of both spermathecal and oviducal muscle contractions. These neurochemicals include a variety of neuropeptides, but also involve amines, such as octopamine and tyramine. Dorsal unpaired median (DUM) neurons expressing octopamine-like and tyramine-like immunoreactivity are found within the penultimate abdominal ganglion with projections to the oviduct muscle. Octopamine-like immunoreactive DUMs in the last abdominal ganglion have been shown to project to the spermathecal muscle. Octopamine and tyramine are released by the innervation to the locust oviducts and inhibit contractions in a dose-dependent manner. The actions of octopamine are mediated by cyclic AMP whereas the mode of action of tyramine is more complex and may involve a variety of second messengers. In contrast, octopamine, acting via cyclic AMP, has stimulatory actions upon contractions of the spermatheca. The involvement of these amines in the control of reproductive tissues will be discussed.

Variation in eye structure in butterflies: how regional variation in acuity scales with body size

JW Merry, RL Rutowski
Life Sciences, Arizona State Univ., P.O. Box 874601, Tempe, AZ 85287-4601, U.S.A.; jmerry@asu.edu

Examining how a structure scales inter- and intraspecifically with body size can provide insight into how selection operates on that structure. Smaller compound eyes should have lower resolving power, as measured by interommatidial angle ($\Delta\varphi$) and facet diameter (*D*), than large eyes because diffraction becomes more severe as lens size decreases. In order to maximize acuity in important regions of the visual field, selection may drive small insects to sacrifice resolution in some parts of their eye so that acuity may be enhanced in other regions. To better understand how patterns of regional variation in visual acuity change with body size, we measured regional differences in $\Delta\varphi$ and *D* in twenty species of butterflies representing three families. We analyzed data at the level of species, family, and the dataset as a whole. We predicted that 1) visual acuity would increase with body size; however 2) smaller insects would have proportionally higher acuity. Furthermore, we predicted 3) that regional differences in acuity would be greater in smaller species. Data analysis revealed that the first two predictions held, while the third prediction did not. We examine outlier species and discuss possible reasons for their deviations from the general regression line.

Analysis of dopamine receptors from the honey bee, *Apis mellifera*

JA Mustard
400D Aronoff Labs, 318 W 12th Ave, Columbus, Ohio 43210 USA; mustard.13@osu.edu

Two dopamine receptor genes, *Amdop1* and *Amdop2* have been cloned from the honey bee (Blenau et al., 1998, J Neurochem 70:15-23; Humphries et al., 2003, J Neurobiol 55:315-330). Both receptors are D1-like in that they upregulate intracellular cAMP levels in the presence of dopamine, however, they exhibit distinctive functional and pharmacological properties (Mustard et al., 2003, Mol Brain Res 113: 67-77). Each receptor also shows an overlapping, but different, expression pattern in larval and adult honey bee brains (Kurshan, et al., 2003, J Comp Neurol 466: 91-103). Taken together, these results suggest that *Am*DOP1 and *Am*DOP2 receptors may play distinct roles in dopamine signaling. Both receptors are highly expressed in the mushroom bodies of worker honey bee brains. Mushroom bodies are believed to be important for learning and memory. To examine the roles of these dopamine receptors in olfactory learning, RNA interference (RNAi) was used to decrease the level of mRNA of each receptor in the mushroom bodies. Using the proboscis extension reflex, bees were then examined for changes in their ability to acquire and/or recall an association between an odor and a sucrose reward. Initial studies suggest that *Am*DOP1 and *Am*DOP2 may play distinct roles in olfactory learning.

Structural and conformational aspects of pyrokinin-like neuropeptide interaction with expressed receptors

RJ Nachman, YJ Kim, H. Williams, GM Coast, R Predel, M Adams
Southern Plains Agricultural Research Center, U.S. Department of Agriculture, College Station, TX 77845, USA; nachman@tamu.edu

The interaction of several classes of pyrokinin-like neuropeptides with their respective expressed receptors is investigated from a structural and conformational perspective. The discussion concerns a broad class of insect neuropeptides that represent products of the Capa-gene. Structural and conformational aspects critical to the interaction of the pyrokinin/PBAN class of neuropeptides and another Capa-gene product, the ecdysis-triggering hormone (ETH), with respective, expressed lepidopteran receptors are described. These ligand-receptor interactions are compared with the structural and conformational requirements for diuretic activity of the CAP2b/PVK sub-class of pyrokinin-like neuropeptides, also of the broad Capa category, in a dipteran. Insect neuropeptides of the classes selected for this discussion are implicated in the regulation of critical processes in pest insects. However, they suffer from a relative lack of biostability and bioavailability that limits their effectiveness as tools for neuroendocrinologists and as pest management agents. Biostable/bioavailable mimetic analog development of insect neuropeptides will be facilitated by a through understanding of structural/conformational aspects of the interaction with their receptors.

Peptidergic signaling pathways in *Drosophila melanogaster*.

R Nichols
University of Michigan Medical School, Biological Chemistry Department, Ann Arbor, MI, USA, 48109-0606; nicholsr@umich.edu

Peptides play crucial roles as transmitters and modulators of numerous biological processes, thus, aberrant peptidergic signaling may result in slowed development or death. Components of regulatory and transduction pathways are targets for the design of a variety of molecules including pesticides, thus, it is important to elucidate mechanisms that underlie peptidergic signaling. An interdisciplinary approach in a scientifically versatile organism is a powerful way to identify molecular components of regulatory and transduction mechanisms. A precursor often contains several peptides, thus, it is important to know how the polyprotein is processed and when and where the gene products are released to elucidate regulatory and transduction mechanisms involved in peptidergic signaling. In the case of structurally-related peptides encoded in either a single precursor or multiple precursors, it is important to decipher structure-activity relationships to avoid ambiguous data or erroneous conclusions. An *in vivo* bioassay is useful to establish the structure-activity relationship of structurally similar peptides, elucidate molecular mechanisms involved in peptidergic signaling, and to suggest peptide function(s). Comparison of peptide structure-activity relationships in different tissue bioassays yields insight into specificity of signaling pathways. We investigate signaling using *Drosophila melanogaster* to delineate peptide transduction pathways and functions.

Eph-ephrin signals may mediate sorting of olfactory sensory axons in *Manduca sexta.*

A Nighorn, M Kaneko
Room 611 Gould-Simpson Bldg, Univ. of Arizona, Tucson, AZ 85721 USA

We are investigating the roles of the Eph family receptor tyrosine kinases and their ligand ephrins in the developing primary olfactory nerve pathway in the moth *Manduca Sexta* using a combination of molecular biological and cell culture experiments. *Manduca* expresses one Eph receptor (MsEph) and one ephrin ligand (MsEphrin). *In situ* labeling with Fc-fusion probes reveals that both Eph receptors and ephrins are expressed on axons of olfactory receptor cells (ORCs) during their ingrowth to the primary center, the antennal lobe (AL). Eph receptors and ephrins are differentially distributed among identifiable glomeruli such that glomeruli with high receptor staining show little or no ligand staining and vice versa, suggesting a complementary Eph/ephrin expression by subsets of ORC axons innervating a particular set of glomeruli. *In vitro*, ephrin-Fc and Eph-Fc, when present homogeneously in the substratum, inhibit neurite outgrowth from olfactory epithelial explants. In patterned substratum, neurites turn or stop upon encountering the test substratum. These observations indicate that MsEphrin can act as an inhibitor/repulsive cue for ORC axons. We hypothesize that Eph receptors and ephrins mediate axon sorting and fasciculation through repulsive axon-axon interactions. We are currently testing that hypothesis using RNAi to knockdown the expression of MsEph and MsEphrin.

Characterization of small motion detection neurons of *Eristalis tenax*

K Nordström, D O'Carroll
Discipline of Physiology, The University of Adelaide, SA 5005, Australia; Karin.Nordstrom@adelaide.edu.au

The hoverfly *Eristalis tenax* exhibits typical syrphid behaviour, with stationary hovering followed by rapid pursuit of conspecifics. Male and (possibly) female flies depend on detection of small rapidly moving targets to find mates and defend their territory. Neurons specialized for detecting small targets against cluttered backgrounds can be found in the lobula complex (3rd optic ganglion) of the fly brain. We are characterizing the morphology and physiology of a range of lobula small target motion detecting (STMD) neurons using dye-fills and electrophysiological techniques. We define STMDs as neurons that give a powerful response to a small object (1-2 degrees square) moving across a bright or cluttered background, but weaker responses to larger size targets. We find a number of classes of STMDs with unique properties in both sexes. These include neurons with small excitatory receptive fields surrounded by distinctly shaped inhibitory areas, and wide-field STMDs that may be used for mate detection. STMDs generally give spiking responses, and have variable degrees of spontaneous spike activity, including neurons that are 'silent' until stimulated by a target. A prominent feature of some STMDs is the robustness of their responses in the presence of background motion.

What gives adaptive gain control in insect motion detection?

DC O'Carroll, TJ Rainsford,
Discipline of Physiology & Centre for Biomedical Engineering, University of Adelaide, S.A. 5005, Australia; david.ocarroll@adelaide.edu.au

The phenomenon of motion adaptation is widespread among animals, having been demonstrated in species as diverse as humans, wallabies and flies. Motion adaptation appears to have evolved to maximize efficiency of visual coding in neurons with limited signaling range. Recent work highlights controversy over the site and mechanism of adaptation. Hypotheses range from simple gain control in 'early' vision (contrast normalization), to adaptive feedback that alters the delay mechanisms within local motion detectors. We have shown that adaptation does not alter the velocity tuning of motion detectors, but instead induces large reductions in contrast gain. Using moving natural scenes and a probe-adapt-probe protocol, we show here that gain reduction is driven by a mechanism with broad velocity tuning. While the tuning of adaptation resembles that of motion detectors themselves (favoring a feedback hypothesis), its broadness suggests extremely high gain in the feedback pathway and permits powerful adaptation to stimuli that drive motion detectors weakly. This mechanism may optimize coding of image velocity independent of the contrast variations between different natural scenes. Our work suggests easily implemented elaborations to existing motion detector models that could impart similar robustness to artificial motion detectors based on the same principle.

Diuresis in the blood-feeding bug, ***Rhodnius prolixus*****: Involvement of serotonergic dorsal unpaired median neurons and peptidergic bilaterally paired neurons.**

I Orchard, VA Te Brugge, D Schooley, AB Lange
"University of Toronto at Mississauga, Mississauga, ON, Canada, L5L 1C6; ian.orchard@utoronto.ca"

The blood-feeding bug, *Rhodnius prolixus*, ingests large blood meals followed by a period of rapid diuresis that is under neurohormonal control. We are interested in determining the identity of the neurohormones controlling diuresis, the timing of their release, their effect on the Malpighian tubules (and other tissues involved in diuresis) and their potential interactions. Within the mesothoracic ganglionic mass (MTGM) of *Rhodnius*, there exists a subpopulation of dorsal unpaired median (DUM) neurons that display serotonin-like immunoreactivity. These, and other DUMs, are also immunoreactive to a variety of insect neuropeptide families (e.g. allatostatin-like and Dippu DH-31-like peptides). Serotonin is a neurohormone in *Rhodnius*, released from neurohaemal sites formed from these serotonergic DUMs, that controls diuresis. We have also mapped the distribution within *Rhodnius* of neuropeptides shown to possess diuretic activity in other insects. Bilaterally-paired neurons of the MTGM display Locusta DP-like, kinin-like and Dippu DH-31-like immunoreactivity. The effects of these peptide families and serotonin on diuresis in *Rhodnius* will be discussed.

Colour vision in the European glow-worm, *Lampyris noctiluca*

D Booth, D Osorio, AJA Stewart.
School of Life Sciences, University of Sussex, BN1 9QG. U.K.; d.osorio@sussex.ac.uk

Traditionally North Americans enjoy twilight watching fireflies (Lampyridae) display. Species first seen after dusk glow yellowish-orange (peak 580nm), while nocturnal species glow green (550nm). Photoreceptor sensitivities match the bioluminescent spectrum. According to a classic account in visual ecology, this communication system is optimized for signal detection: long-wavelength signals of crepuscular species contrast against the leaf background, whilst at night the green signals maximize absolute sensitivity (H.H. Seliger et al. *Photochem. Photobiol.* **36**, 673, 1982). In Britain twilight is boring, with only the nocturnal glow-worm *Lampyris noctiluca*. Wingless females sit near the ground, and attract flying males with a leaf-green light. Male glow-worms have long been known to be insensitive to 480nm light. This insensitivity might be explained by coloured filter pigments. However, in our behavioural tests addition of blue light reduces the attractiveness of green light to male glow-worms. This means that they have colour vision, and implies that their phototaxis uses a chromatic (i.e. opponent mechanism). By comparison, the matched filtering account invokes a spectrally selective achromatic mechanism. Our observation presents a puzzle: why subtract a noisy short-wave receptor's response from a long-wave detector well matched to its task?

Responses of the silkworm tyramine receptor to ligand compounds

Y Ozoe, H Ohta, MAA Khan
Department of Life Science and Biotechnology, Shimane University, Matsue 690-8504, Japan; ozoe-y@life.shimane-u.ac.jp

The physiological study of tyramine lags behind those of octopamine and dopamine. The new discovery of ligands that selectively interact with the insect tyramine receptor would facilitate research into the tyraminergic signal transduction. To this end, we cloned B96Bom from the silkworm (*Bombyx mori*) and expressed it in HEK-293 cells. Tyramine attenuated forskolin-stimulated cAMP production by interacting with the B96Bom receptor more potently than octopamine and dopamine. Yohimbine abolished the tyramine attenuation of cAMP production. These findings indicate that the B96Bom receptor is a tyramine receptor. We synthesized phenyloxazoles and phenylethylamines to test their abilities as ligands for biogenic amine receptors. Most of the compounds showed positive and negative effects on cAMP production in the membrane preparation of the silkworm head. 5-(4-Hydroxyphenyl)oxazole (5PO4) outstandingly attenuated basal, octopamine-stimulated, and forskolin-stimulated cAMP production. Yohimbine, but not *R*(+)-SCH23390 and chlorpromazine, abolished the 5PO4 attenuation. However, 5PO4 failed to attenuate forskolin-stimulated cAMP production in the cloned tyramine receptor, although the compound bound to the receptor. Phenylethylamines showed higher affinity for the cloned tyramine receptor than 5PO4. Although 2-chloro-2-(4-chlorophenyl)ethylamine failed to attenuate forskolin-stimulated cAMP production, the compound abolished the tyramine attenuation of forskolin-stimulated cAMP production.

Leucokinin signal transduction in blood feeding vectors of disease, the mosquito *Aedes aegypti* **(L.) and the southern cattle tick,** *Boophilus microplus* **(Canestrini).**

PV Pietrantonio, C Jagge, SP Holmes.
"Dept. of Entomology, Texas A&M University, MS 2475, College Station, TX 77843-2475 USA; p-pietrantonio@tamu.edu"

Two different blood-feeding arthropods serve the study of leucokinin signal transduction and its relationship to diuresis and water balance. In the mosquito *Aedes aegypti*, the three *Aedes* leucokinin peptides stimulate total urine production in a dose-dependent manner *in vivo* (Cady and Hagedorn, 1999). In contrast, the specific function of myokinins in ticks is unknown and none have yet been isolated from this group of arthropods. We have cloned and functionally characterized a myokinin receptor from the Southern cattle tick (Holmes et al., 2003) and also identified its likely ortholog in the female of *Aedes aegypti*. Tissue localization of the receptors in these vectors was achieved through RT-PCR and/or *in situ* hybridization techniques. Receptor functionality and ligand specificity was analyzed by expressing the receptors in mammalian CHO-K1 cells followed by challenge with peptide agonists and measurements of intracellular calcium by fluorescence cytometry. In this system, the receptors are functional at physiological leucokinin concentrations. Differences in leucokinin signal transduction between *Aedes aegypti* and *Drosophila melanogaster* will be discussed.

Understanding serotonin signal transduction in arthropods vectors of disease: *Aedes aegypti* **and** *Boophilus microplus*

PV Pietrantonio, C Jagge, DW Lee, A Chen.
"Dept. of Entomology, Texas A&M University, MS 2475, College Station, TX 77843-2475 USA; p-pietrantonio@tamu.edu"

In the mosquito *Aedes aegypti*, serotonin (5-HT) changes the rhythm of contractions in the female hindgut and increases fluid secretion in the larval Malpighian tubule. We investigated the potential role of 5-HT as a diuretic hormone in adults. For this we cloned a serotonin receptor cDNA (from female *A. aegypti* Malpighian tubule) that is similar to the 5-HT$_7$ receptor from *Drosophila melanogaster*. The transcript was localized in the tracheolar cells associated with the Malpighian tubules but no signal was detectable in the tubule epithelium. Immunohistochemistry with specific antibodies confirmed the receptor expression in tracheolar cells and hindgut, and western blots of these tissues showed the expected 50kDa band. The results suggest a role for serotonin in respiration. Functional expression of the *Aedes* 5-HT$_7$-like receptor in CHO-K1 cells showed that the receptor positively coupled to a Gs protein, increasing intracellular cAMP in response to 5-HT. Only 5-HT but not octopamine, dopamine or tyramine, induced cAMP. Agonists of the mammalian 5-HT$_7$ receptor had the following order of potency with the *Aedes* receptor: 5-HT >> 5-CT = 8-OH-DPAT >> pimozide. This is the first report on the functional expression of a mosquito neurohormone receptor. The characterization of a tick 5-HT receptor will be presented.

Honeybee vision and navigation: role of associative learning and cross-modal recall

J Reinhard, MV Srinivasan, SW Zhang
The Australian National University, Rsbs Visual Sciences, Gpo Box 475, Canberra, Act, 2601, Australia; Reinhard@Rsbs.Anu.Edu.Au

Insects learn and process environmental cues to orientate in their surroundings. The honeybee, *Apis mellifera*, flies rapidly and accurately to food sources that are often kilometres away. This is achieved by learning visual cues based on the distance and direction of the goal, the landmarks encountered en route, and the shape and colour of the desired flowers. Honeybees also learn chemical cues associated with food sources, such as the scent and the taste of the nectar. We investigated how the honeybee's capacity for associative learning and cross-modal recall assists her in navigating back to a known food source. We find that honeybees, trained to visit a scented sugar feeder placed at a specific outdoor location, can be induced to visit the same location simply by blowing the same scent into the hive, even when the destination no longer carries the food or the scent. Bees can be triggered in this way to fly to a specific location, or to find a specific colour. Our findings suggest that familiar nectar scents brought back into the hive by returning foragers, can induce recall of specific visual and route memories in experienced honeybees, and thus expedite navigation to the food source.

On moth's odorant receptors

A Ruebenbauer, C Löfstedt, JF Picimbon
"Ecology building, Sölvegatan 37, 223 62, Lund, Sweeden; Agnieszka.Ruebenbauer@ekol.lu.se"

Odorant receptors (ORs) are quite essential in chemical communication between and among insects and their environment. Therefore ORs in Noctids were focused in foregoing study. We compared different ORs in antenna of 0-7 days old males and females of *Heliothis zea*. Additionaly the tissue distribution of ORs has been done in different parts of the insect's body: wings, legs, abdomens, thoraces and heads (animals between 0-4 days old). *Agrotis segetum* ORs sequences in antenna have been obtained as well. Following study has been performed using molecular techniques. Various pairs of primers were designed and PCRs have been performed followed by cloning and sequencing the corresponding PCR products. Obtained sequences were analysed by BioEdit computer programme.

PTTH signal transduction in the prothoracic gland: a tangled web with one purpose?

R Rybczynski
"Dept. of Biology, UNC at Chapel Hill, Chapel Hill, NC, 27599, USA; rybczy@bio.unc.edu"

Molting and metamorphosis in insects is controlled by several hormones, with 20-hydroxyecdyone (molting hormone) playing an overarching role. Prothoracicotropic hormone (PTTH), the best-understood regulator of ecdysteroidogenesis, stimulates ecdysteroid synthesis by the prothoracic glands. Work in the 1980s and 1990s revealed that PTTH activated a signal transduction cascade that included Ca^{2+}- influx, cAMP generation, phosphorylation of the ribosomal protein S6 and protein translation. In this talk, I will review more recent work, from our group and others, indicating that the PTTH signal transduction cascade is surprisingly complex. We now know that additional kinases are activated, including an extracellular signal-regulated kinase (ERK), a protein kinase C, and one or more unidentified tyrosine kinases. Ongoing studies also suggest PTTH-stimulated Ca^{2+}- influx is complexly regulated, with increases in cytoplasmic free Ca^{2+} coming from at least three sources, and that phospholipase C activation is among the earliest intracellular events triggered by PTTH. The composite data suggest that (1) PTTH regulates more processes in the prothoracic gland than ecdysteroid synthesis; (2) the study of phosphorylated proteins offers an avenue to identify these additional functions of PTTH; and (3) the control of ecdysteroid synthesis is subject to a Pandora's box of developmentally varying checks and balances.

Candidate Genes for Behavioral QTL in the Honeybee, *Apis mellifera.*

D. I. Schlipalius, E. Guzmán-Novoa, M. Arechavaleta-Velasco, C. Emore, R. E. Page, C. Hill and G. J. Hunt
Department of Entomology, Purdue University, West Lafayette, IN 47907

The Honeybee Genome Project is providing an unprecedented opportunity for identifying and characterizing genes involved in the behaviour and brain function of social organisms. The honeybee genome has an unusually high recombination rate compared to those of other higher eukaryotic organisms. This high recombination rate aids in pinpointing genes because linkage maps rely on crossovers to determine position of markers. To take full advantage of this phenomenon, we have constructed a high-density genetic linkage map of the honeybee that contains over 1000 AFLP, RAPD microsatellite markers and sequence tagged sites (STS). There are more than 315 sequence tags on the genetic linkage map, sourced from sequenced AFLP, RAPD and microsatellite DNA fragments. This genetic map was constructed from a cross between a defensive African-derived strain of honeybee and a "gentle" strain of European honeybee and has allowed us to investigate QTL for defensive behaviours. These QTL regions have produced an intriguing list of candidate genes that may influence stinging and guarding behaviours. We hypothesise that natural selection has acted on genes that influence neuromodulator levels, hormone signaling and the visual system to produce more defensive genotypes of bees.

The role of protein phosphorylation in regulating the function of ecdysone receptor complex

Q Song
Department of Entomology, University of Missouri, Columbia, Missouri, USA

Insect signal transduction systems: current knowledge and future directions

DW Stanley, J Vanden Broeck[2]
Laboratory for Developmental Physiology, Genomics and Proteomics, Naamsestraat 59, B3000 Leuven, Belgium; Jozef.VandenBroeck@bio.kuleuven.ac.be

In biological systems, physiological responses to extracellular signals are elicited by activation of specific receptor proteins. This activation induces cellular effects via a process, generally designated as 'signal transduction'. Interestingly, the main categories of signal transducing receptor proteins are conserved in Arthropods. Moreover, this is also the case for most families of proteins that are components of intracellular signaling pathways. The recent technological revolution in genomics will certainly have an important impact on future signal transduction research. Convenient expression systems and functional assay procedures will be needed for studying the functional properties of the encoded predicted proteins. In this symposium, a number of conserved signaling protein families will be discussed, as well as recent advances and future directions in the analysis of their structural and functional properties. In more detail, we will review the current knowledge concerning the superfamily of G protein-coupled receptors. The study of evolutionary aspects of cellular signaling processes will probably reveal insect-specific features. Future challenges are to study the regulation, function and interplay of many different genes and to analyze the *in vivo* dynamics of functional interactions in biological systems.

Pieris rapae red and deep-red receptors use a green rhodopsin and two red filter types

DG Stavenga, M Kurasawa, M Wakakuwa, K Arikawa
"Neurobiophysics, Groningen University, NL 9747 AG, Groningen; stavenga@phys.rug.nl"

The visual pigments and spectral sensitivities of the long-wavelength photoreceptors of the small white butterfly *Pieris rapae* were studied by combined electrophysiology, molecular biology and optical modeling. *Pieris rapae* appears to have only one long-wavelength rhodopsin, PrL, which is expressed in the two distal photoreceptor cells (R3 and R4) as well as in the proximal photoreceptors (R5-8) in all three types of ommatidia of the *Pieris* fronto-ventral eye. The spectral sensitivities of R3 and R4 well approximate the absorption spectrum of a visual pigment with absorption maximum at 563 nm. The spectral sensitivities of R5-8 photoreceptors in ommatidial type I and III peak at 620 nm and those in type II ommatidia peak at 640 nm. The large shifts of the spectral sensitivities of the R5-8 photoreceptors with respect to the absorption spectrum of their visual pigment, R563, can be explained with the spectral filtering by pale-red (PR) and deep-red () screening pigments that are concentrated in clusters of granules near the rhabdom boundary. The peak absorbance of the two spectral filters appears to be approximately 1 (PR) and 2 ().

Behavioural and optical resolution of the honeybee eye.

M Vorobyev, N Hempel de Ibarra[2]*, O Ganeshina*

Vision Touch and Hearing Research Centre, SBMS, University of Queensland, 4072, Brisbane, Australiua; m.vorobyev@uq.edu.au[2]Institute of Neurobiology, Free University, Berlin

We compared behavioural resolution of the bee eye with the predictions of the optical model. The model assumed that bees failed to detect stimuli whose borders could not be resolved. The resolution of border detectors was estimated from the optics of the honeybee frontal eye. Bees were trained to detect oval stimuli whose diameter in a longitudinal direction was 4 times longer than in a short one. The ovals were either horizontally or vertically oriented. The optical model of border detection predicted the limiting visual angle for such ovals to be 9.5^0 (long diameter) for horizontally oriented ovals and 7.7^0 for vertically orientated ones. In the case of horizontal orientation bees could detect an oval subtending 11^0 (85% correct choices) but they fail to detect one subtending 7.6^0 (51% correct choices). In the case of vertical stimuli bees easily detected an oval subtending 11^0 (91% correct), the 7.6^0 oval was difficult to detect (69% correct) and they could not detect an oval subtending 6.4^0 (53% correct). Thus the results of behavioural experiments agree with the results of the model predictions, indicating that the resolution of the honeybee vision is close to the limit set by the optics of their eyes.

Nocturnal vision and landmark orientation in a tropical halictid bee

EJ Warrant, A Kelber, A Gislén, B Greiner, W Ribi, WT Wcislo
Zoology, Lund University, Helgonav. 3, S-22362 Lund, Sweeden; Eric.Warrant@cob.lu.se

Some bees and wasps have evolved nocturnal behaviour, presumably to exploit night-flowering plants or avoid predators. They display impressive visual behaviour despite having apposition compound eyes, a design adapted for bright light. In theory, this eye design should render these insects blind by mid-dusk. How then are they able to see at night? We studied female tropical nocturnal sweat bees (*Megalopta genalis*) and discovered that they are able to learn landmarks around their nest entrance prior to nocturnal foraging trips, and to use them to locate the nest upon return. This is the first evidence of nocturnal landmark orientation in insects. The morphology and optics of the eye, and the physiological properties of the photoreceptors, have evolved to give *Megalopta's* eyes almost 30 times greater sensitivity to light than the eyes of diurnal honeybees, but this alone is not sufficient to explain their nocturnal visual behaviour. This implies that sensitivity is improved by a strategy of photon summation in time and in space, the latter of which requires the presence of specialised cells that laterally connect ommatidia into groups. Cells absent in diurnal bees have now been identified in the lamina of *Megalopta's* optic lobe that may subserve spatial summation.

The mechanism of the flight motor given respiratory gas exchange in hawkmoths.

LT Wasserthal
Institut of Zoology 1, Staudtstrasse 5, D 91058 Erlangen; ltwthal@biologie.uni-erlangen.de

Intratracheal pressure, O_2-content and CO_2-emission during tethered flight were analyzed at the anterior spiracles and mesortergal air sacs in hawkmoths using electronic pressure sensors, O_2 sensitive optodes and an URAS gas analyzer with split specimen chamber.Electrophysiological measurement of the flight muscles and of a hithertoo neglected special ventilatory muscle contribute to the understanding of the flow through mechanism. Deformations of the lateral thorax and their effect upon the spiracles were recorded under stroboscopic light. During shivering, ventilation pulses are generated by the flight muscles reminiscent of the known autoventilation mechanism with tidal air flow and the intratracheal O_2 content decreases astically. During steady flight, however, a unidirectional airstream is produced with a mean subatmospheric pressure at the first (mesothoracic) spiracles and a mean positive pressure in the mesotergal air sacs resulting in an increasing intratracheal O_2 content. Due to this pressure decrement during flight, CO_2 leaves only at the posterior spiracles. The suction force for the inspiration flow at the anterior spiracles is generated by the flight apparatus and a special ventilatory muscle under prevention of inspiration through the posterior thoracic spiracles. The result is an efficient separation of the CO_2 emission route from the inspiratory air stream.

Robot models of cricket behaviour

B Webb
IPAB, School of Infomatics, King's Buildings, Mayfield Rd, Edinburgh EH9 3JZ, UK; bwebb@inf.ed.ac.uk

Insects demonstrate flexible and adaptable sensory-motor control despite their relatively small nervous systems, suggesting efficient solutions to problems in robotics. Moreover, robots can be used to test our understanding of the mechanisms of animal behaviour, by implementing hypotheses and testing their capabilities in realistic situations. We have built a series of robots based on cricket phonotaxis, that is, the ability of female crickets to locate a mate by moving towards the auditory stimulus of the calling male. Three main aspects of recent work will be described. The first is the use of an outdoor robot, with locomotion inspired by insect walking, to test a spiking neural network mechanism for phonotaxis in natualistic conditions. The second is the integration of additional sensory systems, specifically the optomotor response, onto the robot model. It is shown that a number of different algorithms for combining these behaviours seem to produce similar behaviour in a simulation of cricket experiments. However the algorithms may be distinguished when we consider issues of the different dynamics of the real sensory systems on the robot, and of the plausibility of neural implementation for the different schemes. Third, current collaborative work is aimed at revising and refining the model through parallel behavioural, neurophysiological and modelling investigations on the cricket and the robot. This has led to a number of novel discoveries about the functioning of the biological system.

The curious engineering of the insect flight skeleton

RJ Wootton
"School of Biological and Chemical Sciences, University of Exeter, Hatherly Laboratories, Prince of Wales Road, Exeter EX4 4PS, UK**;**
r.j.wootton@ex.ac.uk"

Insects are unique among flying machines in their use of bending and buckling of thin plates and shells, reinforced where necessary by ridges and tubes, to translate the cyclic contractions of the muscles into the complex, varying kinematics of the wings. While fine adjustments to the form of the wing stroke cycle need to be actively achieved, as much information as possible is stored in the morphology of the skeleton itself: in the disposition of rigid and flexible components in the pterothorax and wings. The degree and nature of rigidity and pliancy are influenced by structure at all levels of scale. Relevant structural variables include the arrangement of apodemes, sutures and sulci in the thorax, of the veins, ridges, relief and flexion-lines in the wings; and the local thickness, microstructural relief, ultrastructure and chemistry of the cuticle. Detailed morphology, manipulation, mechanical testing, and physical, analytical and mathematical modelling are revealing the subtleties of these fascinating, highly automated systems.

The honeybee is able to categorise natural visual images

SW Zhang, MV Srinivasan,
CENTRE FOR VISUAL SCIENCES, RESEARCH SCHOOL OF BIOLOGICAL SCIENCES, AUSTRALIAN NATIONAL UNIVERSITY, PO BOX 475, ACT 2601, AUSTRALIA; SWZHANG@RSBS.ANU.EDU.AU

Recent work has revealed that monkeys as well as pigeons are able to categorise complex visual objects**.** We show here that the ability to group similar natural, visual images together extends to an invertebrate – the honeybee. Bees can be trained to distinguish between different types of naturally occurring scenes in a rather general way, and to group them into four distinct categories: landscapes, plant stems and two different kinds of flowers. They exhibit the same response to novel visual objects that differ greatly in their individual, low-level features, but belonging to one of the four categories. We exclude the possibility that they might be using single, low-level features alone as a cue to categorise these natural visual images and suggest that the categorisation is based on a combination of low-level features and configurational cues.

The visual ecology of hawkmoths

A Balkenius, A Kelber
Vision Group, Department of Cell and Organism Biology, Lund University, Sweden; anna.balkenius@cob.lu.se

The diurnal *Macroglossum stellatarum* and the nocturnal *Deilephila elpenor* are active in amatically different light intensities but both have colour vision. *D. elpenor* can discriminate colours in light intensities a million times weaker than the light intensities normal for *M. stellatarum*. Both species have colour constancy, which allows them to discriminate colours irrespectively of the spectrum of the illumination. This ability is explained by chromatic receptor adaptation according to the von Kries coefficient law. *M. stellatarum* learns the size, patterns and brightness of flowers. Both species learn the spatial location of rewarding stimuli, when they are difficult to distinguish by colour alone. Nocturnal sphingids mostly use odour to localize nectar flowers. However, in the day-active *M. stellatarum*, vision has become the dominating modality. When faced with a colour and an odour stimulus, naive *M. stellatarum* select the colour. The behaviour of flower-naive *D. elpenor* is the opposite. We are currently investigating the role of multi-modal interaction in learning experiments with both species.

Technical perfection in the sensory periphery: spider mechanoreception

F G Barth
Institute for Zoology, University of Vienna, Althanstr.14, A-1090 Vienna, Austria; frieich.g.barth@univie.ac.at

Despite the small size of their brain arthropods show complex and highly refined behavior. One of the foundations making this possible is the refinement and filter action of their sensory periphery. Spider mechanoreceptors exemplify this nicely. Being interfaces between environment and behavior they not only reflect details of the physical properties of the adequate stimulus but also characteristics of species-specific behavior. This will be illustrated taking two different types of sensory hairs as examples. (i) *Trichobothria* are *medium flow sensors* of outstanding sensitivity which is largely due to an intriguingly well "designed" interaction between the moving air and the hair. Using fluid mechanics this interaction can be modelled quantitatively and the hair´s mechanical and nervous responses related to prey catching behavior. (ii) *Tactile hairs* follow mechanical principles different from those of a medium flow sensor as seen from their morphology and mechanical properties and revealed by finite element analysis and micromechanical measurements. Bringing together neurobiology and engineering not only deepens our understanding of sensory systems but also helps in developing new, biology-inspired technical sensors.

Molecular and pharmacological characterization of *Drosophila* octopamine receptors

A Baumann, S Balfanz, S Frings
"Forschungszentrum Jülich, IBI-1, Postfach 1913, D-52425 Juelich, Germany; a.baumann@fz-juelich.de"

In invertebrates, the biogenic amine octopamine regulates physiological functions including locomotion, neuronal development, circadian rhythm, as well as learning and memory. Pharmacological investigations indicate that octopamine mediates these effects by activation of several G protein-coupled receptor types.
We have cloned two genes from *Drosophila melanogaster* that encode three functional octopamine receptors. The first gene (Dm*oa*1) codes for two polypeptides which are generated by alternative splicing. The proteins share identical N-terminal halves but differ in the C-terminal half. When stimulated with nanomolar concentrations of octopamine, both splice variants induce Ca^{2+} release from internal stores. At high concentrations of octopamine ($^{3}10^{-6}$ M) the receptors also cause cAMP production. The second gene (Dm*oa*2) encodes a single polypeptide that specifically causes a rise of intracellular cAMP. The EC_{50} value is ~5×10^{-8} M octopamine. Tyramine activates all three receptors but at ^{3}100 fold higher concentrations. The biogenic amines dopamine and serotonin are non-effective at all. Developmental expression of Dm*oa* genes was assessed by RT-PCR. Overlapping but not identical expression patterns were observed for the individual transcripts. Since native octopamine receptors induce either cAMP production or Ca^{2+} release, the two genes may encode the complete set of octopamine receptors that are expressed in *Drosophila*.

The imaging properties of the dragonfly median ocellus

RP Berry, EJ Warrant, G Stange.RSBS, The Australian National University, GPO Box 475, Canberra, ACT 2601, Australia

Current literature describes the ocelli of pterygote insects as average illumination detectors, which serve to provide attitude information for the maintenance of flight equilibrium. This view has arisen because of several prominent features of the ocelli, including; fields of view centred on the horizon, under-focussed optics and a high rate of convergence from photoreceptors to second-order neurons which output to regions of the nervous system involved in flight control. However, recent research has indicated that dragonfly ocelli possess unusual structural and optical properties that are inconsistent with this view of ocellar function. In particular, from hanging-op preparations of the dragonfly median ocellar lens it has been determined that the image formed by this lens lies close to the underlying retinal layer, that the resolution of the image is dependent upon the orientation of an object and that the image is split laterally into left and right halves. Preliminary investigations also indicate the presence of a gradient of refractive index in the median ocellar lens. The optical properties of this lens and their relevance to dragonfly behaviour will be discussed.

Stop and go with NO: nitric oxide and cyclic nucleotides regulate neuronal motility in an insect embryo

G Bicker, A Haase
School of Veterinary Medicine Hannover, Cell Biology, Bischofsholer Damm 15, D-30173 Hannover, Germany; gerd.bicker@tiho-hannover.de

The dynamic regulation of nitric oxide synthase (NOS) activity and cyclic GMP levels suggests a functional role in the development of nervous systems. Here, we report evidence for a key role of the NO/cGMP signalling cascade on migration of postmitotic neurons in the enteric nervous system of the embryonic grasshopper. During development, a population of enteric neurons migrates on the surface of the midgut. These midgut (MG) neurons exhibit nitric oxide-induced cGMP-immunoreactivity coinciding with the migratory phase. Using a histochemical marker for NOS, we identified potential sources of NO in subsets of the midgut cells below the migrating MG neurons. Inhibition of endogenous NOS, sGC, and protein kinase G (PKG) activity in whole embryo culture results in a significant retardation of MG neuron migration. This inhibition can be rescued by supplementing with protoporphyrin IX free acid an activator of sGC, and membrane-permeant cGMP, indicating that NO/cGMP signalling is crucial for MG neuron migration. Conversely, the stimulation of the cAMP/protein kinase A signalling cascade results in an inhibition of cell migration. Activation of either the cGMP or the cAMP cascade influences the cellular distribution of F-actin in neuronal somata in a complementary fashion. The cytochemical stainings and experimental manipulations of cyclic nucleotide levels provide clear evidence that NO/cGMP/PKG signalling is permissive for MG neuron migration whereas the cAMP/PKA cascade may be a negative regulator. Since NO/cGMP signaling is also involved in axonal extension of pioneer neurons, these investigations reveal an accessible insect model in which the role of the NO/cGMP/PKG signalling cascade on neuronal cell motility can be analyzed in a natural setting.

Excitation-secretion coupling in the salivary glands of *Periplaneta americana*

W Blenau, A Baumann, S Marg, C Krach, O Baumann, B Walz
"Universität Potsdam, Institut Für Biochemie Und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany; blenau@rz.uni-potsdam.de"

The acinar salivary glands of the cockroach, *Periplaneta americana*, are innervated by dopaminergic and serotonergic nerve fibers. Serotonin stimulates the secretion of protein-rich saliva, whereas dopamine causes the production of protein-free saliva. This suggests that dopamine acts selectively on ion-transporting peripheral cells within the acini and the duct cells, and serotonin acts on the protein-producing central cells of the acini. We investigated the pharmacology of the dopamine-induced secretory response by using several dopamine receptor agonists and antagonists. The effects of dopamine can be mimicked by the agonists 6,7-ADTN and R(+)-Lisuride. Dopamine-induced secretions could be blocked by *cis*(Z)-flupentixol, chlorpromazine, and (+)-butaclamol. We performed PCR experiments with degenerate primers in order to clone dopamine and serotonin receptor genes from *Periplaneta.* So far, we obtained four PCR fragments with their sequences being similar to the *Drosophila* serotonin 5-HT1A, the *Drosophila* dopamine DopR2, the honeybee Am*tyr*1, and a non-characterized *Drosophila* biogenic amine receptor-gene, respectively. In addition, we have cloned a cDNA fragment coding for nitric oxide synthase (NOS). Using RT-PCR and NADPH diaphorase staining we proved NOS expression in the salivary glands. Dopamine-induced secretion is reduced by the NO donors sodium nitroprusside and DEA-NONOate. The effects of both substances were dose-dependent and reversible.

Molecular and pharmacological characterization of honeybee biogenic amine receptors

W Blenau, Schlenstedt, L Grohmann, A. Baumann.
"Universität Potsdam, Institut Für Biochemie Und Biologie, Lennéstr. 7a, D-14471 Potsdam, Germany; Blenau@Rz.Uni-Potsdam.De"

Biogenic amines and their receptors are important regulators of physiological and behavioral functions in insects. So far we have cloned the cDNAs encoding a dopamine D1 receptor (AmDOP1), a tyramine receptor (AmTYR1), an octopamine receptor (AmOA1) and a putative serotonin receptor from the honeybee brain. In the honeybee, octopamine acts as a neuromodulator and is involved in learning and memory formation. The AmOA1 receptor is most closely related to octopamine receptors from *Drosophila melanogaster* and the pond snail, *Lymnea stagnalis*. Signaling properties of the cloned receptor were studied in transiently transfected HEK 293 cells. Nanomolar to micromolar concentrations of octopamine induced oscillating increases in the intracellular Ca^{2+} concentration. The Am*oa*1 gene is abundantly expressed in many somata of the honeybee brain, suggesting that this octopamine receptor is involved in the processing of sensory inputs, antennal motor outputs, and in higher-order brain functions. Recently, we have isolated the cDNA of a putative serotonin receptor from *Apis mellifera*. The deduced amino acid sequence of this honeybee receptor shows greatest sequence homology to 5-HT7 receptors from *Drosophila melanogaster* and *Aedes aegypti* as well as to 5-HT1A receptors from vertebrates. The functional properties of this receptor and its tissue distribution are currently under investigation.

Modulation of tyramine signaling by osmolality in the *Drosophila* malpighian tubule

EM Blumenthal
"Dept. of Biological Sciences, Marquette Univ., Box 1881, Milwaukee, WI 53201-1881, USA; edward.blumenthal@marquette.edu"

The biogenic amine tyramine acts as a diuretic agent in the Malpighian tubules of *Drosophila melanogaster*, boosting urine production by increasing the transepithelial chloride conductance. The effects of tyramine can be measured electrically as a depolarization of the transepithelial potential. The response of isolated tubules to tyramine can be modulated by changes in the osmolality of the peritubular bath; an increase in osmolality results in a decreased response to tyramine, while a decrease in osmolality results in an enhanced tyramine response. Because the tyraminergic pathway is likely to be constitutively activated *in vivo*, this modulation may allow for greater responsiveness of the tubule to changes in hemolymph osmolality. In response to a sustained osmotic challenge, the modulation of the tyramine response is not constant but adapts, such that the amplitude of the tyramine response returns towards the control value over the course of 5-10 minutes. Interestingly, in one strain of flies this adaptation does not occur. These flies are also salt-sensitive, dying on food containing 0.4M NaCl. Genetic studies are now underway to determine if both of these phenotypes are due to the same locus and to identify the affected gene. Supported by NIH R21DK60860 and Marquette University.

Rapid evolution of the butterfly eye through multiple independent duplications of the opsin gene family

AD Briscoe, M Sison-Mangus
University of California, Irvine, Dept. of Ecology and Evolutionary Biology, 321 Steinhaus Hall, Irvine, CA 92697, U.S.A.; abriscoe@uci.edu

Lycaena butterflies have four major spectral classes of visual pigments in the compound eye photoreceptors with lambda-max values of 360 nm, 437 nm, 500 nm and 568 nm, respectively (Bernard and Remington 1991). In this study, we characterized these visual pigments molecularly. A cDNA library from the eyes of two male *Lycaena rubidus* was constructed and screened for opsin transcripts using 3’ and 5’ RACE (rapid amplification of cDNA ends), cloning, and automated sequencing. An exhaustive screen yielded four distinct full-length opsin mRNAs with varying lengths of 1738, 1500, 1514, 1521 bp, and which encode opsins of 381, 377, 380 and 382 amino acids. Phylogenetic analysis indicates that these four opsins cluster within clades of UV-, blue- and long wavelength (LW)-sensitive insect opsins, and are most closely related to their nymphalid homologues. Unexpectedly, we found that *L. rubidus* expresses duplicated blue-sensitive opsin genes in the retina. This is the first report of a duplication of the blue-sensitive opsin gene within insects. Secondly, this result suggests that the 500 nm visual pigment has likely evolved from a blue-sensitive ancestral pigment. This therefore represents the most red-shifted blue-sensitive opsin known in insects. Finally, these data indicate that compound eyes (and by extrapolation, color vision) has evolved rapidly between butterflies families with both the lycaenids and papilionids expressing the products of novel, independent opsin gene duplications.

Air flow sensing: from physical ecology in the field to nanotech implementation

J Casas for the CICADA consortium
"Institut de Recherches sur la Biologie de l'Insecte – IRBI UMR CNRS 6035 – Université de Tours, 37200 Tours, France, casas@univ-tours.fr"

Air flow sensing mechanoreceptors on the cricket cerci are amongst the best known sensors in the animal kingdom, working at the limit of thermal noise. They enable crickets to perceive the slightest air movement generated by an approaching predator and to escape. This talk will review the advances of an EU project (IST - Future and Emerging Technologies) in bionics which aims at understanding the natural selection forces in the field and the biomechanical functioning of hairs as well as the integration into a hair canopy response. Our work aims furthermore at reproducing some of the findings at the micro/nanotechnological level as MEMS (micro-electro-mechanical systems) devices and to build a miniature cricket robot in which networks of living cells on silicon chips would be directly connected to the sensors. The talk will also highlight the unusual integrative approach this consortium has, from field ecology, material sciences & nanotechnology up to living computers, and will focus on the biological findings obtained so far. The Consortium is headed by J. Casas and his team, and is made of the teams of G. Krijnen (Micro- and Nanosensors- Twente), A. Offenhaüser (Surfaces and Interfaces - Jülich Forschungzentrum) and G. Jeronimidis (Material Sciences - Reading).

Neurotransmitter transporters in the cabbage looper moth (*Trichoplusia ni*)

BC Donly, H McLean, L Verellen, S Caveney
Southern Crop Protection and Food Research Centre, Agriculture and Agri-Food Canada, 1391 Sandford St., London, ON, Canada N5V 4T3; donlyc@agr.gc.ca

In the nervous system, neurotransmitter signaling molecules are taken back up after release into the synapse by specialized transport proteins located in the membranes of neurons and glial elements bordering the synaptic space. These proteins belong to widely divergent families present throughout eukaryotes and extending even to prokaryotes. We have characterized a group of neurotransmitter transporters from a pest insect, the cabbage looper *Trichoplusia ni*. These include transporters for most of the principal transmitter molecules in the insect nervous system; glutamate, GABA, dopamine, serotonin, octopamine, and a transporter for the acetylcholine precursor and breakdown product, choline. Most of the cabbage looper transporters correspond clearly to orthologous proteins in other insects as well as in other animals. One exception is a transporter we have identified with high affinity for octopamine. Genes for this moth transporter, which may represent an evolutionary counterpart of the vertebrate norepinephrine transporter, are not found in the completed dipteran genomes of either the fruit fly or mosquito. We have therefore compared the distribution of this transporter with those of other monoamine transporters in insects to assess its prevalence and also its potential as an insect or order-selective target for pest control.

Allometry of insect flight performance: the case of hovering orchid bees

R Dudley
Dept. of Integrative Biology, UC-Berkeley, Berkeley, CA 94720 U.S.A.; wings@socrates.berkeley.edu

Limits to insect flight performance are difficult to evaluate because maximum capacity is both context-specific and difficult to identify unequivocally. Most generally, anatomical constraints on stroke amplitude and a systematic decline in wingbeat frequency with increasing body size suggest that the relative capacity for power production should increase in smaller insects. Use of low-density helium-oxygen mixtures and of a load-lifting method that imposes asymptotically increasing loads during ascent has permitted assessment of maximum performance in both hummingbirds and hymenopterans for the specific behavioural context of hovering flight. In orchid bees, load-lifting methods have been applied to twelve species with known phylogenetic relatedness to assess the allometry of force and power production within the subfamily. Vertical force production scales adversely with greater body mass even if flight muscle mass scales isometrically. These results are compared with existing theoretical estimates of the allometry of animal flight performance.

Molecular and pharmacological analysis of an octopamine receptor from American cockroach and fruit fly

LJ Bischof, EE Enan
"Vanderbilt University-School Of Medicine, Department of Biochemistry, 635 Light hall, Nashville, TN 37232, USA; essam.enan@vanderbilt.edu"

Octopamine regulates multiple physiological functions in invertebrates. The biological effects of octopamine and the pharmacology of octopamine receptors have been extensively studied in the American cockroach, *Periplaneta americana*. This study reports the cloning of the first octopamine receptor from *Periplaneta americana*. A cDNA encoding a putative 7 transmembrane receptor was isolated from the head of *Periplaneta americana*. The encoded protein contains 628 amino acids and has sequence similarity to other biogenic amine receptors. This protein was expressed in COS-7 cells for radioligand binding studies using the antagonist ^{3}H-yohimbine. Competitive binding comparing biogenic amines that could potentially function as endogenous ligands demonstrated this receptor had the highest affinity for octopamine (K_i=13.3 μM) followed by tyramine, dopamine, serotonin and histamine. Octopamine increased both cAMP levels (EC_{50}=1.62 μM) and intracellular concentrations of calcium through the receptor expressed in HEK-293 cells. Tyramine increased levels of both of these second messengers but only at significantly higher concentrations than octopamine. The cAMP increase by octopamine was independent of the increase in calcium. Competitive binding with antagonists revealed this receptor is similar to Lym oa_1 from *Lymnaea stagnalis*. The data indicate this cDNA is the first octopamine receptor cloned from *Periplaneta americana* and therefore has been named Pa oa_1.

Bio-inspired legged locomotion on land

RJ Full
Dept. Integrative Biology, University Of California At Berkeley, 94720, USA; rjfull@socrates.berkeley.edu

Running insects bounce from one tripod of legs to another. A single tripod functions as one leg in a human, two legs in a trotting dog or four legs in a trotting crab. All produce the same pattern of ground reaction forces that can be modelled by a mass atop a spring – much like a pogo stick. Remarkably, the relative stiffness of an insect's leg is similar to other runners that differ in skeletal type and posture. Dynamic testing of legs shows that they can be represented by a damped-spring. Insects run over rough terrain possessing obstacles three times their "hip" height without even decreasing their preferred speed. Dynamic models reveal that running insects can function as a passive, dynamic self-stabilizing system. Models respond to perturbations of the body by self-correcting without using sensory information from the environment. Tuned visco-elastic legs respond to perturbations *preflexively* – before reflexes. Perturbations of running insects reveal that recovery begins in less than 10 msec challenging the fastest known reflexes. New materials manufacturing techniques have resulted in bio-inspired tuned legs. The concepts of control discovered in insects have biologically inspired the fastest, most stable legged robots yet built.

The trans-membrane topology of an *Epiphyas postvittana* odourant receptor protein expressed using baculovirus in Sf9 cells

LN Gatehouse.
HortResearch, Palmerston North Research Centre, Tennentive, Private Bag 11030, Palmerston North, New Zealand; lgatehouse@hortresearch.co.nz

Odourant receptor molecules in insects are thought to be G-protein receptors and hence members of the seven transmembrane protein super family of genes, characterised by having seven transmembrane domains but little or no sequence homology. However, the known insect odourant receptors have a number of conserved amino acids, particularly within the last third of the proteins that allow the alignment of the sequences and the assignment to a family. The candidate odourant receptor was mined from an *Epiphyas postvittana* antennal EST library and the sequence was extended by 5′ RACE. The green fluorescent protein gfp5 gene was translationally fused onto the 3′ end to track where in the insect cell the candidate receptor protein was targeted. A bona fide receptor protein would be targeted to the cell membrane where it would insert itself leaving its 3′ end inside the cell. A series of deletions were planned where the gfp was fused progressively further towards the 5′ end of the receptor based on an *in silico* model of the transmembrane domains. The fate of the gfp was determined with fluorescent anti-gfp antibodies which will bind to the undisrupted cells only if the gfp is on the outside of the cell membrane.

Structure and properties of hairy attachment devices

SN Gorb
Evolutionary Biomaterials Group, Mpi For Metals Research, Heisenbergstr. 3, D-70569 Stuttgart, Germany; s.gorb@mf.mpg.de

Many animals bear leg attachment pads with an excellent ability to adhere to a smooth surface as well as to a variety of natural surfaces with rough profiles. There are two alternative designs of such systems: smooth and hairy. The smooth systems consist of soft deformable structures with a relatively smooth surface. Pads of geckos, flies, beetles, and spiders are covered by relatively long, deformable setae which, due to individual bending, increase the number of contacting points with the surface. Most recent data on hairy systems demonstrated their excellent adhesion and high defect tolerance of contact. The size of single points gets smaller and their density higher as the body mass increases. We provided the first experimental evidence of adhesion enhancement by division of contact area. A patterned surface, made out of polyvinylsiloxane (PVS), has significantly higher tenacity on a glass surface than a smooth sample made out of the same material. This effect is even more pronounced on curved substrata. An additional advantage of patterned surfaces is the reliability of contact on various surface profiles and the increased tolerance to defects of individual contacts.

Biomechanics of insect wing folding: a model for robotic applications

F Haas
"Staatliches Museum für Naturkunde Stuttgart, Rosenstein 1, D-70191 Stuttgart, Germany; haas.smns@naturkundemuseum-bw.de"

Insect hind wings are densely folded to fit two requirements. Firstly they need to have a minimum size to be flight worthy, too small wings are not usable as aerofoils. Secondly, they need to fit in a small casing, which is usually formed by stiff fore wings. These are, however, small to ensure mobility of the insect, which has to find crevices or is swiftly hunting. To meet these specifications, wings are folded in a taxon-specific manner, and so Dermaptera (earwigs) and Coleoptera (beetles) were examined to detect general principles as well as ‚customized' solutions. Additionally, wings were compared with other folded structures and computer simulations. Insect wings use a remote and distributed iving system with muscles exclusively located in the thorax proper, and resilin in the wing span. In Dermaptera, wings are unfolded with the cerci while folding is driven by elasticity, whereas in Coleoptera, wings unfold by the muscles, and fold by abdomen action. Folding lines divide the wing span into a system of stiff areas, which do not follow the veins and work as a lever system. Resilin is used to prevent material fatigue and fracture. Insect wings are smart structures with functionality built into their design.

Colour pattern recognition in bees

N Hempel de Ibarra
Neurobiology, Free University, Königin-Luise-Str. 28/30, 14195 Berlin, Germany; nhempel@neurobiologie.fu-berlin.de

Colours are meaningful signals to bees, used to optimise their choices during foraging. In flowers they are often arranged in more or less complex patterns increasing the display variability between species. Little is known about which spectral and spatial cues are available to bees in floral patterns and how bees perceive and learn them. Behavioural studies revealed that achromatic visual cues determine the detectability of coloured patterns. Stimuli with bright surroundings and dim centres are detected from a greater distance than those with dim surroundings and bright centres. A quantitative analysis of natural floral displays evinces that plants exploit this visual ability. Chromatic cues seem to be mainly involved in pattern recognition. Bees evince two evaluation strategies for the colour elements of a learned concentric pattern which are related either to the area occupied by a colour or to a colour's salience correlating with the strength of chromatic contrast. In the latter case bees ignore obvious spatial cues while discriminating patterns. This perceptual salience is based on the properties of the bee's visual system, rather than its experience in the field.

Quantification of silk trails made by lepidopteran larvae.

M-L Johnson, BW Cribb, DJ Merritt Queensland Department of Primary Industries, Zoology and Entomology Department, University of Queensland, St Lucia, Qld, 4072, Australia; mjohnson@zen.uq.edu.au

Lepidopteran silk is made up of fibrous proteins extruded by a spinneret located near the mouthparts. The silk produced by lepidopteran larvae is known to play a role in feeding, survival, shelter and dispersal. It is also suspected that silk plays an important role in the adherence of larvae to substrates. Most studies have described the function of lepidopteran silking behaviour in relation to shelter building and construction of pupal cocoons. Our aim was to investigate the role of Lepidopteran silk in foraging behaviours such as crawling and feeding using the larvae of *Helicoverpa armigera* Hübner (Lepidoptera: Noctuidae), a major lepidopteran pest of crops world wide. Given that silk is practically invisible to the naked eye we developed a method for visualising silk trails in early instars using a fluorescent stain and fluorescence microscopy. This was combined with timelapse digital video-recording to correlate larval behaviour and rate of movement with the type and density of silk laid down over the animal's path. Distinctive silking patterns occur in association with larval foraging. Studies were conducted on whole plant material as well as a variety of artificial surfaces, leading to the development of a suitable model substrate.

Is *Papilio* color vision tetrachromatic?

M Kinoshita, H Koshitaka, K. Arikawa
"Graduate School of Integrated Science, Yokohama City University, 22-2 Seto, Kanawaza-ku, Yokohama 246-0027, Japan; kinokom@yokohama-cu.ac.jp"

Papilio butterflies use color vision when searching for food. Their retina contains six types of spectral receptor; UV, violet, blue, green, red and broad-band. Do all of them contribute to color vision? To answer this question, we measured the discrimination ability of wavelength difference ($\Delta\lambda$ function) of foraging *Papilio.*
We trained female butterflies to take nectar on a certain wavelength of monochromatic light projected on a transparent screen from below. After 10 days of training we presented two monochromatic lights on the screen at the same time to the butterflies, one at the training wavelength and another at 0~10nm away from the training wavelength. We then let the butterflies select one of the lights by extending the proboscis towards it. It appeared that the butterflies are able to discriminate 5nm difference over the wavelength range from 400 to 600nm. In this range, there are high resolution regions at 430, 500 and 560nm. The behaviorally-determined $\Delta\lambda$ function well fitted to the predicted function with the assumption that UV, blue, green, and red receptors contribute to the behavioral task. Consequently we conclude that the *Papilio* butterfly has a tetrachromatic color vision system.

The aminergic control of reproductive tissues in the female locust, *Locusta migratoria***.**

AB Lange, I Orchard
"University Of Toronto At Mississauga, Mississauga, ON, Canada, L5L 1C6; alange@utm.utoronto.ca"

Successful fertilization of eggs in the female locust, *Locusta migratoria*, relies upon the coordination of spermathecal muscle movements with those of the oviducts during oviposition. We have examined the neurochemicals involved in the control of both spermathecal and oviducal muscle contractions. These neurochemicals include a variety of neuropeptides, but also involve amines, such as octopamine and tyramine. Dorsal unpaired median (DUM) neurons expressing octopamine-like and tyramine-like immunoreactivity are found within the penultimate abdominal ganglion with projections to the oviduct muscle. Octopamine-like immunoreactive DUMs in the last abdominal ganglion have been shown to project to the spermathecal muscle. Octopamine and tyramine are released by the innervation to the locust oviducts and inhibit contractions in a dose-dependent manner. The actions of octopamine are mediated by cyclic AMP whereas the mode of action of tyramine is more complex and may involve a variety of second messengers. In contrast, octopamine, acting via cyclic AMP, has stimulatory actions upon contractions of the spermatheca. The involvement of these amines in the control of reproductive tissues will be discussed.

Variation in eye structure in butterflies: how regional variation in acuity scales with body size

JW Merry, RL Rutowski
Life Sciences, Arizona State Univ., P.O. Box 874601, Tempe, AZ 85287-4601, U.S.A.; jmerry@asu.edu

Examining how a structure scales inter- and intraspecifically with body size can provide insight into how selection operates on that structure. Smaller compound eyes should have lower resolving power, as measured by interommatidial angle ($\Delta\varphi$) and facet diameter (D), than large eyes because diffraction becomes more severe as lens size decreases. In order to maximize acuity in important regions of the visual field, selection may drive small insects to sacrifice resolution in some parts of their eye so that acuity may be enhanced in other regions. To better understand how patterns of regional variation in visual acuity change with body size, we measured regional differences in $\Delta\varphi$ and D in twenty species of butterflies representing three families. We analyzed data at the level of species, family, and the dataset as a whole. We predicted that 1) visual acuity would increase with body size; however 2) smaller insects would have proportionally higher acuity. Furthermore, we predicted 3) that regional differences in acuity would be greater in smaller species. Data analysis revealed that the first two predictions held, while the third prediction did not. We examine outlier species and discuss possible reasons for their deviations from the general regression line.

Analysis of dopamine receptors from the honey bee, *Apis mellifera*

JA Mustard
400D Aronoff Labs, 318 W 12th Ave, Columbus, Ohio 43210 USA; mustard.13@osu.edu

Two dopamine receptor genes, *Amdop1* and *Amdop2* have been cloned from the honey bee (Blenau et al., 1998, J Neurochem 70:15-23; Humphries et al., 2003, J Neurobiol 55:315-330). Both receptors are D1-like in that they upregulate intracellular cAMP levels in the presence of dopamine, however, they exhibit distinctive functional and pharmacological properties (Mustard et al., 2003, Mol Brain Res 113: 67-77). Each receptor also shows an overlapping, but different, expression pattern in larval and adult honey bee brains (Kurshan, et al., 2003, J Comp Neurol 466: 91-103). Taken together, these results suggest that *Am*DOP1 and *Am*DOP2 receptors may play distinct roles in dopamine signaling. Both receptors are highly expressed in the mushroom bodies of worker honey bee brains. Mushroom bodies are believed to be important for learning and memory. To examine the roles of these dopamine receptors in olfactory learning, RNA interference (RNAi) was used to decrease the level of mRNA of each receptor in the mushroom bodies. Using the proboscis extension reflex, bees were then examined for changes in their ability to acquire and/or recall an association between an odor and a sucrose reward. Initial studies suggest that *Am*DOP1 and *Am*DOP2 may play distinct roles in olfactory learning.

Structural and conformational aspects of pyrokinin-like neuropeptide interaction with expressed receptors

RJ Nachman, YJ Kim, H. Williams, GM Coast, R Predel, M Adams
Southern Plains Agricultural Research Center, U.S. Department of Agriculture, College Station, TX 77845, USA; nachman@tamu.edu

The interaction of several classes of pyrokinin-like neuropeptides with their respective expressed receptors is investigated from a structural and conformational perspective. The discussion concerns a broad class of insect neuropeptides that represent products of the Capa-gene. Structural and conformational aspects critical to the interaction of the pyrokinin/PBAN class of neuropeptides and another Capa-gene product, the ecdysis-triggering hormone (ETH), with respective, expressed lepidopteran receptors are described. These ligand-receptor interactions are compared with the structural and conformational requirements for diuretic activity of the CAP2b/PVK sub-class of pyrokinin-like neuropeptides, also of the broad Capa category, in a dipteran. Insect neuropeptides of the classes selected for this discussion are implicated in the regulation of critical processes in pest insects. However, they suffer from a relative lack of biostability and bioavailability that limits their effectiveness as tools for neuroendocrinologists and as pest management agents. Biostable/bioavailable mimetic analog development of insect neuropeptides will be facilitated by a through understanding of structural/conformational aspects of the interaction with their receptors.

Peptidergic signaling pathways in *Drosophila melanogaster***.**

R Nichols
University of Michigan Medical School, Biological Chemistry Department, Ann Arbor, MI, USA, 48109-0606; nicholsr@umich.edu

Peptides play crucial roles as transmitters and modulators of numerous biological processes, thus, aberrant peptidergic signaling may result in slowed development or death. Components of regulatory and transduction pathways are targets for the design of a variety of molecules including pesticides, thus, it is important to elucidate mechanisms that underlie peptidergic signaling. An interdisciplinary approach in a scientifically versatile organism is a powerful way to identify molecular components of regulatory and transduction mechanisms. A precursor often contains several peptides, thus, it is important to know how the polyprotein is processed and when and where the gene products are released to elucidate regulatory and transduction mechanisms involved in peptidergic signaling. In the case of structurally-related peptides encoded in either a single precursor or multiple precursors, it is important to decipher structure-activity relationships to avoid ambiguous data or erroneous conclusions. An *in vivo* bioassay is useful to establish the structure-activity relationship of structurally similar peptides, elucidate molecular mechanisms involved in peptidergic signaling, and to suggest peptide function(s). Comparison of peptide structure-activity relationships in different tissue bioassays yields insight into specificity of signaling pathways. We investigate signaling using *Drosophila melanogaster* to delineate peptide transduction pathways and functions.

Eph-ephrin signals may mediate sorting of olfactory sensory axons in *Manduca sexta*.

A Nighorn, M Kaneko
Room 611 Gould-Simpson Bldg, Univ. of Arizona, Tucson, AZ 85721 USA

We are investigating the roles of the Eph family receptor tyrosine kinases and their ligand ephrins in the developing primary olfactory nerve pathway in the moth *Manduca Sexta* using a combination of molecular biological and cell culture experiments. *Manduca* expresses one Eph receptor (MsEph) and one ephrin ligand (MsEphrin). *In situ* labeling with Fc-fusion probes reveals that both Eph receptors and ephrins are expressed on axons of olfactory receptor cells (ORCs) during their ingrowth to the primary center, the antennal lobe (AL). Eph receptors and ephrins are differentially distributed among identifiable glomeruli such that glomeruli with high receptor staining show little or no ligand staining and vice versa, suggesting a complementary Eph/ephrin expression by subsets of ORC axons innervating a particular set of glomeruli. *In vitro*, ephrin-Fc and Eph-Fc, when present homogeneously in the substratum, inhibit neurite outgrowth from olfactory epithelial explants. In patterned substratum, neurites turn or stop upon encountering the test substratum. These observations indicate that MsEphrin can act as an inhibitor/repulsive cue for ORC axons. We hypothesize that Eph receptors and ephrins mediate axon sorting and fasciculation through repulsive axon-axon interactions. We are currently testing that hypothesis using RNAi to knockdown the expression of MsEph and MsEphrin.

Characterization of small motion detection neurons of Eristalis tenax

K Nordström, D O'Carroll Discipline of Physiology, The University of Adelaide, SA 5005, Australia; Karin.Nordstrom@adelaide.edu.au

The hoverfly *Eristalis tenax* exhibits typical syrphid behaviour, with stationary hovering followed by rapid pursuit of conspecifics. Male and (possibly) female flies depend on detection of small rapidly moving targets to find mates and defend their territory. Neurons specialized for detecting small targets against cluttered backgrounds can be found in the lobula complex (3rd optic ganglion) of the fly brain. We are characterizing the morphology and physiology of a range of lobula small target motion detecting (STMD) neurons using dye-fills and electrophysiological techniques. We define STMDs as neurons that give a powerful response to a small object (1-2 degrees square) moving across a bright or cluttered background, but weaker responses to larger size targets. We find a number of classes of STMDs with unique properties in both sexes. These include neurons with small excitatory receptive fields surrounded by distinctly shaped inhibitory areas, and wide-field STMDs that may be used for mate detection. STMDs generally give spiking responses, and have variable degrees of spontaneous spike activity, including neurons that are 'silent' until stimulated by a target. A prominent feature of some STMDs is the robustness of their responses in the presence of background motion.

What gives adaptive gain control in insect motion detection?

DC O'Carroll, TJ Rainsford,
Discipline of Physiology & Centre for Biomedical Engineering, University of Adelaide, S.A. 5005, Australia; david.ocarroll@adelaide.edu.au

The phenomenon of motion adaptation is widespread among animals, having been demonstrated in species as diverse as humans, wallabies and flies. Motion adaptation appears to have evolved to maximize efficiency of visual coding in neurons with limited signaling range. Recent work highlights controversy over the site and mechanism of adaptation. Hypotheses range from simple gain control in 'early' vision (contrast normalization), to adaptive feedback that alters the delay mechanisms within local motion detectors. We have shown that adaptation does not alter the velocity tuning of motion detectors, but instead induces large reductions in contrast gain. Using moving natural scenes and a probe-adapt-probe protocol, we show here that gain reduction is driven by a mechanism with broad velocity tuning. While the tuning of adaptation resembles that of motion detectors themselves (favoring a feedback hypothesis), its broadness suggests extremely high gain in the feedback pathway and permits powerful adaptation to stimuli that drive motion detectors weakly. This mechanism may optimize coding of image velocity independent of the contrast variations between different natural scenes. Our work suggests easily implemented elaborations to existing motion detector models that could impart similar robustness to artificial motion detectors based on the same principle.

Diuresis in the blood-feeding bug, *Rhodnius prolixus*: Involvement of serotonergic dorsal unpaired median neurons and peptidergic bilaterally paired neurons.

I Orchard, VA Te Brugge, D Schooley, AB Lange
"University of Toronto at Mississauga, Mississauga, ON, Canada, L5L 1C6; ian.orchard@utoronto.ca"

The blood-feeding bug, *Rhodnius prolixus*, ingests large blood meals followed by a period of rapid diuresis that is under neurohormonal control. We are interested in determining the identity of the neurohormones controlling diuresis, the timing of their release, their effect on the Malpighian tubules (and other tissues involved in diuresis) and their potential interactions. Within the mesothoracic ganglionic mass (MTGM) of *Rhodnius*, there exists a subpopulation of dorsal unpaired median (DUM) neurons that display serotonin-like immunoreactivity. These, and other DUMs, are also immunoreactive to a variety of insect neuropeptide families (e.g. allatostatin-like and Dippu DH-31-like peptides). Serotonin is a neurohormone in *Rhodnius*, released from neurohaemal sites formed from these serotonergic DUMs, that controls diuresis. We have also mapped the distribution within *Rhodnius* of neuropeptides shown to possess diuretic activity in other insects. Bilaterally-paired neurons of the MTGM display Locusta DP-like, kinin-like and Dippu DH-31-like immunoreactivity. The effects of these peptide families and serotonin on diuresis in *Rhodnius* will be discussed.

Colour vision in the European glow-worm, *Lampyris noctiluca*

D Booth, D Osorio, AJA Stewart.
School of Life Sciences, University of Sussex, BN1 9QG. U.K.; d.osorio@sussex.ac.uk

Traditionally North Americans enjoy twilight watching fireflies (Lampyridae) display. Species first seen after dusk glow yellowish-orange (peak 580nm), while nocturnal species glow green (550nm). Photoreceptor sensitivities match the bioluminescent spectrum. According to a classic account in visual ecology, this communication system is optimized for signal detection: long-wavelength signals of crepuscular species contrast against the leaf background, whilst at night the green signals maximize absolute sensitivity (H.H. Seliger et al. *Photochem. Photobiol.* **36**, 673, 1982). In Britain twilight is boring, with only the nocturnal glow-worm *Lampyris noctiluca.* Wingless females sit near the ground, and attract flying males with a leaf-green light. Male glow-worms have long been known to be insensitive to 480nm light. This insensitivity might be explained by coloured filter pigments. However, in our behavioural tests addition of blue light reduces the attractiveness of green light to male glow-worms. This means that they have colour vision, and implies that their phototaxis uses a chromatic (i.e. opponent mechanism). By comparison, the matched filtering account invokes a spectrally selective achromatic mechanism. Our observation presents a puzzle: why subtract a noisy short-wave receptor's response from a long-wave detector well matched to its task?

Responses of the silkworm tyramine receptor to ligand compounds

Y Ozoe, H Ohta, MAA Khan
Department of Life Science and Biotechnology, Shimane University, Matsue 690-8504, Japan; ozoe-y@life.shimane-u.ac.jp

The physiological study of tyramine lags behind those of octopamine and dopamine. The new discovery of ligands that selectively interact with the insect tyramine receptor would facilitate research into the tyraminergic signal transduction. To this end, we cloned B96Bom from the silkworm (*Bombyx mori*) and expressed it in HEK-293 cells. Tyramine attenuated forskolin-stimulated cAMP production by interacting with the B96Bom receptor more potently than octopamine and dopamine. Yohimbine abolished the tyramine attenuation of cAMP production. These findings indicate that the B96Bom receptor is a tyramine receptor. We synthesized phenyloxazoles and phenylethylamines to test their abilities as ligands for biogenic amine receptors. Most of the compounds showed positive and negative effects on cAMP production in the membrane preparation of the silkworm head. 5-(4-Hydroxyphenyl)oxazole (5PO4) outstandingly attenuated basal, octopamine-stimulated, and forskolin-stimulated cAMP production. Yohimbine, but not *R*(+)-SCH23390 and chlorpromazine, abolished the 5PO4 attenuation. However, 5PO4 failed to attenuate forskolin-stimulated cAMP production in the cloned tyramine receptor, although the compound bound to the receptor. Phenylethylamines showed higher affinity for the cloned tyramine receptor than 5PO4. Although 2-chloro-2-(4-chlorophenyl)ethylamine failed to attenuate forskolin-stimulated cAMP production, the compound abolished the tyramine attenuation of forskolin-stimulated cAMP production.

Leucokinin signal transduction in blood feeding vectors of disease, the mosquito *Aedes aegypti* (L.) and the southern cattle tick, *Boophilus microplus* (Canestrini).

PV Pietrantonio, C Jagge, SP Holmes.
"Dept. of Entomology, Texas A&M University, MS 2475, College Station, TX 77843-2475 USA; p-pietrantonio@tamu.edu"

Two different blood-feeding arthropods serve the study of leucokinin signal transduction and its relationship to diuresis and water balance. In the mosquito *Aedes aegypti*, the three *Aedes* leucokinin peptides stimulate total urine production in a dose-dependent manner *in vivo* (Cady and Hagedorn, 1999). In contrast, the specific function of myokinins in ticks is unknown and none have yet been isolated from this group of arthropods. We have cloned and functionally characterized a myokinin receptor from the Southern cattle tick (Holmes et al., 2003) and also identified its likely ortholog in the female of *Aedes aegypti*. Tissue localization of the receptors in these vectors was achieved through RT-PCR and/or *in situ* hybridization techniques. Receptor functionality and ligand specificity was analyzed by expressing the receptors in mammalian CHO-K1 cells followed by challenge with peptide agonists and measurements of intracellular calcium by fluorescence cytometry. In this system, the receptors are functional at physiological leucokinin concentrations. Differences in leucokinin signal transduction between *Aedes aegypti* and *Drosophila melanogaster* will be discussed.

Understanding serotonin signal transduction in arthropods vectors of disease: *Aedes aegypti* **and** *Boophilus microplus*

PV Pietrantonio, C Jagge, DW Lee, A Chen.
"Dept. of Entomology, Texas A&M University, MS 2475, College Station, TX 77843-2475 USA; p-pietrantonio@tamu.edu"

In the mosquito *Aedes aegypti*, serotonin (5-HT) changes the rhythm of contractions in the female hindgut and increases fluid secretion in the larval Malpighian tubule. We investigated the potential role of 5-HT as a diuretic hormone in adults. For this we cloned a serotonin receptor cDNA (from female *A. aegypti* Malpighian tubule) that is similar to the 5-HT$_7$ receptor from *Drosophila melanogaster*. The transcript was localized in the tracheolar cells associated with the Malpighian tubules but no signal was detectable in the tubule epithelium. Immunohistochemistry with specific antibodies confirmed the receptor expression in tracheolar cells and hindgut, and western blots of these tissues showed the expected 50kDa band. The results suggest a role for serotonin in respiration. Functional expression of the *Aedes* 5-HT$_7$-like receptor in CHO-K1 cells showed that the receptor positively coupled to a Gs protein, increasing intracellular cAMP in response to 5-HT. Only 5-HT but not octopamine, dopamine or tyramine, induced cAMP. Agonists of the mammalian 5-HT$_7$ receptor had the following order of potency with the *Aedes* receptor: 5-HT >> 5-CT = 8-OH-DPAT >> pimozide. This is the first report on the functional expression of a mosquito neurohormone receptor. The characterization of a tick 5-HT receptor will be presented.

Honeybee vision and navigation: role of associative learning and cross-modal recall

J Reinhard, MV Srinivasan, SW Zhang
The Australian National University, Rsbs Visual Sciences, Gpo Box 475, Canberra, Act, 2601, Australia; Reinhard@Rsbs.Anu.Edu.Au

Insects learn and process environmental cues to orientate in their surroundings. The honeybee, *Apis mellifera*, flies rapidly and accurately to food sources that are often kilometres away. This is achieved by learning visual cues based on the distance and direction of the goal, the landmarks encountered en route, and the shape and colour of the desired flowers. Honeybees also learn chemical cues associated with food sources, such as the scent and the taste of the nectar. We investigated how the honeybee's capacity for associative learning and cross-modal recall assists her in navigating back to a known food source. We find that honeybees, trained to visit a scented sugar feeder placed at a specific outdoor location, can be induced to visit the same location simply by blowing the same scent into the hive, even when the destination no longer carries the food or the scent. Bees can be triggered in this way to fly to a specific location, or to find a specific colour. Our findings suggest that familiar nectar scents brought back into the hive by returning foragers, can induce recall of specific visual and route memories in experienced honeybees, and thus expedite navigation to the food source.

On moth's odorant receptors

A Ruebenbauer, C Löfstedt, JF Picimbon
"Ecology building, Sölvegatan 37, 223 62, Lund, Sweeden; Agnieszka.Ruebenbauer@ekol.lu.se"

Odorant receptors (ORs) are quite essential in chemical communication between and among insects and their environment. Therefore ORs in Noctids were focused in foregoing study. We compared different ORs in antenna of 0-7 days old males and females of *Heliothis zea*. Additionaly the tissue distribution of ORs has been done in different parts of the insect's body: wings, legs, abdomens, thoraces and heads (animals between 0-4 days old). *Agrotis segetum* ORs sequences in antenna have been obtained as well. Following study has been performed using molecular techniques. Various pairs of primers were designed and PCRs have been performed followed by cloning and sequencing the corresponding PCR products. Obtained sequences were analysed by BioEdit computer programme.

PTTH signal transduction in the prothoracic gland: a tangled web with one purpose?

R Rybczynski
"Dept. of Biology, UNC at Chapel Hill, Chapel Hill, NC, 27599, USA; rybczy@bio.unc.edu"

Molting and metamorphosis in insects is controlled by several hormones, with 20-hydroxyecdyone (molting hormone) playing an overarching role. Prothoracicotropic hormone (PTTH), the best-understood regulator of ecdysteroidogenesis, stimulates ecdysteroid synthesis by the prothoracic glands. Work in the 1980s and 1990s revealed that PTTH activated a signal transduction cascade that included Ca^{2+}- influx, cAMP generation, phosphorylation of the ribosomal protein S6 and protein translation. In this talk, I will review more recent work, from our group and others, indicating that the PTTH signal transduction cascade is surprisingly complex. We now know that additional kinases are activated, including an extracellular signal-regulated kinase (ERK), a protein kinase C, and one or more unidentified tyrosine kinases. Ongoing studies also suggest PTTH-stimulated Ca^{2+}- influx is complexly regulated, with increases in cytoplasmic free Ca^{2+} coming from at least three sources, and that phospholipase C activation is among the earliest intracellular events triggered by PTTH. The composite data suggest that (1) PTTH regulates more processes in the prothoracic gland than ecdysteroid synthesis; (2) the study of phosphorylated proteins offers an avenue to identify these additional functions of PTTH; and (3) the control of ecdysteroid synthesis is subject to a Pandora's box of developmentally varying checks and balances.

Candidate Genes for Behavioral QTL in the Honeybee, *Apis mellifera.*

D. I. Schlipalius, E. Guzmán-Novoa, M. Arechavaleta-Velasco, C. Emore, R. E. Page, C. Hill and G. J. Hunt
Department of Entomology, Purdue University, West Lafayette, IN 47907

The Honeybee Genome Project is providing an unprecedented opportunity for identifying and characterizing genes involved in the behaviour and brain function of social organisms. The honeybee genome has an unusually high recombination rate compared to those of other higher eukaryotic organisms. This high recombination rate aids in pinpointing genes because linkage maps rely on crossovers to determine position of markers. To take full advantage of this phenomenon, we have constructed a high-density genetic linkage map of the honeybee that contains over 1000 AFLP, RAPD microsatellite markers and sequence tagged sites (STS). There are more than 315 sequence tags on the genetic linkage map, sourced from sequenced AFLP, RAPD and microsatellite DNA fragments. This genetic map was constructed from a cross between a defensive African-derived strain of honeybee and a "gentle" strain of European honeybee and has allowed us to investigate QTL for defensive behaviours. These QTL regions have produced an intriguing list of candidate genes that may influence stinging and guarding behaviours. We hypothesise that natural selection has acted on genes that influence neuromodulator levels, hormone signaling and the visual system to produce more defensive genotypes of bees.

The role of protein phosphorylation in regulating the function of ecdysone receptor complex

Q Song
Department of Entomology, University of Missouri, Columbia, Missouri, USA

Insect molting and metamorphosis are regulated by ecdysteroids. The action of ecdysteroids is mediated via ecdysone receptor (EcR) and its heterodimer, ultraspiracle protein (USP). Both EcR and USP are members of the nuclear receptor superfamily and ligand dependent transcriptional factors. Our recent data have shown that both EcR and USP are phosphoproteins and the expression and phosphorylation of EcR and USP are regulated by 20-hydroxyecdysone (20E). Phosphorylation has been shown to play a role in regulating the ligand-binding activity of the EcR/USP complex, presumably leading to the feedback regulation of ecdysteroid biosynthesis in the prothoracic gland of *Manduca sexta*. Protein kinase consensus recognition sequence analysis of *Drosophila* EcR and USP along with specific protein kinase inhibitor assays reveals that protein kinase (PKC), not casein kinase II (CKII), is involved in the EcR and USP phosphorylation. Our preliminary data indicate that inhibition of EcR and USP phosphorylation by specific PKC inhibitors blocks 20E-induced protein expression. The composite data suggest that protein phosphorylation plays an important role in regulating 20E-signaling pathway.

Insect signal transduction systems: current knowledge and future directions

DW Stanley, J Vanden Broeck[2]
Laboratory for Developmental Physiology, Genomics and Proteomics, Naamsestraat 59, B3000 Leuven, Belgium; Jozef.VandenBroeck@bio.kuleuven.ac.be

In biological systems, physiological responses to extracellular signals are elicited by activation of specific receptor proteins. This activation induces cellular effects via a process, generally designated as 'signal transduction'. Interestingly, the main categories of signal transducing receptor proteins are conserved in Arthropods. Moreover, this is also the case for most families of proteins that are components of intracellular signaling pathways. The recent technological revolution in genomics will certainly have an important impact on future signal transduction research. Convenient expression systems and functional assay procedures will be needed for studying the functional properties of the encoded predicted proteins. In this symposium, a number of conserved signaling protein families will be discussed, as well as recent advances and future directions in the analysis of their structural and functional properties. In more detail, we will review the current knowledge concerning the superfamily of G protein-coupled receptors. The study of evolutionary aspects of cellular signaling processes will probably reveal insect-specific features. Future challenges are to study the regulation, function and interplay of many different genes and to analyze the *in vivo* dynamics of functional interactions in biological systems.

Pieris rapae red and deep-red receptors use a green rhodopsin and two red filter types

DG Stavenga, M Kurasawa, M Wakakuwa, K Arikawa
"Neurobiophysics, Groningen University, NL 9747 AG, Groningen; stavenga@phys.rug.nl"

The visual pigments and spectral sensitivities of the long-wavelength photoreceptors of the small white butterfly *Pieris rapae* were studied by combined electrophysiology, molecular biology and optical modeling. *Pieris rapae* appears to have only one long-wavelength rhodopsin, PrL, which is expressed in the two distal photoreceptor cells (R3 and R4) as well as in the proximal photoreceptors (R5-8) in all three types of ommatidia of the *Pieris* fronto-ventral eye. The spectral sensitivities of R3 and R4 well approximate the absorption spectrum of a visual pigment with absorption maximum at 563 nm. The spectral sensitivities of R5-8 photoreceptors in ommatidial type I and III peak at 620 nm and those in type II ommatidia peak at 640 nm. The large shifts of the spectral sensitivities of the R5-8 photoreceptors with respect to the absorption spectrum of their visual pigment, R563, can be explained with the spectral filtering by pale-red (PR) and deep-red () screening pigments that are concentrated in clusters of granules near the rhabdom boundary. The peak absorbance of the two spectral filters appears to be approximately 1 (PR) and 2 ().

Behavioural and optical resolution of the honeybee eye.

M Vorobyev, N Hempel de Ibarra[2], O Ganeshina

Vision Touch and Hearing Research Centre, SBMS, University of Queensland, 4072, Brisbane, Australiua; m.vorobyev@uq.edu.au [2]Institute of Neurobiology, Free University, Berlin

We compared behavioural resolution of the bee eye with the predictions of the optical model. The model assumed that bees failed to detect stimuli whose borders could not be resolved. The resolution of border detectors was estimated from the optics of the honeybee frontal eye. Bees were trained to detect oval stimuli whose diameter in a longitudinal direction was 4 times longer than in a short one. The ovals were either horizontally or vertically oriented. The optical model of border detection predicted the limiting visual angle for such ovals to be 9.5^0 (long diameter) for horizontally oriented ovals and 7.7^0 for vertically orientated ones. In the case of horizontal orientation bees could detect an oval subtending 11^0 (85% correct choices) but they fail to detect one subtending 7.6^0 (51% correct choices). In the case of vertical stimuli bees easily detected an oval subtending 11^0 (91% correct), the 7.6^0 oval was difficult to detect (69% correct) and they could not detect an oval subtending 6.4^0 (53% correct). Thus the results of behavioural experiments agree with the results of the model predictions, indicating that the resolution of the honeybee vision is close to the limit set by the optics of their eyes.

Nocturnal vision and landmark orientation in a tropical halictid bee

EJ Warrant, A Kelber, A Gislén, B Greiner, W Ribi, WT Wcislo
Zoology, Lund University, Helgonav. 3, S-22362 Lund, Sweeden; Eric.Warrant@cob.lu.se

Some bees and wasps have evolved nocturnal behaviour, presumably to exploit night-flowering plants or avoid predators. They display impressive visual behaviour despite having apposition compound eyes, a design adapted for bright light. In theory, this eye design should render these insects blind by mid-dusk. How then are they able to see at night? We studied female tropical nocturnal sweat bees (*Megalopta genalis*) and discovered that they are able to learn landmarks around their nest entrance prior to nocturnal foraging trips, and to use them to locate the nest upon return. This is the first evidence of nocturnal landmark orientation in insects. The morphology and optics of the eye, and the physiological properties of the photoreceptors, have evolved to give *Megalopta's* eyes almost 30 times greater sensitivity to light than the eyes of diurnal honeybees, but this alone is not sufficient to explain their nocturnal visual behaviour. This implies that sensitivity is improved by a strategy of photon summation in time and in space, the latter of which requires the presence of specialised cells that laterally connect ommatidia into groups. Cells absent in diurnal bees have now been identified in the lamina of *Megalopta's* optic lobe that may subserve spatial summation.

The mechanism of the flight motor given respiratory gas exchange in hawkmoths.

LT Wasserthal
Institut of Zoology 1, Staudtstrasse 5, D 91058 Erlangen; ltwthal@biologie.uni-erlangen.de

Intratracheal pressure, O_2-content and CO_2-emission during tethered flight were analyzed at the anterior spiracles and mesortergal air sacs in hawkmoths using electronic pressure sensors, O_2 sensitive optodes and an URAS gas analyzer with split specimen chamber.Electrophysiological measurement of the flight muscles and of a hithertoo neglected special ventilatory muscle contribute to the understanding of the flow through mechanism. Deformations of the lateral thorax and their effect upon the spiracles were recorded under stroboscopic light. During shivering, ventilation pulses are generated by the flight muscles reminiscent of the known autoventilation mechanism with tidal air flow and the intratracheal O_2 content decreases astically. During steady flight, however, a unidirectional airstream is produced with a mean subatmospheric pressure at the first (mesothoracic) spiracles and a mean positive pressure in the mesotergal air sacs resulting in an increasing intratracheal O_2 content. Due to this pressure decrement during flight, CO_2 leaves only at the posterior spiracles. The suction force for the inspiration flow at the anterior spiracles is generated by the flight apparatus and a special ventilatory muscle under prevention of inspiration through the posterior thoracic spiracles. The result is an efficient separation of the CO_2 emission route from the inspiratory air stream.

Robot models of cricket behaviour

B Webb
IPAB, School of Infomatics, King's Buildings, Mayfield Rd, Edinburgh EH9 3JZ, UK; bwebb@inf.ed.ac.uk

Insects demonstrate flexible and adaptable sensory-motor control despite their relatively small nervous systems, suggesting efficient solutions to problems in robotics. Moreover, robots can be used to test our understanding of the mechanisms of animal behaviour, by implementing hypotheses and testing their capabilities in realistic situations. We have built a series of robots based on cricket phonotaxis, that is, the ability of female crickets to locate a mate by moving towards the auditory stimulus of the calling male. Three main aspects of recent work will be described. The first is the use of an outdoor robot, with locomotion inspired by insect walking, to test a spiking neural network mechanism for phonotaxis in natualistic conditions. The second is the integration of additional sensory systems, specifically the optomotor response, onto the robot model. It is shown that a number of different algorithms for combining these behaviours seem to produce similar behaviour in a simulation of cricket experiments. However the algorithms may be distinguished when we consider issues of the different dynamics of the real sensory systems on the robot, and of the plausibility of neural implementation for the different schemes. Third, current collaborative work is aimed at revising and refining the model through parallel behavioural, neurophysiological and modelling investigations on the cricket and the robot. This has led to a number of novel discoveries about the functioning of the biological system.

The curious engineering of the insect flight skeleton

RJ Wootton
"School of Biological and Chemical Sciences, University of Exeter, Hatherly Laboratories, Prince of Wales Road, Exeter EX4 4PS, UK; r.j.wootton@ex.ac.uk"

Insects are unique among flying machines in their use of bending and buckling of thin plates and shells, reinforced where necessary by ridges and tubes, to translate the cyclic contractions of the muscles into the complex, varying kinematics of the wings. While fine adjustments to the form of the wing stroke cycle need to be actively achieved, as much information as possible is stored in the morphology of the skeleton itself: in the disposition of rigid and flexible components in the pterothorax and wings. The degree and nature of rigidity and pliancy are influenced by structure at all levels of scale. Relevant structural variables include the arrangement of apodemes, sutures and sulci in the thorax, of the veins, ridges, relief and flexion-lines in the wings; and the local thickness, microstructural relief, ultrastructure and chemistry of the cuticle. Detailed morphology, manipulation, mechanical testing, and physical, analytical and mathematical modelling are revealing the subtleties of these fascinating, highly automated systems.

The honeybee is able to categorise natural visual images

SW Zhang, MV Srinivasan,
CENTRE FOR VISUAL SCIENCES, RESEARCH SCHOOL OF BIOLOGICAL SCIENCES, AUSTRALIAN NATIONAL UNIVERSITY, PO BOX 475, ACT 2601, AUSTRALIA; SWZHANG@RSBS.ANU.EDU.AU

Recent work has revealed that monkeys as well as pigeons are able to categorise complex visual objects. We show here that the ability to group similar natural, visual images together extends to an invertebrate – the honeybee. Bees can be trained to distinguish between different types of naturally occurring scenes in a rather general way, and to group them into four distinct categories: landscapes, plant stems and two different kinds of flowers. They exhibit the same response to novel visual objects that differ greatly in their individual, low-level features, but belonging to one of the four categories. We exclude the possibility that they might be using single, low-level features alone as a cue to categorise these natural visual images and suggest that the categorisation is based on a combination of low-level features and configurational cues.

Insect visuomotor control & guidance & stabilisation of aerial robots.

An evolutionary constraint linking innate immunity and development of the lepidopteran *Galleria mellonella*

A. Vilcinskas
Institute of Biochemistry and Biology, University of Potsdam, Lennestr. 7a, 14471 Potsdam, Germany, E-Mail: vilcinsk@rz.uni-potsdam.de

The impressive progress in *Drosophila* molecular genetics led to the discovery that homologues signalling pathways control both innate immunity and developmental processes in this insect. Toll-like signalling pathways mediate expression of genes encoding for antimicrobial peptides and those involved e.g in formation of the dorso-ventral polarity in *Drosophila*. Investigating molecular physiology of innate immunity and metamorphosis of the lepidopteran *Galleria mellonella* we identified a number of novel proteinase inhibitors that contribute to antimicrobial defence and developmental processes as well. Amazingly, we found that the vast majority of immune-related proteins are also induced upon release of non-regulated metalloproteinases in the haemolymph, independently whether they are of pathogen or endogenous origin. The presence of metalloproteinases in the haemolymph generates particular haemplymph protein fragments smaller than 3 kDa which represent potent activators of the Toll-pathway. The inability of the *G. mellonella* immune system to discriminate haemolymph proteins fragments produced by either pathogen-associated metalloproteinases or endogenous matrix metalloproteinases expressed during metamorphosis points to an evolutionary constraint that may explains involvement of Toll-like signalling pathways in distinct biological functions. As a hypothesis, this evolutionary constraint limits the physiological efficacy of insect innate immunity and influenced the coevolution of entomopathogens and their host insects.

Studies on food consumption and utilization of cabbage leaves by the larva of diamondback moth, *Plutella xylostella* **(L.) (Lepidoptera : Yponomeutidae).**

K C Sharma, Sonika Chandel A K Verma and Usha Chauhan
"Department of Entomology Dr Y S Parmar University of Horticulture and Forestry, Nauni, Solan, India Fax: 0091-1792-252242 rakeshd4@yahoo.co.in"

In the North-Western Himalayan region cabbage is an important vegetable crop. Diamondback moth, *Plutella xylostella* is one of the several insect pests which causes damage to this crop. Studies on food consumption and utilization of cabbage leaves by the larva of the diamondback moth were carried out at 30^0C. The larva consumed 23.76 mg of fresh foliage of cabbage or 8.12 mg dry matter during its entire larval period, of which it passed out 5.34 mg (wet weight) or 1.78 mg (dry weight) as faecal matter. Food consumption also increased progressively, maximum being during IV instar (14.64 mg fresh weight or 4.94 mg dry matter). The maximum growth rate of 0.33 was observed during the II and IV instar. Maximum consumption index (CI) was recorded for the IV instar on fresh (3.09) as well as dry weight-fresh weight basis (1.04). Approximate digestibility (AD) was observed to be maximum during the IV instar (83.13% on fresh weight basis and 72.26% on dry weight-fresh weight basis). Efficiency of conversion of ingested/food (ECI) was maximum during the II instar on fresh weight basis (27.36%). On fresh weight basis, the efficiency of conversion of digested food (ECD) was maximum (47.27%) during the II instar.

An antimicrobial substance from the egg wax of the African bont tick *Amblyomma hebraeum.*

MC Arrieta, BK Leskiw, WR Kaufman
CW-312 Biological Sciences Building, University of Alberta, Edmonton, CANADA T6G 2E9; marrieta@ualberta.ca

Arthropods have a remarkable capacity to resist microbial infections. Although dead tick females tend to suffer microbial infestation after oviposition, the eggs next to them remain clean. When incubated with bacteria, tick (*A. hebraeum*) eggs inhibit the growth of *Escherichia coli* and *Serratia marcescens* (Gram-negative), but not the growth of *Staphylococcus epidermidis* and *Bacillus subtilis* (Gram-positive). Tick eggs are covered with a waterproofing material that also protects them against desiccation. This wax was extracted according to the Folch method. When incubated with bacteria in liquid cultures, the organic phase of the egg-wax extract appeared inactive, but the aqueous phase inhibited the growth of *S. epidermidis*. The aqueous phase was heat stable (100°C for 10 min), resistant to proteinase K treatment (15 min @ 55^0C) and has an amino acid concentration of ~1.1 mmol/mg. Egg wax is secreted by Géné's organ (a female accessory gland) during oviposition, and Géné's organ also appears to inhibit the growth of bacteria, suggesting that it may also secrete the antimicrobial substance.

Identification of cuticular specific protein with newly found motifs from the silkworm, *Bombyx mori*.

T Asano
Department of Biology, Tokyo Metropolitan University, Hachioji-shi, Tokyo, 192-0397, Japan; asano-tsunaki@comp.metro-u.ac.jp

Recent studies have shown that insect cuticle contains immune factors, such as prophenoloxidase cascade components, antimicrobial peptides, recognition proteins. To find new immune factors in insect cuticle, a primitive proteomic technic was performed. Silkworn larvae were treated with sandpaper and after 24 hours, cuticle proteins were extracted. The extract was subjected into SDS-PAGE and the electrophoregram was compared between injured larva and non-injured larva. As a result, a protein of about 130k Da was present only in injured cuticle. The band of this protein (cp130) was cut from the gel and treated with trypsin followed by LC-MS analysis. Several genes were listed as candidates for a gene encoding the cp130. Among them, a gene encoding 115k Da wing disk protein (*CB10*) was further investigated. Northern analysis resulted in that strong signal of *CB10* was observed in the epidermal cells of injured larva. This result suggested that *CB10* gene encodes cp130. The product of *CB10* had not been studied and its function remained unknown. The only characteristic of this protein is a presence of repeated motifs of 10 amino acids, which had never identified so far and may be identified for the first time in this study.

pH regulation and its physiology in the silk gland of *Bombyx mori*

M Azuma, S Miyake, S Morita
Faculty of Agric., Tottori Univ., Tottori 680-8553, Japan; azuma@muses.tottori-u.ac.jp

The silk gland of lepidopteran larvae produces vast amounts of silk proteins and stores them in the glandular lumen as liquid silk temporarily. We have explored the system regulating pH in the silk gland, because the gelation of fibroin is pH-dependent. By injecting the pH-sensitive dye (phenol red) into silkworm larvae, we have estimated the rough pH in the glandular lumen. In *B. mori*, the lumen of the middle silk gland (MSG: major reservoir of liquid silk) was acidic (~ pH 5) in the vigorous feeding period, which leads to gelation of silk proteins at MSG. When the larvae started spinning, the lumen in the MSG became neutral gradually. The acidification in the glandular lumen is established by the proton pump (V-ATPase) at the apical plasma membrane of MSG cells as well as that of the anterior silk gland (ASG) cells. Non-cocoon producing strain of *B. mori* (fibroin-deficient type) showed lesser acidification nature. Thus, the V-ATPase function seems to be linked to the presence of fibroin. Similar results were obtained in the silk gland of the wild silkworm, *Samia cynthia ricini*. The pH regulation in the silk gland seems to be common in the cocoon-producing larvae of Lepidoptera.

Immune-induced lebocin-like gene devoid of antibacterial lebocin peptide sequence from eri-silkworm, *Samia cynthia ricini*

Y Bao, Y Yamano, I Morishima
Department of Biochemistry and Biotechnology, Faculty of Agriculture, Tottori University, Tottori 680-8553, Japapn; byy@phanes.muses.tottori-u.ac.jp

For more complete understanding of the insect immune responses, we have studied the genes that are differentially expressed in the fat body of *S. ricini* after bacterial challenge using suppression subtractive hybridization (SSH) method. One of the cDNA fragments from the subtracted cDNA library had a homology to lebocin gene from *Trichoplusia ni*, and the full length cDNA was obtained by 3' and 5'RACE methods. Lebocin is O-glycosylated proline-rich antibacterial peptide with 32 amino acid residues isolated from immunized hemolymph of *Bombyx mori*. *Bombyx* lebocin cDNA encoded precursor protein of 179 amino acid residues, from which the mature lebocin was thought to be cut out. The *Samia* lebocin-like protein with 162 amino acid residues has high homology with *Bombyx* and *Trichoplusia* lebocin in "prosegment" region, but no significant homology in the "mature" lebocin segment. Moreover, the segment of *Samia* corresponding to "mature" lebocin contained no O-glycosylation site and only 2 proline residues instead of 7 in *Bombyx*. The gene transcript was not detected in naive *Samia* larvae, but the expression was strongly induced by an injection of bacteria or peptidoglycan. The results suggest that the *Samia* gene does not code for antibacterial peptide, but an immune related protein of unknown function.

A respiratory hemocyanin from the stonefly *Perla marginata*

T Burmester, S Hagner-Holler
Institute of Zoology, University of Mainz, Germany; burmeste@uni-mainz.de

Hemocyanins are large copper-proteins that serve for the transport of oxygen in many arthropod species. We have shown for the first time that hemocyanins also occur in insects. The hemocyanin of the stonefly *Perla marginata* is present at high concentrations the hemolymph of both nymphs and adults. It is a hexamer with of two distinct subunit types of 659 and 655 amino acids, respectively, which has a moderate oxygen affinity ($P_{50} \sim 8$ torr) and displays cooperative oxygen binding. No evidence was found for a hemocyanin in holometabolan insects, indicating that this type of respiratory protein was lost later in insect evolution. However, our results suggest that the evolution of the insect tracheal system was not accompanied by a loss of the respiratory pigment. In addition to the hemocyanin, *P. marginata* possess a hexamerin. Four distinct hexamerin cDNA sequences were obtained. Phylogenetic analyses show that the insect hemocyanins group with the insect hexamerins, both forming a common clade with the crustacean hemocyanins. The insect hemocyanins are paraphyletic in terms of the hexamerins, suggesting that these insect storage proteins evolved only from a particular hemocyanin subunit.

Characterisation of *Drosophila* hemoglobin: evidence for hemoglobin-mediated respiration in insects

T Burmester, T Hankeln
Institute of Molecular Genetics, University of Mainz, Germany; burmeste@uni-mainz.de

In contrast to previous assumptions probably most insects possess hemoglobins. The function of these respiratory proteins is still uncertain. We have characterised the hemoglobin of the fruitfly *Drosophila melanogaster*. It is a monomer of about 17 kDa that is not exported into the hemolymph. Recombinantly expressed *Drosophila*-hemoglobin exhibits a hexacoordinated oxygen-binding scheme, with an oxygen-affinity of 0.12 torr. Hemoglobin expression is mainly associated with the trachea and tracheoles, but is also present in the fat body cells surrounding the adult and larval organs. Embryos show additional expression in the yolk sac and vitellophages. The hemoglobin gene of *Drosophila* (*DmeGlob*1) is located on chromosome 3 at position 89A13-B1. Four different transcripts have been identified that use two distinct promoters, but which are identical in their coding regions. These transcripts are differentially expressed through development. Putative binding sites for hypoxia-regulated transcription factors have been identified in the promoter regions. In fact, the *Drosophila* hemoglobin is down-regulated in response to hypoxia. The exact function of this protein remains to be established, but it is conceivable that the hemoglobin serve as an oxygen-buffer that prevents the cells from oxidative stress.

Effects of some antibiotics on the total protein content of the endoparasitoid *P. turionellae* L. (Hymenoptera: Ichneumonidae) pupae

K Büyükgüzel, E Büyükgüzel
Department of Biology, Karaelmas University, Science and Art Faculty 67100, İncivez, Zonguldak,Turkey; buyukguzel69@hotmail.com

Effects of gyrase inhibitors novobiocin, nalidixic and oxolinic acid on the pupal wet weight and total protein content of hymenopterous endoparasitoid, *Pimpla turionellae* L. were investigated by rearing the larvae aseptically on chemically defined synthetic diets. Higher dietary levels of the antibiotics tested had positive effects on the total protein content of this parasitic wasp. Oxolinic acid, at all levels tested, had the most positive effects on the protein synthesis of the young pupae. A dietary level of this antibiotic, at 2.25 mg, caused an increase in the total protein content by about 30 per cent. However, this antibiotic did not affect the wet weight of these pupae. The highest level of novobiocin also increased the protein content of the pupae, whereas its lower levels had no significant effects. Inversely, the low levels of novobiocin significantly increased wet weight of the pupae but had no effects on the protein content. The highest tested level of nalidixic acid caused a significant decrease in the wet weight while it increased total protein content of the pupae.

Infestins, blood coagulation inhibitors from insect *Triatoma infestans*, are always the answer in the blood feeding process

ITN Campos, AM Tanaka, DV Lovato, AS Tanaka
UNIFESP Rua Tres de Maio, 100, 04044-020 São Paulo, SP, Brazil; ivan.bioq@epm.br

Haematophagous animals are a rich source of anti-hemostatic and anti-inflammatory substances, since they have to deal with their host´s inflammatory and hemostatic systems. Recently, we have cloned several Kazal-type serine protease inhibitors from midgut of *Triatoma infestans* bug, which are encoded by one gene composed by seven Kazal-type domains in tandem. In this work, we describe the purification and characterization of recombinant infestin 4, a serine protease inhibitor with a single Kazal-type domain. Infestin 4 DNA sequence was derivated from infestin gene and its molecular mass is about 6 kDa. Infestin 4 inhibited factor XIIa (Ki = 0.1 nM), factor Xa (Ki = 53 nM), plasmin (Ki = 2.1 nM) and trypsin (Ki = 11 nM). Infestin 4 prolonged the TTPA coagulation time in about 3 times by inhibiting factor XIIa. We also identified and partially purified a native factor XIIa inhibitor from the anterior midgut of *T. infestans*. We believe that infestins perform a role in the *T. infestans* midgut during meal acquisition and digestion mainly because different infestins (1-2 and 4) present in the midgut can control blood coagulation inhibiting thrombin, factor Xa, and factor XIIa activities. Supported by FAPESP and CNPq.

Antioxidant and detoxifying enzyme activities in two strains of *Oncopeltus fasciatus* (Heteroptera: Lygaeidae) exposed to cadmium: II. chronic exposure.

A Cervera, AC Maymó, R Martínez-Pardo, MD Garcerá
Departamento de Biología Funcional y Antropología Física, Universitat de València, Moliner 50, 46100 Burjassot, Valencia, Spain; amelia.cervera@uv.es

Catalase (CAT), general esterase (EST), glutathione reductase (GR), glutathione S-transferase (GST), peroxidase activity of glutathione S-transferase (GSTpx), and superoxide dismutase activity (SOD) were determined in adult *O. fasciatus* exposed to Cd in inking water from egg eclosion to adult moult. Two different strains were studied: OS, a laboratory-reared strain, and OC, a strain subjected to Cd selection, form which two consecutive generations, F_{49} and F_{50}, were analysed. Differences in median lethal mortalities (LC_{50}, defined as failure to reach the adult stage) were observed between strains, and also between early and late insects within each OC generation; recorded LC_{50}s were 25 mg Cd/l for OS, 83/36 mg Cd/l for early/late F_{49} insects, and 62/52 mg Cd/l for early/late F_{50} insects, respectively. All enzyme activities were slightly increased in F_{49} and early F_{50} insects when compared to OS insects, whereas they were slightly decreased in late F_{50} insects. Chronic exposure to Cd caused an increase in CAT and GST activities in all strains. EST activity was also increased in OS and F_{50} exposed insects. No clear pattern was observed for GR, GSTpx and SOD activities.

Dosage effects between dietary niacin and other B vitamins on larval development of *Ceratitis capitata* (Diptera: Tephritidae)

CL Chang and QX Li
USDA-ARS-Honolulu, 2727 Woodlawn ive, Honolulu, HI 96822

The nutritional interaction between niacin and a nine other B vitamins group in the larval diet was evaluated. Four doses of niacin and a mixture of nine other B vitamins were cross-tested. Diets with doses ≥ 70.7 ppm of the other B vitamins and ≤0.2 ppm of niacin resulted in no pupal recovery. A delayed larval duration and reduced pupal recovery resulted when no niacin and ≤7.07 ppm of the other B vitamins in a diet. With omission of the other B vitamins, larval duration was delayed, but was not dose dependent on niacin and pupal recovery was not affected if niacin levels were maintained at ≥ 0.2 ppm. With 20 ppm of niacin in the diet, the larval duration and pupal recovery were dependent on the dose of the other B vitamins. The more the other B vitamins was, the shorter the larval durations and the more the pupal recoveries were. The other B vitamins reduced the larval duration when niacin was maintained at ≥ 2 ppm. When the niacin levels decreased to ≤ 0.2 ppm, doses of the other vitamins has to be reduced to below 7.07 ppm in order to maintain normal larval development.

Circadian rhythm of a-amylase isoform expression in *Drosophila melanogaster*

MA Ciuk, P Bębas, B Cymborowski
"Warsaw University, Ul. Miecznikowa 1, 02-096, Warsaw, Poland; mciuk@biol.uw.edu.pl[AGM1]"

Little is known about peripheral oscillator output in digestion. The goal of this project was to describe the circadian regulation of the a-amylase isozymes Amy-p and Amy-d in Canton-S wild type *Drosophila melanogaster*. To correct for the effect of dietary sugars which stimulate a-amylase expression, a restricted diet variant was also employed. Under control dietary conditions, in LD 12:12, amylase expression exhibited a bimodal oscillation, with a morning and early night peak. This rhythm was less robust in females than in males. In constant darkness, DD, both sexes also showed a bimodal rhythm, phase-delayed with respect to LD. Under constant light, LL, both males and females expressed a trimodal rhyhm, with an early day peak, and two smaller peaks at night. This rhythm was significant in the females but not in the males. In all cases Amy-d was expressed at a much higher level than Amy-p. Under the restricted diet, in LD, DD and LL the rhythms of expression of amylase were very similar to the control. In all cases, both isoforms were expressed at an equal level, or with Amy-p dominating, confirming the hypothesis that Amy-d expression is more strongly inhibited by glucose.

Effect of serotonin analogues on foregut contraction in the black field cricket

PD Cooper, S Dennis, N Plovanic
Botany & Zoology, Aust. Nat. Univ., Canberra, ACT, Australia; paul.cooper@anu.edu.au

Serotonin (5-hydroxytryptamine) stimulates contractions in the isolated foregut of the black field cricket, *Teleogryllus commodus* (Walker). Although several types of serotonergic receptors are known in vertebrates, whether such a diverse range of receptors is present in insects is not clear. Using analogues of serotonin characterised by their binding to specific vertebrate receptors (types 5-HT$_2$, 5-HT$_3$ and 5-HT$_4$), we investigated which receptors might be present on the foregut or associated nerve system. The foregut increased contraction to each of these analogues, although the analogue that binds to the 5-HT$_2$ receptor appeared to have the greatest effect. As immunohistochemistry indicates that the ingluvial ganglion and nerves going to the crop contain serotonin, we suggest that this might be the normal chemical released following feeding that initiates crop movement and food mixing.

A pH-dependent shift in protein digestion in *Tenebrio molitor* larvae

EN Elpidina, KS Vinokurov, DP Zhuzhikov, YE Dunaevsky, MA Belozersky
Moscow State University, Moscow 119992, Russia; elp@belozersky.msu.ru

Anterior (AM) and posterior (PM) parts of *Tenebrio molitor* larval midgut differ significantly in pH: 5.6 and 7.9, respectively. This difference is reflected in the proteinase sets in AM and PM. Cysteine proteinases (CP) presented by 4 fractions are dominant in AM. All fractions display maximal activity at pH 5.0-7.0, are stable at pH 5.6 and loose up to 80% of activity at pH 7.9. Their instability in PM-like environment makes very likely participation of CP in performing and regulation of only initial stages of food proteolysis. The major part of PM proteolytic activity belongs to serine proteinases. The most active trypsin-like proteinase is a cationic protein located predominantly in PM. Three anionic trypsin-like activities are distributed more evenly between both midgut parts. The main chymotrypsin-like proteinases are presented by 1 cationic and 4 anionic active fractions. Two of them including the cationic one are located mainly in PM while others are evenly distributed in AM and PM. pH-optima of serine proteinases are between 7.0 and 10.0. Thus, digestive proteolysis in *T. molitor* larvae depends on pH and is performed by a wide range of different proteinases. The work was supported by RFBR (02-04-48808) and CRDF (RB2-2396-MO-02).

Bemisia tabaci B biotype whitefly cathepsin B-like proteases

E Espineli, L Hatfield, RC Rosell, DR Frohlich
Department of Biology, University of St. Thomas, 3800 Montrose Blvd., Houston TX 77006, USA; frohlich@stthom.edu

Bemisia tabaci B biotype whiteflies are harmful to a variety of crop species because, as vectors of plant viruses, they ingest virions as they feed on the phloem of infected plants, and transmit them when they feed on uninfected plants. As part of our ongoing interest in the digestive systems of plant feeding insects, we have demonstrated significant activity of cysteine proteases at the protein level. However, our most recent findings suggest that there is a mixture of more than one family of proteases. Because we know that the proteolytic pH optimum in whole whitefly extracts is at pH 5.5, we feel that the proteases must be able to function in acidic environments. Using Cathepsin B, an acidic cysteine protease commonly found in hemipterans, as a positive control, we have optimized our protease inhibition assays. Based on the knowledge of a cDNA for the same enzyme from a related homopteran rice pest, *Nilaparvata lugens*, and related insect sequences, we have also designed PCR primers that have allowed us to 'fish' in genomic DNA preparations. We hope that future experiments will yield products that will allow us to develop probes that will eventually lead to a characterization of the gene.

Changes in haemagglutination activity in the different developmental stages of *Culex pipiens* s.l. caused by insect hormones

I Gelbic, J Olejnicek
Institute Of Entomology, As Cr, Branisovská 31, 370 05 Ceske Budejovice, Czech Republic; gelbic@ENTU.CAS.CZ

Effects of methoprene and 20-hydroxyecdysone on development and haemagglutination activity (HA) were studied in both sexes of anautogenous *C. p. quinquefasciatus* and autogenous *C. p. molestus*. Methoprene and 20-hydroxyecdysone induced larval mortality, prolongation of the intermolt period in preimaginal stages, morphological changes in metamorphosis and changes in HA. HA was found in larval and adult stage of both sexes. Our results show that HA in the adult female was not dependent on blood sucking, but on the age of the females. This conclusion has been confirmed by the results obtained with autogenous *C. p. molestus,* where HA does not change in hungry or engorged females. The conclusion has been further confirmed by findings of high HA in the gut of last larval instars, developmental stages that never take blood. Methoprene caused a significant decrease of HA in the gut of the last larval instar and in adults of both sexes. On the other hand, 20-hydroxyecdysone decreased HA only in the female gut. Results obtained indicate that HA depends on the sex, on the studied organ and on the level of hormones and could be induced in different ways, not only by ingesting of blood or protein meal.

Transferrin in *Galleria mellonella*: molecular characterization and regulation by PAMPs

J Han, KP Nam, HJ Ahn, SJ Seo, CY Yun
Dept. of Biology, Daejeon Univ., Daejeon 300-716, Korea; dibs1004@eamwiz.com

Complete mRNA sequence of *Galleria mellonella* transferrin was obtained and compared with those of other species. Until now, two types of insect transferrins have been reported. Transferrins in cockroach and termite have two iron-binding sites while those in other most insect groups, studied for the protein, have only one. It was suggested that the presence of two types of the protein was related with transferrin evolution because vertebrate transferrins have two iron-binding sites, called N- and C-terminal lobe respectively. From the cDNA sequence, it was shown that *G. mellonella* transferrin also has only one iron-binding site (N-terminal lobe), and the sequence of the protein was most similar to those of *Manduca sexta* and *Bombyx mori*. In addition, regulation of transferrin mRNA and the protein itself was detected by semi-quantitative RT PCR and Western blot analysis after injection of pathogen-associated molecular patterns (PAMPs) into larval hemolymph.

Immune-induced tyrosine 3-hydroxylase gene in eri-silkworm, *Samia cynthia ricini*

K Hashimoto, Y Bao, Y Fukui, Y Yamano, I. Morishima
Department of Biochemistry and Biotechnology, Faculty of Agriculture, Tottori University, Tottori 680-8553, Japan; moris@muses.tottori-u.ac.jp

We have studied the genes that are differentially expressed in the fat body of *Samia cynthia ricini* after bacterial challenge using suppression subtractive hybridization (SSH) method. One of the cDNA fragments from the subtracted cDNA library had high homology with tyrosine 3-hydroxylase (TH), and the full length cDNA was obtained by 3' and 5'RACE methods. TH is the rate-limiting enzyme in the synthesis of catecholamine, which catalyzes the oxidization of L-tyrosine to L-dopa in the presence of tetrahydropteridine as cofactor. TH has not known so far to be involved in any of immune responses in insect, and is apparently different enzyme from phenoloxydase which similarly catalyzes the oxidation of L-tyrosine to dopaquinone via L-dopa. The deduced amino acid sequence of *Samia* TH had approx. 75% and 50% homology with those of *Drosophila* and rat TH, respectively. The *Samia* TH gene was induced in the fat body, midgut and hemocyte 9 to 18 hr after injection of bacteria.

Suitability of five danaid butterflies for parasitization by the tachinid, *Sturmia bella*

N Hirai, M Ishii
Entomological Laboratory, Graduate School of Agriculture and Biological Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan; n_hirai@plant.osakafu-u.ac.jp

The tachinid fly, *Sturmia bella*, is a principal parasitoid of the migrant danaid, *Parantica sita* in Japan. Female adults deposit microtype eggs on foliage of host's food plants, and parasitization starts by host ingestion of eggs with leaf tissue. Eggs of *S. bella* were found on leaves of *Hoya carnosa, Tylophora tanakae, Parsonsia laevigata, Cynanchum liukiuense* and *Ficus microcarpa,* host plants of 5 danaids, *P. sita, Ideopsis similis, Idea leuconoe, Salatura genutia* and *Euploea mulciber,* respectively, in Ryukyu Islands. However, there have been few records of parasitization of these danaids except *P. sita*. In this study, we gave a piece of artificial diet with *S. bella* eggs to 4th or 5th instar larvae of the 5 danaids to compare parasitism rates. Most of *P. sita* and *E. mulciber* larvae died from parasitization, while most individuals of *I. similis, I. leuconoe* and *S. genutia* emerged as healthy-looking adults. We found melanized larvae of *S. bella* within the abdomen of most *I. similis* adults emerging, while no sign of parasitization was observed inside the body of *I. leuconoe* and *S. genutia.* The results show that larvae of *I. similis, I. leuconoe* and *S. genutia* have the ability to overcome the parasitization by *S. bella* and develop into adults. We will discuss the relationship between migratory activities and food plant preference of these danaids from a view of defence ability against parasitoids.

Clip-domain serine proteases involved in *Manduca* immune reactions

J Ishibashi, H Jiang, MR Kanost
1-2 Owashi, Tsukuba, Ibaraki 305-8634, Japan, bishiba@affrc.go.jp

Clip-domain serine proteases are involved in insect immune reactions such as the Toll pathway (induction of antimicrobial peptides) and the phenoloxidase activation cascade. We identified clip-domain serine proteases HP6, 8, 15, 17 and 21 from the tobacco hornworm, *Manduca sexta* that are cleaved after stimulation with microbial elicitors. HP6 is similar to *Drosophila* persephone, which is involved in the Toll pathway in antifungal response. HP8 is similar to *Drosophila* easter, which acts in the Toll pathway by cleaving prospätzle in dorsal-ventral patterning. HP15 and HP21 are similar to *Manduca* prophenoloxidase activating protease (PAP) 2. HP17 is similar to *Drosophila* CG1299, whose function is not known. We analyzed functions of HP6 using an inactive mutant protease, in which the active site Ser was substituted with Ala. The mutant protease inhibited cleavage of HP8 stimulated by elicitors *in vitro* and suppressed induction of antimicrobial peptides *in vivo*. The results suggested that HP6 is located up-stream of HP8 in an immune reaction cascade that stimulates antimicrobial peptide synthesis. Immunoprecipitation of plasma samples with anti-HP17 antibody inhibited activation of HP21 *in vitro*, suggesting HP17 is upstream of HP21 in an immune reaction cascade.

"Recent climate [AGM2]warming promotes the northward invasion in the swallowtail butterfly, *Papilio memnon* in Japan"

M Ishii, M Yoshio
Entomological Laboratory, Graduate School of Agriculture and Biological Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, Japan; ishii@plant.osakafu-u.ac.jp

The swallowtail, *Papilio memnon*, is distributed widely from tropical to temperate zones in the Oriental region, and the northern limit of its distribution lies in western Japan. Recently the distribution has been expanding to northeastern areas in central Honshu. To investigate the relationship between the phenomena and characteristics of pupal diapause of this species, the photoperiodic response of 4 Japanese populations including the subtropical and northernmost ones was examined. Also we compared cold hardiness of pupae among the 4 populations. The critical photoperiod for inducing pupal diapause at 20C was 12 h 30 min in the subtropical population, and about 13 h in the 3 temperate ones. However, the differences in diapause intensity (about 100 days) and supercooling point (about -21C) among the 4 populations was small. Thus it may be difficult to explain the change in the distribution of this species from the change in characteristics of pupal diapause and cold hardiness of pupae. These results show that rising winter temperatures may be responsible for the recent northward invasion of this species.

The fate of foreign proteins in tobacco budworm, *Heliothis virescens***.**

LA Jeffers, RM Roe
Department of Entomology, Campus Box 7647, North Carolina State University, Raleigh, NC 27695-7647, USA; lajeffer@ncsu.edu

The oral delivery of protein insecticides to target sites in the insect hemocoel is made difficult due to degradation in the gut by endo- and exo-peptidases and their limited movement across the gut epithelium. Overcoming these obstacles to using protein toxins as insecticides requires better understanding the physiology of protein movement and fate in pest species. In previous studies we used Bovine Serum Albumin (BSA) and anti-BSA polyclonal antibody as model polypeptides to determine protein fate in tobacco budworms, *Heliothis virescens.* Oral delivery of anti-BSA or BSA results in the appearance of both proteins in the hemolymph over time. In contrast if anti-BSA or BSA are injected into the hemocoel both proteins turnover with time through protease degradation and/or tissue sequestration. The accumulation of foreign proteins in insect hemolymph reflects the competing rates of transfer from the diet across the midgut and turnover in the hemolymph. These results were extended to include loss of anti-BSA and BSA over time in the insect whole body. This identifies any protein sequestration that might have reduced the protein concentration in the hemolymph. Finally individual tissues were dissected after injections and tested for the presence of both proteins to determine where proteins are sequestered.

Stage-dependent expression of *Chelonus inanitus* polydnavirus genes in the host & the parasitoid

M Bonvin, D Kojic, F Blank, M Annaheim, I Wehrle, S Wyder, M Kaeslin, B Lanzrein
Institute of Cell Biology, University of Berne, Baltzerstrasse 4, 3012 Bern

Successful parasitism of many endoparasitic wasps depends on the supporting action of symbiontic polydnaviruses. These unique viruses have a segmented genome and are produced in the ovary; at parasitization they are injected along with the parasitoid egg into the host. In the parasitized host polydnaviruses do not replicate. In its proviral form the polydnavirus is integrated into the wasp's genome. *Chelonus inanitus* induces in its host a precocious onset of metamorphosis and a developmental arrest in the prepupal stage. The polydnavirus prevents encapsulation of the parasitoid and causes the developmental arrest. We report that the expression of six genes located on five fully sequenced segments is stage specific. Two genes are expressed only in the early phase of parasitization, two in both the early and late stages, one in the middle phase and one only at the end of parasitization. This suggests that expression of viral genes is regulated by factors from the host. For four genes the tissue distribution of transcripts was measured and it was found that the majority is located in haemocytes and fat body. Some viral genes are also expressed, although at low levels, in the parasitoid larva and pupa, i.e. from the proviral form.

Immune activation of apolipophorin-III and its distribution in hemocyte from *Hyphantria cunea*

HJ Kim, HJ Je, R Chandrasekar, RC, SY Park , IH Lee, BR Jin, HK Yun, CY Yun, YS Han, YJ Kang, SJ Seo
Division of Life Science, Department of Pharmacology, Gyeongsang National University, Jinju, Korea

Apolipophorin-III is a hemolymph protein whose function is to facilitate lipid transport in an aqueous medium. Recently, apolipophorin-My Presentation for in *Galleria mellonella* larvae was shown to play an unexpected role in insect immune activation. We identified the cDNA sequence of *Hyphantria cunea* apolipophorin-III by oligonucleotide-primed amplification, and 5′- and 3′-RACE PCR. Since *H. cunea* has an unusually low level of apolipophorin- III in the hemolymph, a recombinant apolipophorin- III was overexpressed using a baculovirus expression system to investigate its biological activity. Recombinant apolipophorin- III and *E. coli* were injected into the hemocoel of last instar larvae, and the expression of antimicrobial peptide from fat body was determined by Northern blot. Injection of apolipophorin- III as well as *E. coli* induced slight up-regulation of its transcription rate in fat body. While the expression of antimicrobial peptide amatically induced by the injection of apolipophorin- III and *E. coli*. *H. cunea* hemocytes had apolipophorin- III in the granules and expressed its transcript, albeit at a much lower level than in the fat body. Upon bacterial injection, a subpopulation of hemocytes showed degranulation and degradation. Local discharge of apolipophorin- III from hemocytes caused by the injection of *E. coli* should be related to the immune response through an unknown mechanism.

Development of innovative anti-infective drugs derived from insects

B Cavallini, M Guenneugues, M Legrain, R Lupoli, JP Meyer, V Schott, JP Starck, F Tiberghien, M Tissot
Entomed S.A. Rue Tobias Stimmer F67400 Illkirch, France

Insects are major players of terrestrial ecosystems forming the largest and the most cosmopolitan group of metazoans. A key factor that has contributed to this success is the extraordinary chemical versatility of these animals. Insects are amazingly adapted to a multiplicity of ecological niches that they colonize. Insect have the capacity to manufacture a broad range of biologically active molecules, including peptides and small molecules, which ultimately may find applications in a wide range of therapeutic fields. They can survive in inclement infectious environments which reflects their capacity to mount a potent immune response and to produce defence molecules with strong antimicrobial properties. These natural substances, either peptides or small molecules, represent promising templates to derive innovative classes of therapeutics to face the declining efficacy of classical antibiotics.

Molecular cloning and expression of aquaporin from the silk gland of *Bombyx mori*

S Miyake, M Azuma
Faculty of Agric., Tottori Univ., Tottori 680-8553, Japan; miyachan@phanes.muses.tottori-u.ac.jp

We have explored the system regulating pH and water in the silk gland, because this gel-like solution is maintained within the glandular lumen without irreversible coagulation and/or denaturation until the completion of spinning. In this study, to elucidate the water regulation in the silk gland, we have cloned the cDNA encoding the putative aquaporin (AQP) with a homology cloning strategy. Using degenerate primers with cDNA of anterior silk gland (ASG) followed by 5′- and 3′-RACE PCR techniques, we have obtained one candidate with homologous to other insect AQPs. The deduced amino acid sequence of AQP from ASG showed 50-60% identity with several insect AQPs such as that from *Aedes aegypti*, *Haematobia irritans exigua* and *Cicadella viridis*. The AQP expression in the ASG correlates well with the growth and development of the silk gland during the final larval instar, reaching to maximum level at the start of spinning, then declined quickly. This homologus transcript (~2.3 kb) of putative AQP from ASG was distributed not only in the midgut and the rectum, but also less in Malpighian tubules and rather lower in the tracheal systems.

Functional structure of the silk apparatus in the comb-footed spider, *Achaearanea tepodariorum* (Araneae: Theridiidae)

MJ Moon, JS An
Department of Biological Sciences, Dankook University, Cheonan 330-714, KOREA, moonmj@dankook.ac.kr

It has been known that functional specialization of silk producing apparatus involving precise modifications of the shape of the spinnerets, the number and morphology of spinning tubes, and anatomical characteristics of the silk glands. Although the spinning apparatus often undergoes adaptative variations, some basic familial characteristics usually remain unchanged, so their shape and number of spinning apparatus can also classify spiders. Here we describe the fine structural organization of the silk glands and its spinning apparatus in the comb-footed spider, *Achaearanea tepodariorum*, with light and electron microscopes. The silk glands of the adult female spider were located in seven groups on the spinnerets including each pair of major and minor ampullates, tubuliforms, flagelliforms, aggregates, pyriforms and aciniforms. Each group of silk gland feed silk into one of the three pairs of spinnerets. Commonly the secretory silk is synthesized from rough endoplasmic reticulum (rER) of glandular epithelial cells and is transported from the rER into the secretory vesicles which are grown up by fusion with the surrounding small vesicles including the secretory silk.

The entry of polyembryonic egg-larval parasitoid into host embryo *in vitro*

A Nakaguchi, T Hiraoka, K Iwabuchi
Tokyo University of Agriculture and Technology, Saiwai-cho, Fuchu, Tokyo 183-8509, Japan; azusan@cc.tuat.ac.jp

Copidosoma floridanum is a polyembryonic egg-larval parasitoid of the plussine Lepidoptera. The *C. floridanum* egg cleaves holoblastically to form a morula that is spherical mass of embryonic cells surrounded by a polynucleate membrane. The embryo proliferates clonally in the growing host larva. In this species, the female oviposits her eggs in host eggs of any stage of development. When 30-36 hour–old host eggs were parasitized, 75 % of *C. floridanum* eggs were laid in vitellophages of host *Thysanoplusia intermixta* eggs (outside of the host embryos), although the final percentage parasitism at adult emergence was 83%. To determine whether or not *C. floridanum* embryos secondarily enter into the host embryo, we examined *C. floridanum* embryos co-cultured with host embryos. Histological observations showed that the morula-stage embryo of *C. floridanum* had mobility and could enter the host embryo. The entry of foreign objects into *T. intermixta* embryos was not observed with latex beads or other parasitoid *Ascogaster ridiculatus* eggs *in vitro*, suggesting that *C. floridanum* embryos actively enter the host embryos. This study also suggested that the embryonic entry into the host embryos was accomplished by different ways according to the age of the host eggs when parasitized.

Immunization of *Manduca sexta* larvae with *E. coli* causes immunity to subsequent infection by *Photorhabdus luminescens*: induction of antimicrobial activity in haemolymph and the cost of defence.

SE Reynolds, I Eleftherianos, J Marokhazi, A Sriboonlert, R French-Constant
Department of Biology & Biochemistry, University of Bath, Bath, BA2 7AY, United Kingdom; S.E.Reynolds@bath.ac.uk

Injection of living cells of the normally non-pathogenic Gram negative bacterium *E. coli* into fifth instar larvae of the lepidopteran *Manduca sexta* causes subsequent strong immunity to challenge by the normally extremely pathogenic Gram negative bacterium *Photorhabdus luminescens*. Immunity is evident after only one hour and is fully developed by 12 h. We show that immunization with *E. coli* induces increased expression of a factor in haemolymph that prevents the growth of *Photorhabdus* in vitro. This is at least in part due to the presence of antimicrobial peptides. Immunity is not due to lysozyme, although this enzyme is expressed at elevated levels following immunization. The results of RNAi knockdown experiments on these and other known insect immune-related genes will be described. These results indicate that the many virulence genes present in the *Photorhabdus* genome are probably not redundant, but are required in an ecological context where host insects are not bacteriologically naïve, as in the laboratory situation. They also show that *Manduca* normally does not express its many defences against microbial infection, presumably because to do so would be costly. We describe attempts to estimate the cost of such antimicrobial defences.

In vitro and *in vivo* activity of synthetic antimicrobial peptides designed based on the insect defensin

H Saido-Sakanaka, J Ishibashi, M Yamakawa
Innate Immunity Laboratory, National Institute of Agrobiological Sciences, 1-2 Owashi, Tsukuba, Ibaraki 305-8634, Japan; sakanaka@affrc.go.jp

Synthetic antimicrobial 9-mer peptides were designed from the amino acid sequence of an active site of insect defensin to increase the number of positively charged amino acid residues. These peptides, RLRLRIGRR-NH_2, RLLLRIGRR-NH_2, RLYLRIGRR-NH_2 and ALYLAIRRR-NH_2, showed strong antimicrobial activity against bacteria and fungus. The peptides showed no growth inhibition activity against murine fibroblasts or macrophages and no hemolytic activity against rabbit erythrocytes *in vitro*. Furthermore, the administration of these peptides protected mice from a lethal methicillin-resistant *Staphylococcus aureus* (MRSA) challenge. In addition, the peptides suppressed tumor necrosis factor alpha (TNF-) gene expression and production induced by lipopolysaccharide (LPS) or lipoteichoic acid (LTA) in murine macrophages, providing an interesting problem of the contribution to protection of mice from lethal MRSA infections *in vivo*. The results suggest that these peptides are potential candidates for future therapeutic agents against antibiotic-resistant bacterial infection.

Isolation and characterization of serine proteases inhibitors from tick, *Boophilus microplus*

SD Sasaki, RJS Torquato and AS Tanaka
UNIFESP, Rua Três de Maio, 100, Cep 04044-020, São Paulo, SP, Brazil; ssasaki.bioq@epm.br

The present work describes the isolation and characterization of several protease inhibitors from hard tick *B. microplus*: larvae, eggs and egg washed solution. These inhibitors were purified by classical purification methods. The purified inhibitors from larvae were named BmTI A to E and BmTI 1 to 6; they showed molecular masses between 7.5 and 18 kDa and inhibited trypsin, neutrophil elastase and human plasma kallikrein (HuPK). The best inhibitors for neutrophil elastase (Ki = 12 nM) and HuPK (Ki = 0.5 nM) were BmTI 3 and BmTI D, respectively. The N-terminal sequences of BmTI D, BmTI 2, and BmTI 3 allowed us classify them in Kunitz-BPTI inhibitor family. Two subtilisin and neutrophil elastase inhibitors (BmSIs) from eggs were purified, they presented molecular masses around 7 kDa and dissociation constants (Ki) in nM range for both enzymes. Finally, neutrophil elastase and trypsin inhibitory activities were also observed in egg washed solution. Serine proteases secreted by *Metarhizium anisopliae* fungal in culture medium were inhibited for BmTIs and BmSIs. These results suggest that BmTIs and BmSIs can have a role in the tick defense mechanisms against fungal infection. Supported by: FAPESP and CNPq.

Change of ferritin of wax moth, ***Galleria mellonella*** **on dietary heavy metal ions**

DH Seo, CW Choi, JE Yuk, KP Nam, J Han, SJ Seo, CY Yun
Dept. of Biology, Daejeon Univ., Daejeon 300-716, South Korea; insectlab@hotmail.com

A tissue ferritin (T-ferritin) was purified from the haemolymph-free whole body extract of wax moth, *Galleria mellonella*. This protein was distinguished from haemolymph ferritin (H-ferritin) in that it had an additional subunit of 34 kDa. H-Ferritin of this moth has been known to be composed of three subunits of 26, 30, and 32 kDa. However, the sequence of N-terminal 20 amino acid residues of the tissue specific 34 kDa polypeptide was shown to be identical with that of 32-kDa subunit of *G. mellonella* H-ferritin. It was also observed that the T-ferritin had cross-reactivity against anti-haemolymph ferritin serum. T-Ferritin was detected in fat body, gut, Malpighian tubule, and haemocyte by Western blot analysis. T-Ferritin responded differently from H-ferritin to the heavy metal injection. T-Ferritin was induced earlier than H-ferritin by $HgCl_2$ injection. T-Ferritin was sensitively increased by Cd^{2+}, Cu^{2+}, Mn^{2+}, Zn^{2+}, and Ni^{2+} ions. Hg^{2+} was a highly effective ion for the H-ferritin induction. These results suggest that there are different response mechanisms to heavy metals between T-ferritin and H-ferritin.

Proteome analysis of brush border membrane vesicles from the lightbrown apple moth, *Epiphyas postvittana*

RM Simpson, J Cooney, D Jensen, DG Greenwood
HortResearch, Tennent , Private Bag 11030, Palmerston North, New Zealand; rsimpson@hortresearch.co.nz

Brush border membrane vesicles (BBMV), formed from intestinal villae, were prepared from the midgut of fifth instar lightbrown apple moth (*Epiphyas postvittana*) larvae by differential centrifugation in the presence of a protease inhibitor cocktail. These were lysed using water, and the contents collected to give a first extract. The BBMV membranes were then sequentially extracted with a standard urea/CHAPS buffer then with thiourea/urea/SB3-10 buffer to yield two further protein extracts of membrane proteins. The extracts were separated by two-dimension gel electrophoresis (2-DE) on 7cm NuPage Novex 4-12% Bis-Tris Zoom gels using pH ranges of 4-7 and 3-10. For protein identification, protein spots on gels stained with colloidal Coomassie Brilliant Blue G-250 were excised, digested in gel with trypsin, and analysed by peptide mass fingerprinting after electrospray MS-MS mass spectrometry. The 2-DE of Extract 2 was heavily degraded, with few protein spots greater than 20 kDa, suggesting that there was trouble with proteases despite the addition of a protease inhibitor cocktail. Extracts 1 and 3 contained many distinct spots. A number of these have been identified and include ATPase components, proteases, glycosidases, ribosomal and heat shock proteins.

Hsp70 and Fib-L are over-expressed proteins in immunized *Bombyx mori* larvae

KH Song, SJ Jung, SW Kang, SM Yoe, SS Han
136-701, Lab. of Cell engineering and 3-D structure, School of Life Science and Biotechnology, Korea University, Seoul, Korea; sshan@korea.ac.kr

Hemocytes play a major role in insect cellular immune response. In infected with foreign invaders, hematopoiesis was more actively occured. The current study was performed to understand hemocyte differentiation patterns and expressed proteins of immunized *Bombyx mori* larvae. Heat-inactivated bacteria (*Bacillus megaterium*) was injected into *B. mori* 5th instar 4 day after ecdysis. After six hours, circulating hemocytes were examined. The THC were increased of 905×10^3 in immune response. The DHC indicated that granulocytes were increased of 687.5×10^3 and accounted for half of THC in immunized larvae. These results indicated that hematopoiesis were occurred actively and granulocytes were increased prominently in immunized *B. mori* larvae. Hemocytes and hemolymph proteins observation revealed that some proteins were newly expressed or up-regulated in immune response. In hemocytes, over 300 spots were counted, only one spot was newly detected and four spots were up-regulated in immunized larvae. In hemolymph proteins, about 200 spots were detected and three spots were appeared newly. Heat shock 70kDa protein (hsp70) was one of the hemocyte up-regulated proteins and fibroin light chain precursor (Fib-L) was among the hemolymph new entry proteins. Hsp70 and Fib-L were purified from immunized larvae and carry out an experiment on larvae with these proteins. These results suggest that hsp70 of hemocytes and Fib-L of hemolymph are associated with the regulation of THC and GR increasing in immune response.

Utilisation of protein in litter dwelling larvae *Bibio marci* **(Diptera: Bibionidae)**

V Šustr, J Frouz, X Li and A Brune
Institute of Soil Biology ASCR, Na Sádkách 7, 37005, České Budějovice, Czech Republic; sustr@upb.cas.cz

Saprophagous invertebrates may play crucial role in modification many ecosystem processes by its influence on decomposition and soil structure. Leaf litter contains hardly utilisable substances and is deficient for protein. Moreover protein is typically immobilised by phenols of humic-acids. Protease pH optima, its distribution in the gut, distribution of amino-acids and ammonia in gut compartments were studied in bibionid larva *Bibio marci*. Protein digestion was studied using ^{14}C-labelled protein either pure protein or as protein stabilised by humic-acids were used. Contribution of larvae to protein mineralisation was estimated as proportion of protein mineralised in the presence of larvae and in control litter. Protease showed alkaline pH optimum corresponding with pH in anterior gut. Trypsin activity was high in caeca, anterior and mesenteron but lowered in hindgut. Content of amino-acids decreased inside gut, ammonia content increased. Serine and valine proportions decreased, methionine proportion increased during gut passage. High methionine proportion occurred in hindgut. Larvae utilised both pure and humic-acid stabilised protein. Larvae used pure protein more efficiently than bounded one. Contribution of larvae to protein mineralisation is higher in bounded protein. Gut alkaline pH gut probably supported humic-acid bounded protein utilisation by larvae similarly as already documented in termites and some scarabeid larvae.

Boophilus microplus trypsin inhibitor-A (Bmti-A): is a serine or cysteine proteinase inhibitor?

AS Tanaka, SD Sasaki, SS Azzolini, A Seixas, C Termignoni, SS Cotrin, AK Carmona
Departamento De Bioquímica, Unifesp, Rua 3 De Maio, 100, 04044-020 São Paulo, Sp, Brazil. Tanaka.Bioq@Epm.Br

Ticks are arthropod blood feeders and to control their host's haemostatic system, they secreted coagulation and platelet aggregation inhibitors in the saliva during feeding process. Among them tick anticoagulant protein (Tap), A factor Xa inhibitor, And ornithodorin, both purified from *Ornithodoros moubata*; savignin A thrombin inhibitor and savignygrin, a platelet aggregation inhibitor from *O. Savignyi* species, all these proteins have in common the Kunitz-Bpti structure fold. Beside these anti-haemostatic molecules, several proteinase inhibitors with unknown physiological function were described in *B. microplus* and *Riphicephalus Sanguineus* species. In the present work, we describe a new function for the Bmti-A, as a cysteine proteinase inhibitor. Bmti-A belongs to the Bpti-Kunitz type family; it inhibited trypsin, chymotrypsin, plasma kallikrein and neutrophil elastase and presented molecular mass around 18 Kda, containing two kunitz domains. Our present results showed that Bmti-A strongly inhibited cathepsin L (Ki = 23 Pm), a cysteine proteinase. Confirming this data, Bpti, a kunitz type inhibitor, also inhibited the following cysteine proteinases: cathepsin L (Ki = 50 Pm), papain (Ki = 3.4 Nm) and Vtdce (0.12 Nm), a cysteine proteinase from *B. microplus* eggs. Our recently findings showed a bifunctional activity of Bpti-Kunitz type inhibitors. Supported by: Fapesp and Cnpq.

Functional analysis of BmRel proteins

H Tanaka, S Furukawa, A Sagisaka, M Yamakawa.
National Institute of Agrobiological Sciences, 1-2 Owashi, Tsukuba, Ibaraki, 305-8634 Japan; htanaka1@nias.affrc.go.jp

Antibacterial peptide genes are known to be up-regulated by bacterial infection in insect. In *Bombyx mori*, the B-like motifs, suggesting an important role in gene activation, are located on the 5′-upstream region of these genes. Two cDNAs encoding BmRelA and BmRelB were cloned as candidates for binding factors on B-like motifs. From the nucleotide sequence information, it is suggested BmRelA and B have the same amino acid sequences except BmRelA has extra 52 amino acids in the N terminal region. Transient luciferase assay indicated BmRelA and BmRelB differentially activated *Bombyx mori* antibacterial peptide genes. In order to identify the transcriptional activation domain of BmRel, luciferase assay experiments were carried out using deletion constructs of BmRel. Results showed proline rich region (86 amino acids) was involved in the activation of attacin gene by BmRelB. On the other hand, for the activation of lebocin4 gene by BmRelA, both proline rich region and A specific 52 amino acid were necessary. This 52 amino acid sequence also had a function as the transcriptional activation domain in yeast. This sequence was occupied by mainly hydrophobic and acidic amino acids, one of the typical amino acid sequence as transcriptional activation domain.

Alteration of cellulolytic systems in termites

G Tokuda, N Lo, H Watanabe
Center of Molecular Biosciences, University of the Ryukyus, Nishihara, Okinawa, 903-0213, Japan; tokuda@comb.u-ryukyu.ac.jp

Cellulolytic systems in the gut of termites was examined by measuring hydrolysis of crystalline and carboxymethyl cellulose as well as performing reverse transcription-PCR and phylogenetic analyses of endogenous endo- -1,4-glucanase cDNAs from termites of diverse feeding habits. In cellulolytic flagellate-harbouring termites, carboxymethyl cellulose, which is a highly soluble cellulose ether, was primarily hydrolysed in the salivary glands, whereas microcrystalline cellulose was degraded primarily in the hindgut. In non flagellate-harbouring termites, a fungus-growing termite retains both the cellulolytic activities in the salivary glands, while other wood-feeding and soil-feeding termites possess both the cellulolytic activities primarily in the midgut. RT-PCR and phylogenetic analyses revealed that multiple endogenous endo- -1,4-glucanase genes are expressed in the salivary glands of the flagellate-harbouring termites as well as the fungus-growing termite and are expressed in the midgut of the wood- and soil-feeding non flagellate-harbouring termites, which are likely to be related to diversification of feeding habits in termites of the family Termitidae. In the light of these results, as well as recently accrued phylogenetic data, we discuss scenarios for the evolution of cellulose digestion in termites.

The effects of bacteria and TLCK on hemocyte morphology of *Manduca sexta*

E Willott, HQ Tran
Entomology, Forbes 410, University of Arizona, Tucson, AZ, USA; Willott@u.arizona.edu

Conflict and war are everywhere. The microscopic world is no exception. Battle is just as necessary for survival. For *Manduca sexta*, the tobacco hornworm, invaders include parasites, bacteria, or other foreign material. Our general question is: how do *M. sexta* hemocytes (mainly plasmatocytes and granular cells) respond to threats. Hemocytes phagocytose or form nodules around bacteria; they form capsules around larger pathogens like parasites. In vitro, we looked at hemocytes from immune activated (bacteria injected) and control larvae. For immune activated compared to control larvae: plasmatocytes had significantly greater mean length; granular cells had greater mean area. At 20 hr, hemocytes from immune activated larvae organized into a uniform network substantially faster than the control cells. We also studied the effect of TLCK, a serine protease inhibitor. With immune activation, at 20 hr, TLCK resulted in: (1) greater granular cell mean area; (2) more and larger vesicles in granular cells; (3) fewer plasmatocytes connect the network nodes. Regardless of immune activation, TLCK showed no effect on plasmatocyte length at 1 hr; nevertheless, TLCK inhibited network formation at 20 hr.

"Carotenoid binding protein is encoded by Y gene which transport carotenoid into hemolymph of *Bombyx mori*.[AGM3]"

K Tsuchida, W Hara, S Sosnicki, N Takada, H Maekawa, M Kobayashi
Div. Radiol. Pro., Natl. Inst. Infectious Diseases, Shinjuku, Tokyo 162-8640; kozo@nih.go.jp

Fundamental aspects of carotenoid absorption are largely unknown, such as luminal and intracellular factors related to absorb and transport of carotenoid. These mutants offer unique research tools for studying lipid specific transporter in insects. In the +Y gene, the transport of the other lipids except carotenoid is normal, only the transfer of lutein is affected. A carotenoid binding protein (CBP) has been isolated from *Bombyx mori* larvae. Immunoblotting analysis and immunocytochemistry confirmed the presence of CBP in larvae with the dominant Y gene only. RFLP mapping analysis shows almost certainly that Y gene encode CBP. In both Y and +Y mutants, CBP gene and CBP mRNA were found by Southern and Northern hybridization. The difference of sequences of CBP cDNA from Y and +Y strains was not found. mRNA size of +Y mutant is smaller than Y . It is not clear why +Y strain can not make CBP. $+^{Y}$ might have a mutation on the regulatory region related to CBP expression.

Immune evasion mechanisms of the endoparasitoid wasp *Hyposoter didymator* (Hym.: Ichneumonidae) in four lepidopteran host species

M Schneider, F Budia, S Pineda and E Viñuela
Protección De Cultivos, E.T.S.I. Agrónomos, Polytechnic University Of Maid. E-28040 Maid, Spain; evinuela@pvb.etsia.upm.es

The relationship between immune suppression response and host range has been evaluated in four lepidopteran hosts of the ichneumonid *Hyposoter didymator.* Parasitism inhibited the growth of permissive (*Helicoverpa armigera*) and semi-permissive hosts (*Spodoptera littoralis* and *S. exigua*), whereas the non-permissive *Trichoplusia ni* was not significantly affected. Encapsulation mechanisms were only detected in semi and non-permissive hosts. The presence and the role of polydnavirus in ovaries of *H. didymator* females was evaluated by electronic transmission microscopy. Polydnavirus were always detected, but the semi-permissive and non-permissive hosts encapsulated eggs and larvae of the parasitoid. Hyperparasitism was detected in semi and non-permissive species and in the former, one or more larvae were found floating free in the hemolymph. The host range of *H. didymator* seems to be determined by whether or not the parasitoid ichnovirus is able to establish persistent infections in parasitized host larvae to provide long-term suppression of host immunity system.

Studies about the immune response of four lepidopteran species & the immune evasion mechanisms of the parasitoid wasp *Hyposoter Didymator* (Hym., Ichneumonidae).

M Schneider, F Budia, S Pineda E. Viñuela
"Unidad de Protección de Cultivos, E.T.S.I. Agrónomos, E-28040 Maid, Spain; evinuela@pvb.etsia.upm.es"

To evaluate the relationship between immune suppression and host range, four lepidopteran hosts were parasitized by ichneumonid parasitoid *Hyposoter didymator.* **Parasitism inhibited the growth of permissive (***Helicoverpa armigera***) and semi-permissive hosts (***Spodoptera littoralis* **and** *S. exigua***), whereas growth in non-permissive host (***Trichoplusia ni***) was not significantly affected. Encapsulation mechanisms were detected in species semi and non-permissive but not in permissive host. In the second part of this work, the presence of polidnavirus in ovaries of** *H. didymator* **females exposed to these hosts has been evaluated by electronic transmission microscopy. Polidnavirus were detected in all tested females, although some hosts (semi-permissive and non-permissive) encapsulated eggs and larvae of the parasitoid. Moreover, hyperparasitism was detected in semi and non-permissive species but one or more larvae were detected floating free in the hemolinfa in semi-permissive host. The host range of** *H. didymator* **seems to be determined by whether or not the parasitoid ichnovirus is able to establish persistent infections of parasitized larvae to provide long-term suppression of host immunity.**

Glycosyde-hydrolases in the digestive systems of lower termites

H Watanabe
National Institute of Agrobiological Sciences, Owashi, Tsukuba, Ibaraki, 305-8634 Japan; hinabe@affrc.go.jp

Since the finding of the endogenous cellulase genes belonging to the glycoside-hydrolase family 9 (GH9) from the termite *Reticulitermes speratus* in 1998 (Watanabe et al., 1998), we have found expressions of -glucosidase (GH1) in the salivary glands of the lower termite *Neotermes koshunensis*, endo- -1,4-glucanases (Tokuda et al., 2002) and cellobiohydrolase homologues (both GH7) in the hindgut parabasalian symbionts (protozoa) (Nakashima et al., 2002; Watanabe et al., 2002) by purification and N-terminal amino-acid sequencing of the enzymes, and following cDNA cloning. To elucidate further details of the lower termite digestive systems, EST analysis was employed for mRNA extracted from the salivary glands of *R. speratus*. The EST clones (about 400 at the submission) analyzed preliminarily encoded endo- -1,4-glucanase (GH9, 55.8%), -amylase (GH1, 4.7%), -glucosidase (GH1, 0.5%), -1,3-glucanase (GH16, 0.5%) and a possible glycosyl-transferase (0.5%), but no cellobiohydrolase homologue encoding cDNAs have not found. The result suggested importance of protozoan cellobiohydrolase generally responsible for degradation of crystalline region of the substrate.

Morphology & function of cuticular nanostructure arrays on insect wings-an investigation using atomic force microscopy

JA Watson, GS Watson
School of Science, Griffith University, Nathan, QLD, 4111, Australia; J.Blach@griffith.edu.au

The characteristics of naturally occurring nano-structured arrays has been of great interest to physicists and biologists as these evolutionary refined structures provide ideal models, or templates, for man-made fabricated materials and devices. Ordered hexagonal packed array structures on cicada (e.g., *Pflatoda claripennis*) and termite (e.g., family *Rhinotermitidae*) wings have been investigated in this study. The spacings range from ca. 200 to more than 800 nm. The structures tend to have a rounded or in some cases a near-paraboloid shape at the apex and protrude some 150 to 350 nm out from the membrane surfaces. Array structures with spacings at the lower end of the range are most likely optimised to serve as an anti-reflective coating. The structures with spacings at the upper end of the range are unlikely to offer these properties in the visible spectrum, thus indicating that they confer additional, and most likely different, evolutionary advantages to those of camouflage. Atomic force microscopy has been utilised in this study for determining topography, membrane stiffness and adhesion properties at the micro and nanometre scales. The results indicate that the array structures have multiple functions including, anti-reflective properties, self-cleaning mechanisms and structural support elements.

Members of the viral ankyrin (vankyrin) gene family in the *Campoletis sonorensis* ichnovirus (*Cs*IV) exhibit tissue-specific expression in parasitized *Heliothis virescens* larvae & differential biological effects *in vitro*.

JA Kroemer, BA Webb
U. of KY, Dept. of Entomology, S-226 Ag. Sci.Ctr. N., Lexington, KY 40546; jakroe@uky.edu

Polydnaviruses (PDVs) occur in obligate symbiotic associations with Ichneumonid (Ichnoviruses or IVs) and Braconid (Bracoviruses or BVs) wasps. PDVs are injected during parasitization, and viral gene products alter host physiology enabling endoparasitoid development. Our data represent investigations of a gene family (*vankyrin*) that is shared by both IV and BV genomes. Vankyrin proteins possess ankyrin repeats that resemble the inhibitory domains of NF-κβ transcription factor inhibitors (Iκβs). *vankyrin* genes from the *Campoletis sonorensis* IV (*Cs*IV) genome are expressed with different tissue specificities early during parasitization in *Heliothis virescens* larvae and can be divided into two subclasses: those that target host fat body nuclei, and those that target host hemocyte nuclei. The two different subclasses of *vankyrin* genes in *Cs*IV also exhibit different biological effects when expressed from recombinant *Ac*MNPV baculoviruses *in vitro*. Insect cell lines infected with viruses expressing fat body specific genes exhibit enhanced longevity compared to those infected with viruses expressing hemocyte specific genes. Preliminary electrophoretic mobility shift assays indicate that *Cs*IV vankyrin proteins can disrupt the ability of nuclear extracts to bind insect NF-κβ target sites *in vitro*. We hypothesize that *Cs*IV *vankyrin* proteins may suppress NF-κβ activity during immune responses and developmental cascades in parasitized hosts.

Using flow cytometry to determine differential hemocyte counts in suitable and unsuitable stemborer hosts parasitized by *Cotesia flavipes*.

M Alleyne, JB Nardi, BK Pilas, RN Wiedenmann
Center for Ecological Entomology, Illinois Natural History Survey, 607 E. Peabody ive, Champaign, Illinois 61820 USA, rnwieden@uiuc.edu

We used flow cytometry to determine differential hemocyte counts in partially suitable and unsuitable hosts (*Diatraea grandiosella* and *Ostrinia nubilalis*, respectively) parasitized by novel-association *Cotesia* spp. parasitoids around the time encapsulation occurred and compared results with those from the suitable host (*Diatraea saccharalis*). Flow cytometry has been useful to rapidly classify individual cells based on light scatter and fluorescence emission characteristics. The autofluorescence emission patterns of host hemocytes were analyzed, as well as emission patterns after labeling with florescein peanut agglutin (PNA). PNA selectively labels granular cells thought to be important in the host's immune response, but does not label plasmatocytes. We determined that flow cytometry is a useful method for studying the hemocytes of different lepidopteran species. Using this method we determined that there are clear differences in the proportions of plasmatocytes and granular cells depending on host species and developmental stage. However, differences in hemocyte proportions did not correlate with successful parasitization or the occurrence of encapsulation. In the future we will try to determine if functioning of the hemocytes involved in the immune response is altered after parasitization of suitable and unsuitable hosts.

Cytotoxic activity in the colleterial glands of *Antheraea yamamai* **against rat hepatoma cells**

M Yago, H Horaguchi, K Suzuki
Iwate Medical University, Morioka 020-8505, Japan; myago@iwate-med.ac.jp

Female insects, on oviposition, secrete a viscous fluid from their reproductive accessory glands, i.e., the colleterial glands, for fixing eggs. So far, some compounds have been found in the secretions of several species. For example, in praying mantises, phenolic compounds and enzymes have been found in addition to structural proteins as a main component, which are involved in the hardening of the ootheca or the eggcase (Yago *et al.*, 1984). Recently several anti-bacterial polypeptides have been found in the glandular secretions of flies (Marchini *et al.*, 1989, 1991, 1997; Tirone *et al.*, 2000), which protect the genital tract, eggs and larvae from microbial invasion. These findings suggest that such secretions in other species may also contain some new and bioactive substances. Thus, the colleterial gland of the Japanese wild silkmoth, *Antheraea yamamai,* was examined. When a crude extract of the glands was added to a suspension of rat hepatoma cells (Lh84 cell line), a majority of the cells were found to be dead after 24 h of incubation. The extract was further purified using HPLC and fractions were obtained exhibiting the same activity. The characterization of the active substance is currently under way.

Effects of venoms from two different species of pteromalid wasps on the spreading, viability & encapsulation capacity of *Pieris rapae* hemocytes

GY Ye, Z Zhang, J Cai, H Cui
Institute of Applied Entomology, Zhejiang University, Hangzhou 310029, China; chu@zju.edu.cn

Effects of venom from a pupal-stage endoparasitoid, *Pteromalus puparum* (Hymenoptera: Pteromalidae) on hemocytes of its host *Pieris rapae* pupae both *in vivo* and *in vitro* were measured by comparison with venom from a pupal-stage ectoparasitoid, *Nosonia vitripennis* (Hymenoptera: Pteromalidae) with no ability to parasitize *Pieris rapae* in nature. The spreading and viability as well the capability to encapsulate Sephadex A-50 beads of *Pieris rapae* pupae hemocytes were significantly reduced after treatment by *Pteromalus puparum* venom. The medium concentrations of the venom to inhibit encapsulation of host hemocytes *in vivo* and in *vitro* were 0.0425 VRE/pupa and 0.00007 VRE/µl, respectively. In contrast, *Nosonia vitripennis* venom did not appear to have any effect on *P. rapae* hemocytes either *in vivo* or *in vitro* under conditions as the same as treated by *P. puparum* venom. To compare these different findings, it is apparent that the physiological effect of the venom from a defined species against insect target hemocytes has its host specificity.

"Characterization & cDNA sequence of lysozyme of *Agrius convolvuli*"

JW Kim, BS Chang, SM Yoe
Dankook University, Cheonan 330-714, Korea; smyoe@dankook.ac.kr

A new family member of insect lysozyme, an antibacterial peptide, has been isolated from the hemolymph of the fifth instar larvae of *Agrius convolvuli*. *Agrius* lysozyme was isolated by cation-exchange chromatography and RP-FPLC, and sequenced by HPLC system. It was observed that the purified *Agrius* lysozyme was heat-stable and had a molecular weight of approximately 15 kDa by SDS-PAGE. The N-terminal amino acid sequence of *Agrius* lysozyme is K-H-F-S-R-C-G-L-V-Q-E-L-F-W-Q-G-F-P with the highest similarity to that of *Heliothis virescence*, and it has been identified that the *Agrius* lysozyme belongs to *c* type lysozyme. A cDNA clone encoding a lysozyme was isolated and its complete sequence was determined. The coding region indicates that this lysozyme consists of a 19 residues signal peptide and a 120 residues mature protein which is very similar to the other lepidopteran lysozymes. Total numbers of negatively charged residues (Asp and Glu) were 13 and positively charged residues (Arg, Lys and His) were 22. Eight Cys residues were conserved in the same positions as that of other insect lysozymes.

Purification and cloning of lysozyme from hemolymph of *Spodoptera litura*

JW Kim, YS Baek, SM Yoe
Dankook University, Cheonan 330-714, Korea; smyoe@dankook.ac.kr

Lysozyme is one of the components of the innate immunity of the insects. The lysozyme has been isolated by heat treatment, cation exchange, and reversed-phase chromatography from immunized hemolymph of last instar larvae of *Spodoptera litura*. Lysozyme level in immunized hemolymph was measured by ECL western blot analysis and was very high at 48 hours after injection with E. coli K12 (1×10^7). The molecular weight of *Spodoptera* lysozyme was estimated to be about 15 kDa by SDS-PAGE and it is great similarity with *Agrius* lysozyme, which recently purified from larval hemolymph of *Agrius convolvuli*. The 3' and the 5' regions of the lysozyme gene were amplified using the PCR protocol for the rapid amplification of cDNA ends (RACE). We will discuss this lysozyme.

The purification & characterization of a lipid transfer particle from wax moth, *Galleria mellonella* L.

JH Joe, HK Yun
Department of Biology, Hanseo University, 360 Daegok-Ri, Haemi-myen, Seosan, Choongnam, 356-706, South Korea; kyung813@hanseo.ac.kr

A lipid transfer particle (LTP) was purified from the larval hemolymph of wax moth, *Galleria mellonella* by two step KBr density gradient ultracentrifugation, anion exchange chromatography (DEAE-Trisacryl M), YM-50 ultrafiltration (Amicon) and gel permeation chromatography (Sephadex G-100). LTP is composed of three subunits (apoLTP-I, apoLTP-II, and apoLTP-III). Molecular weights of each subunit were determined (apoLTP-I = 280 kDa, apoLTP-II = 84kDa, and apoLTP-III = 55kDa). The confirmation of LTP was determined by western blotting with polyclonal antibody for *Bombyx mori* LTP because LTP is non species – specific. ApoLTP-I and apoLTP-III of *G. mellonella* react intensively with that of *B. mori* LTP whereas apoLTP-II react weakly with that of *B. mori* LTP.

Is the *Cotesia rubecula* venom protein calreticulin involved in the suppression of host defensive responses?

G Zhang, O Schmidt and S Asgari
Insect Molecular Biology Laboratory, Plant and Pest Science, Waite Campus, University of Adelaide, Glen Osmond SA 5064, Australia; guangmei.zhang@Adelaide.edu.au

Encapsulation is a major cellular defensive response of insects against intruding pathogens and parasitoids. Parasitoids have developed numerous mechanisms to suppress the host encapsulation by interfering with every step including recognition, adherence and spreading. During egg deposition, most endoparasitoid wasps inject maternal factors into hosts to suppress host immune reactions and ensure successful development of the parasitoid progeny. In previous studies, we isolated some *Cotesia rubecula* venom proteins, which inhibit melanization of host hemolymph by interfering with the pro-phenoloxidase activation cascade. Here we report the isolation and characterization of a novel venom protein, calreticulin, from *C. rubecula*. Results indicate that the protein may prevent encapsulation reactions. It is possible that the protein might function as an antagonist molecule competing for binding sites with the host calreticulin, which is involved in non-self recognition. Such inactivation might have synergistic effects in conjunction with the immunosuppressive action of a calyx protein Crp32, which protects the parasitoid eggs prior to expression of polydnaviruses.

Recent climate warming promotes the northward invasion in the swallowtail butterfly, *Papilio memnon* in Japan

M. Ishii & M. Yoshio
Entomological Laboratory, Graduate School of Agriculture and Biological Sciences, Osaka Prefecture University, Sakai, Osaka 599-8531, JAPAN, ishii@plant.osakafu-u.ac.jp

The swallowtail, *Papilio memnon*, is distributed widely from tropical to temperate zones in the Oriental region, and the northern limit of its distribution lies in western Japan. Recently the distribution has been expanding to northeastern areas in central Honshu. To investigate the relationship between the phenomena and characteristics of pupal diapause of this species, the photoperiodic response of 4 Japanese populations including the subtropical and northernmost ones was examined. Also we compared cold hardiness of pupae among the 4 populations. The critical photoperiod for inducing pupal diapause at 20C was 12 h 30 min in the subtropical population, and about 13 h in the 3 temperate ones. However, the differences in diapause intensity (about 100 days) and supercooling point (about -21C) among the 4 populations was small. Thus it may be difficult to explain the change in the distribution of this species from the change in characteristics of pupal diapause and cold hardiness of pupae. These results show that rising winter temperatures may be responsible for the recent northward invasion of this species.

The emergency life-history stage and immunosuppression in insects

SA Adamo
1355 Oxford St, Dalhousie University, Halifax, NS B3H 4J1 Canada sadamo@dal.ca

Events such as the appearance of a predator require an immediate, coordinated response from any animal, including insects. In vertebrates and mollusks, part of this rapid, emergency response typically involves a change in immune function, although the adaptive function of these changes remains unclear. In male crickets (*Gryllus texensis*) short bouts of flying (3 min, n=63), restraint stress (10 min, n=126), or cold stress (4° C for 10 min, n=69) resulted in increased susceptibility to the bacterium *Serratia marcescens* relative to controls. The immunosuppression lasted for approximately 20 min, depending on the stressor. Immediately after flight (n=12) and restraint stress (n=9), octopamine concentration increased in the hemolymph. Injections of octopamine (10^{-6} M) also reduced resistance to *S. marcescens* relative to saline injected controls. Crickets reared at high vs. low density showed no difference in their sensitivity to *S. marcescens*, nor did they differ in their baseline octopamine hemolymph concentrations. By examining how stressful events induce immunosuppression in insects, it may be possible to determine its functional significance across phyla.

Parasites may exploit a host's immune-neural connections to alter host behaviour

SA Adamo
1355 Oxford St., Dalhousie University, Halifax, NS B3H 4J1 Canada; e-mail: sadamo@dal.ca

The parasitoid wasp, *Cotesia congregata*, attacks the tobacco hornworm, *Manduca sexta*. Previous work has demonstrated that the inhibition of host feeding is mediated, in part, by elevated concentrations of octopamine in the host's hemolymph. The source of the excess octopamine is not the parasitoid. In this paper I show that the behavioural change in the host correlated with a decrease in the number of hemocytes in the host's hemolymph. The amount of octopamine in the cellular fraction of the hemolymph declined while the amount in the non-cellular fraction increased. Octopamine degradation in the plasma was also decreased. These results suggest that at least part of the increase in octopamine came from the host's hemocytes. Injections of lipopolysaccharides derived from *Serratia marcescens* (bacterium) increased octopamine concentrations in the hemolymph and suppressed feeding in normal *M. sexta*. Feeding was also suppressed by injecting octopamine or an octopamine agonist. An octopamine antagonist had no effect. These results suggest that the parasitoid may suppress host feeding partly by activating a possible immune-neural connection in the host.

A serine proteinase homolog venom protein inhibits activation of prophenoloxidase in insect haemolymph

S Asgari, G Zhang, Z-Q. Lu, H Jiang
University of Queensland, School of Biological Sciences, St Lucia QLD 4072, s.asgari@uq.edu.au

Most endoparasitic wasps inject maternal factors into their host haemocoel at parasitization to suppress the host immune system and ensure successful development of their progeny. Melanization, one of the insect defence mechanisms against intruding pathogens or parasites, is often inhibited following parasitization. We have isolated a 50 kDa protein in size from the venom of *Cotesia rubecula* (Hym: Braconidae) that blocks melanization in the haemolymph of its host, *Pieris rapae* (Lep: Pieridae). This protein, designated Vn50, is a serine proteinase homolog (SPH) containing an amino-terminal clip domain. Bacterially expressed Vn50 bound *P. rapae* haemolymph components that were recognized by antisera to prophenoloxidase (proPO) and proPO-activating proteinase (PAP). Vn50 is stable in the host hemolymph, remaining intact for at least 72 h after parasitization. Using *Manduca sexta* as a model system, we found that Vn50 efficiently down-regulated proPO activation mediated by *M. sexta* PAP-1, SPH-1, and SPH-2. Possible mechanisms of inhibition of proPO activation by Vn50 will be discussed.

Investigation on physiological effects of pyriproxyfen on greenhouse whitefly (*Trialeuroides vaporariorum* Westwood)

A Baghdadi
Plant protection department, Aboureihan campus, university of Tehran, Tehran-Iran. mbaghdadius@yahoo.com

Juvenoid compound pyriproxyfen is a potent suppressor of embryogenesis and adults formation of greenhouse whitefly, *T. vaporariorum.* Dipping of tobacco and tomato seedling infested with 0-1 day old eggs in 2.5 mg (AI) /liter resulted in total suppression of egg hatch. Older eggs were affected to lesser extent. Exposure of *T. vaporariorum* male and female for 48 h to tobacco and tomato leaves treated with 5 mg (A.I.)/liter resulted I oviposition of infertile eggs. This effect lesser persisted for an additional 2 day after transfer to untreated leaves. Treatment of second instars with 0.04-5 (A.I.)/ Liter pyriproxyfen resulted in normal development until suppressed in 5 m (A.I.)/Liter. At similar concentration the suppression of third instars observed. Second instars exposed to 5-25 mg (A.I)/Liter pyriproxyfen excreted honeydew at a level similar to the control until the pupation, after which reduction was observed. Inhibition of egg hatch on the lower surface of tobacco leaves was observed when their upper surface was treated with 1-25 mg (A.I.)/Liter indication a significant translational effect.

Does bioluminescence constitute an auxiliary mechanism against oxygen toxicity in click-beetles?

E Bechara
PO Box 26077, 05513-970 São Paulo, SP, Brazil, ebechara@iq.usp.br

A wealth of spectroscopic, chemical and biological data evidences molecular oxygen consumption to sustain the light reaction of the vast majority of bioluminescent (BL) organisms. In the case of BL beetles, all lampyrids, elaterids, and phengodids studied till now use the same luciferin to emit light, which ranges from green to red, depending on the specific luciferase tertiary structure. Interestingly, the levels of superoxide dismutase (SOD) – an important enzymatic antioxidant defence – are much lower (5x) in non-luminescent larval elaterids than in larvae of (luminescent) *Pyrophorus divergens* and respond to the pO_2 in the habitat: 3-fold higher in larval *Pyrearinus termitilluminans*, which lives in well-aerated tunnels excavated into termite mounds, than in *P. candelarius*, which dwells in decaying logs. Moreover, the bright thoracic segments of the *P. termitilluminans* larva are significantly richer (2-fold) in SOD than its abdominal dim segments. Exposure of *P. termitilluminans* larvae to hyperoxia induced both their luciferin concentration (50%) and luciferase activity (2-fold); total SOD activity also increased 50%. These and complementary data obtained from SOD, luciferase and urate studies carried out during the natural and the 20-hydroxyecdysone-induced development of larval *P. termitilluminans* suggest that bioluminescence and antioxidant systems may cooperate to minimize oxidative stress. Support: FAPESP, CNPq, PRONEX.

Host-parasitoid hormonal signaling and parasitism by *Cotesia congregata* in the tobacco hornworm *Manduca sexta*

NE Beckage, DB Gelman
Departments of Entomology & Cell Biology and Neuroscience, University of California-Riverside, Riverside, CA 92521 USA. nancy.beckage@ucr.edu

Hormones play a critical role in the growth and development of insect parasitoids. Host juvenile hormone and ecdysteroid levels are disrupted during parasitism of the tobacco hornworm by the gregarious braconid wasp *Cotesia congregata*. Following parasitization of host larvae in the fourth instar, the wasps emerge from developmentally arrested fifth instar larvae which have ceased feeding. Both juvenile hormone (JH) and ecdysteroids are produced by the parasitoids and secreted into the hemolymph of the host. In the host's last instar, the ecdysteroid titer of the host peaks at a level four-fold higher than the peak concentration found in prewandering unparasitized larvae, and in contrast to nonparasitized control larvae the parasitized larvae fail to expose the dorsal vessel or exhibit wandering behavior. The application of methoprene to parasitized larvae suppresses the emergence of parasitoids from the host, and also appears to interfere with the release of ecdysis-triggering hormone in the parasitoid. Results in this system will be compared to recent findings in other host-parasitoid associations.

Identification of the polydnavirus CrV1 gene homolog in *Cotesia congregata*

N Beckage, J Lenz, C Núñez , K Amaya, MA Roíguez-Pérez
Departments of Entomology & Cell Biology and Neurosciences, University of California, Riverside, CA 92521, USA, nancy.beckage@ucr.edu.

The CrV1 gene of *Cotesia rubecula* polydnavirus (PDV) suppresses the cellular immune system of *Pieris rapae* larvae. Although the gene was originally described in *C. rubecula*, CrV1 gene homologs exist in several *Cotesia* species. A CrV1 homolog gene has been identified in *C. congregata* PDV. The *C. congregata* PDV not only suppresses the immune response but it may also be involved in causing hemocyte apoptosis in parasitized *Manduca sexta* larvae. Although CrV1 is expressed in a transient manner (4-8 hpp) in *P. rapae*, it is continuously expressed (from parasitization to emergence of the parasitoid wasp) in *M. sexta*. This paper reports the cloning and sequencing of the CrV1 gene homolog in *C. congregata*. The final goal is to develop a hybrid baculovirus containing the immune-suppressive gene of the PDV that can be tested against several important insect pests.

Why do insects breath discontinuously?

TJ Bradley
Dept. of Ecol. & Evol. Biology, Univ. of California, Irvine, CA, USA 92697-2525

The insect respiratory system consists of a branching tracheal system controlled at the openings to the atmosphere by spiracular valves. Insect physiologists have long been fascinated and puzzled by the complex control patterns observed in these spiracular valves. In particular, the Discontinuous Gas Exchange Cycles (DGC) with its Open, Flutter and Closed Phases has been the subject of much study. The most widely accepted explanation for discontinuous ventilation is that it reduces respiratory water loss. I will provide evidence in support of an additional explanation, namely that insects close their spiracles not to impede the loss of water but to reduce internal partial pressures of oxygen. The Open Phase is necessitated by the accumulation of carbon dioxide in the insect's hemolymph, tissues and tracheae. Following the Open Phase, the insect's tissues are "over-oxygenated" posing the risk of oxidative damage. The Flutter and Closed Phases serve the purpose of reducing internal oxygen partial pressures. The insect respiratory system is designed to provide oxygen and remove carbon dioxide at rapid rates during periods of high metabolic demand. At rest, DGC serves the purpose of protecting the insect's tissues from the damaging effects of elevated partial pressures of oxygen.

Oxygen transport and storage proteins in insects

T Burmester
Institute of Zoology, University of Mainz, Germany, email: burmeste@uni-mainz.de

The aerobic metabolism of animals requires the supply of the internal tissues with sufficient amount of oxygen. Gas-exchange in insects and other terrestrial arthropods is mediated via trachea. For this reason, specialized O_2-transport or -storage proteins have long been regarded unnecessary in most insects, though high concentrations of hemoglobin in the millimolar range have been observed in the hemolymph of species that live under hypoxic conditions, such as the chiromonid midges, the horse botfly *Gasterophilus intestinalis*, or some aquatic Hemiptera. However, we have recently shown that intracellular hemoglobins are also present at lower concentrations (< 10 µM) in various insect species. In the fruitfly *osophila melanogaster* prominent hemoglobin expression is mainly associated with the trachea. In addition, in the hemolymph of some basal insects (e.g. Plecoptera, Thysanura), we isolated a hemocyanin that that reaches concentrations typical for arthropod hemocyanins. Oxygen binding characteristics are similar to that of crustacean hemocyanins. These observations suggest that oxygen supply in insects is more complex than previously thought, and may depend on protein-mediated transport and storage in addition to simple tracheal diffusion.

Physiological regulation of the same lepidopteran host, *Cotesia plutellae* Kurdjumov, by parasitoid's products of three different hymenopteran endoparasitoid species

XX Chen, SF Bai, WD Li, JA Cheng
Institute of Applied Entomology, Zhejiang University, 268 Kaixuan Road, Hangzhou 310029, China. xxchen@zju.edu.cn

Three hymenopteran endoparasitoids, *Cotesia plutellae* (Braconidae), *Diadegma semiclausum* (Ichneumonidae) and *Oomyzus sokolowskii* (Eulophidae) were used to evaluate the effects of parasitoid's products on the lepidopteran host, *Plutella xylostella* L. *C. plutellae* injects PDVs (BVs) and venom into host during its oviposition and teratocytes are produced after parasitoid's embryos develop in host, *D. semiclausum* deliveries PDVs (IVs) and venom into host but no teratocytes are developed, while *O. sokolowskii* only has venom. The results showed that the last-instar host larvae were significantly prolonged and failed to pupate when they were parasitized by *C. plutellae*, while the hosts were also arrested but still could reach the pre-pupal stage when they were parasitized by *D. semiclausum*, whereas host development and metamorphosis were not significantly interfered by *O. sokolowskii*. Similarity analyses of haemolymph proteins of parasitized host larvae proved that the parasitoid's products determine the regulatory ability of parasitoids on host development. Inter-specific competition experiments testified that *C. plutellae* has the strongest ability of parasitism, which partly resulted from the function of teratocytes that also prevent synparasitism from occurrence. The results also showed that different parasitoids have different physiological effects on the host fat bodies. The physiological mechanisms for inter-specific competition of endoparasitoids were discussed in the end.

Ecological and evolutionary patterns in insect metabolic rate and gas exchange

SL Chown, E Marais
Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland 7602, South Africa, e-mail: slchown@sun.ac.za

Metabolic rate is one of the most significant characteristics of organisms. It provides an estimate of the costs of living, and can therefore provide insight into the evolution of life histories across a range of environments. In consequence, much attention has been given to the factors explaining metabolic rate variation, and the way in which gases are exchanged to meet metabolic demands whilst not compromising other aspects of an organism's physiology. Despite this attention, surprisingly little is known about many aspects of variation in insect metabolic rates and gas exchange patterns. Here, we explore ecological and evolutionary patterns in insect metabolic rate and gas exchange. In particular we consider phylogenetic variation in gas exchange patterns and the way in which this variation can be analyzed, environmental (particularly temperature and water availability) correlates of metabolic rate and gas exchange pattern, and body size related variation in metabolic rate.

Identification of isopeptidase activity in the midgut of insects: purification and properties of a *Hofmannophila pseudospretella* (Lepidoptera: Oecophoridae) larval enzyme and possible nutritional ecology

RM Simpson, JT Christeller
Horticulture and Food Research Institute of NZ, Tennant drive, Palmerston North, Private Bag 11 030, New Zealand. jchristeller@hortresearch.co.nz

A g–glutamyl transpeptidase (isopeptidase) has been purified 580-fold to homogeneity from the midgut of keratinophagous larvae of *Hofmannophila pseudospretella*. The enzyme is a single peptide of molecular mass 80 kDa. The enzyme was identified by its hydrolytic activity against the synthetic substrate, g–glutamyl-AMC, its molecular mass and inhibition profile compared to other g–glutamyl transpeptidases and by its fragmentation pattern during mass spectrometry. The enzyme is low or absent from most other insect digestive systems apart from other keratinophagous lepidopteran larvae and predatory carabids. While isopeptide bonds are present in high levels of the proteins in the diet of keratinophages their presence in the diet of predatory beetles has not been established.

Regulation of protein expression of *Heliothis virescens* parasitized by *Toxoneuron nigriceps* at the transcriptional level.

FL Cônsoli, SB Vinson.
Department of Entomology, Texas A&M University, College Station, TX, 77843-2475, USA. e-mail: f-consoli@tamu.edu; bvinson@tamu.edu

The endoparasitoid *Toxoneuron nigriceps* has been shown to alter the availability of circulating proteins in the hemolymph of parasitized hosts. Some of the proteins affected are the host storage proteins, and they represent the majority of the proteins available and are key in sustaining processes associated with host metamorphosis. They are also thought to be an important nutritional resource to the developing parasitoid, serving as a source of phenolic amino acids that will be required at the end of the parasitoid larval development. We will report the changes in the level of expression of host proteins involved in developmental processes regulated by this parasitoid, and discuss its implications in the manipulation of the host as a nutritional environment.

DISEASE RESISTANCE IN CROWDS, DENSITY-DEPENDENT PROPHYLAXIS IN THE EGYPTIAN ARMYWORM

SC Cotter, RS Hails, JS Cory, K Wilson
CSIRO Entomology, Private Bag 5, PO Wembley, WA 6913, Australia. Sheena.Cotter@csiro.au

Several insect species display altered phenology and behaviour during outbreaks, a phenomenon known as density dependent phase-polyphenism. The crowded phase is characterised by darkening or melanization of the cuticle, making these individuals more conspicuous than solitary phase individuals. The adaptive value of melanism in the crowded phase is unclear but it may be linked to disease resistance. The density-dependent prophylaxis hypothesis, states that as the risk of parasitism is expected to increase with population density, so species that encounter large fluctuations in density may alter their investment in costly immune defences to match the probability of exposure. Despite growing evidence that insects in high-density populations show increased resistance to certain pathogens, few studies have examined any underlying alteration in immune function. The aim of this study was to quantify variation in immunity associated with solitary and crowded phases in a phase-polyphenic Lepidopteran species (*Spodoptera littoralis*). Relative to pale individuals, melanic larvae exhibited higher haemolymph and cuticular phenoloxidase (PO) activity, and exhibited a stronger encapsulation response to an artificial parasite. Conversely, pale larvae had higher antibacterial activity than melanic larvae. These results are examined in relation to pathogen resistance, and the possibility of a trade-off within the immune system is discussed.

Pharma-entomology: From bugs to drugs

J-L Dimarcq

Scientific Partnering Director, Entomed S.A. Rue Tobias Stimmer F67400 Illkirch, France

For decades, natural products, originating largely from plants and microbes, have been a wellspring of new drugs generating more than half of the new drugs registered. However, many pharmaceutical companies have abandoned natural products in favour of mass-produced fully synthetic combinatorial libraries. The expected surge in productivity has not materialized resulting in a marked decline in the output of the R&D programs and, as a consequence, putting a new emphasis on the exploration of biodiversity. Insects represent a major untapped source of novel candidates for drug development. Although they represent the largest and arguably the most successful group of organisms in the world, insects are still largely overlooked as a source of new drug molecules. Insect-derived molecules have a huge variety of potential uses for treating human diseases. From anti-microbial peptides that use completely novel mode of action, to anti-proliferative small molecule drugs, via anti-inflammatory, anti-viral and ion channel modulator molecules, the full scope and breadth available is yet to be realized. Entomed has recognized the promise held by the extraordinary insect chemical versatility and is combining expertise in insect biology, ethno-pharmacology with essential drug discovery and development skills to build the new field of 'pharma-entomology'.

Respiratory strategies used by desert beetles

FD Duncan
School of Animal, Plant and Environmental Sciences, University of the Witwatersrand, Private Bag 3, WITS 2050, South Africa,
duncanfd@biology.biol.wits.ac.za

This comparative study investigated the different spiracles and forms of respiration used by arid-dwelling beetles to reduce respiratory water loss. The beetles were collected from arid areas within southern Africa and Australia, and possessed a sealed subelytral cavity. Thus, in these beetles, the first pair of spiracles (mesothoracic) opens into the external dry air whereas all the other seven pairs (metathoracic and abdominal) open into the more humid air within the subelytral cavity. Using flow-through respirometry the carbon dioxide emission and oxygen uptake was measured from the mesothoracic spiracles separately and simultaneously with that from around the elytral case. The mesothoracic spiracles were not the main site of gas exchange in all the beetle species, although increased use of these spiracles was associated with increased habitat aridity. The discontinuous gas exchange pattern, another method used by beetles to reduce respiratory water loss, was not observed in all the species. However, most of the species used more convection than diffusion for carbon dioxide emission, regardless of whether the spiracles were closed intermittently or not. The site of oxygen ingress was also determined. These results are explained in the context of elytra shape, food type and activity pattern of the different species.

Dielectric waveguide antenna theory helps explain insect detection of enantiomers

TM Dykstra
Dykstra Laboratories, Inc. 3499 NW 97th Blvd., Suite 6 Gainesville, FL 32606 USA

Many decades ago, a debate arose as to how insects detected semiochemicals. One group maintained that detection was accomplished by electromagnetic energy emanating from the semiochemical, while the other group maintained that the molecule fit into a receptor in order for it to be detected. The latter group's theory is termed the "lock and key model". It is the predominant theory today. The former group's theory was termed the "vibrational theory of odor" by Robert Wright in the 1950's. In the 1960's, Philip Callahan offered a mechanism for this detection whereby the insect sensillae act as dielectric antennae. Behavioral and electrophysiological tests involving the detection of enantiomers could not be easily explained by either theory. Some insects could differentiate between enantiomers while others could not. A more thorough knowledge of antenna theory reveals that enantiomer detection can be explained by the dielectric antenna model. Additionally, replicas of insect sensillae can be artificially reproduced by conventional lasers to make efficient infrared detectors.

Towards an integrative analysis of midgut function in *Helicoverpa armigera*

P East, A Cao, P Campbell, G Colebatch, K Gordon
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia. Peter.East@csiro.au

CSIRO Entomology has a significant research effort on lepidopteran gut physiology, focussed on digestion, dietary adaptation to natural host plant defence chemistry and the molecular and genetic basis of polyphagy. Our principal target insect is the noctuid *Helicovera armigera* and the project is taking an integrative approach that employs genomic, proteomic and molecular cell biology techniques in conjunction with more traditional physiological methods. The presentation will summarise our recent progress. An Expressed Sequence Tag database was constructed for genes expressed in the larval midgut. From approximately 10,000 clones, a non-redundant gene set consisting of approximately 3900 sequences was identified. This non-redundant gene set has formed the basis for construction of cDNA microarrays that are being used to analyse transcriptional responses to larval feeding on a range of synthetic and natural diets, including chickpea species and *Arabidopsis* ecotypes with differing levels of resistance to *H. armigera* feeding. To complement the genomics-based work, we are concurrently analysing the midgut proteome using 2D-PAGE display, mass spectrometry and functional protein iling. The major classes of digestive hydrolases, including proteinases, carbohydrases and lipases, have been identified from the EST database. The information obtained considerably extends our current understanding of these gene families in lepidopteran insects.

Insects as flying machines

CP Ellington
Dept. of Zoology, Univ. of Cambridge, Downing Street, Cambridge CB2 3EJ, UK. c.ellington@zoo.cam.ac.uk

Insects are small flying machines with an apparent disregard of good aerodynamic practice. Instead of producing lift with their wings, some butterflies rely on ag for slow flight. Tiny insects were predicted to 'swim' through the air using ag, but they rely more on lift. Hovering dragonflies and hoverflies flap their wings in a plane inclined to the horizontal. They use dynamic stall on the downstroke to support their weight, and their lift-to-ag ratio is necessarily less than 2. Most hovering insects flap their wings in a horizontal plane, using lift on both the downstroke and upstroke to support their weight. A leading-edge vortex created by dynamic stall enhances lift production. Because of flow separation at the leading edge, the resultant aerodynamic force is approximately normal to the wing surface, and the lift-to-ag ratio is again typically less than 2. The lift-to-ag ratios for all high-force mechanisms employed by insects are appallingly low by conventional standards, and would entail a high power consumption for fixed and rotary wing designs. For small man-made flying machines to exploit these mechanisms, a flapping motion is essential to ensure that weight is supported by the resultant aerodynamic force and not just the lift.

Caterpillar secretions and induced plant responses: multiple glands mediate plant responses

GW Felton
Department of Entomology, Penn State University, University Park, Pennsylvania. 16802. United States of America. Email: gwf10@psu.edu

Noctuid larvae produce secretions from several glands during feeding. The secretions originate from two separate salivary glands (i.e., labial and mandibular) and from the eversible cervical gland. Each of these secretions may play a significant role in mediating induced responses in their host plants. We have employed a variety of techniques including physical ablation of the structures and genetic ablation (RNAi suppression of genes) to investigate the functional roles of these secretions. The noctuid *Helicoverpa zea* secretes massive amounts of the salivary protein glucose oxidase during feeding on its host plants. We have found that in certain hosts, this enzyme suppresses the induced defenses of the plant, but in other instances may act as an elicitor.

Citrus leafhopper IPM in Queensland, Australia

CG Freebairn
Queensland Department of Primary Industries & Fisheries, Maroochy Research Station, PO Box 5083, SCMC, Nambour, 4560;
chris.Freebairn@dpi.qld.gov.au

Empoasca smithi, is a serious pest of the valuable early varieties Imperial mandarin and Navel orange, and in bad years also of mid- and late-season varieties in Queensland's Central Burnett area. Adults, which breed and feed on flush growth through spring and summer, switch in autumn and winter to green mature and colouring fruit where they cause skin blemishes, downgrading of up to 80% of fruit. Two mymarid wasp parasitoids, *Stethynium empoascae* and *Anagrus baeri*, kill up to 100% of eggs, but need insecticide assistance in most years. Endosulfan at 30 ml/100 L is cheap and effective, killing both nymphs and adults, but must be re-applied to kill hatching nymphs. The insect growth regulator buprofezin kills only nymphs, but also is very effective, though expensive - but contributes significantly to red scale and mealybug control. An orchard-wide strategy and good scouting and decision making is required to prevent re-infestation of treated trees by adults dispersing from hardening flush in untreated trees, especially in late autumn from mid-season varieties with non-susceptible fruit to early season varieties with maturing fruit, and from the common exotic weed tree species *Celtis sinesis*. The benefit to growers of this research is estimated at $11,250-$38,500/ha.

Host-parasite interactions between whiteflies and their parasitoids

DB Gelman, D Gerling
Insect Biocontrol Lab, USDA, ARS, Bldg. 011A, Rm. 214, BARC West, 10300 Baltimore Ave., Beltsville, MD 20705, USA, gelmand@ba.ars.usda.gov

Host-parasite interactions that occur between lepidopterans and their parasitoids are well-documented, but little is known about similar interactions between whiteflies and their parasitoids. Currently, there is no evidence to support the existence of wasp-associated polydnaviruses or venom in redirecting whitefly metabolism, including interference with the immune response. The production of teratocytes by whitefly parasitoids (may play a role in protecting the parasitoid) has been observed for *Encarsia berlesei* and *E. citrina*. Manipulation of hormone titers, so common in parasitized lepidopterans, also occur in parasitized whiteflies. In the *Eretmocerus-Bemisia* system, ecdysteroid titers decrease upon parasitization. However, *Encarsia. formosa* developing in both the greenhouse whitefly (*Trialeurodes vaporariorum*) and the sweet potato whitefly (*Bemisia tabaci*, biotype B) will not molt to its 3rd (last) instar until the whitefly has initiated adult development, a time when host ecdysteroid titers are known to peak. In the *Trialeurodes lauri-Encarsia. scapeata* system in which host and parasitoid enter diapause in May-June, it appears that *E. scapeata* is able to prematurely trigger the initiation of its host's development. These and other host-parasite interactions will be discussed.

Calyx fluid proteins of two biotypes of *Cotesia sesamiae* (Hymenoptera: Braconidae) in Kenya: Implications to biocontrol of *Busseola fusca* (Lepidoptera: Noctuidae)

CW Gitau, AJ Ngi-Song, D Stephane, F Schulthess, E. Osir
ICIPE-WAU, P O Box 30772-00100, Nairobi, Kenya, cgitau@icipe.org

Busseola fusca Fuller (Lepidoptera: Noctuidae) is a major stem borer causing damage to cereal crops, especially maize, in most of sub-Saharan Africa. *Cotesia sesamiae* (Cameron) (Hymenoptera: Braconidae) is an indigenous gregarious larval endoparasitoid of *B. fusca* in Kenya and other countries of Africa. There is renewed interest in expanding the geographic range of biocontrol agents of cereal crops in sub-Saharan Africa. One of the targeted agents is *Cotesia sesamiae*, whose importance varies considerably between regions for yet unknown reasons. In Kenya, reports suggest that *C. sesamiae* occurs in two biotypes with different abilities to develop in *Busseola fusca*. A *C. sesamiae* population from coastal Kenya, where *B. fusca* does not occur, does not complete development in *B. fusca* and all its eggs are encapsulated. However, *C. sesamiae* successfully parasitizes *B. fusca* in western Kenya where they occur sympatrically. Recent studies showed that calyx fluid of the two strains is involved in suppression of the immune system of *B. fusca*. Hence the proteins involved in the suppression are genetically different. This study analyses and compares proteins of calyx fluid of these two *C. sesamiae* populations using 2d-Gel electrophoresis and discusses the implications of using *C. sesamiae* as a biocontrol agent in Africa.

Mechanism in the bug *Coreus marginatus* (Heteroptera, Coreidae)

PJ P Goodwyn, SN Gorb
Evolutionary Biomaterials Group, Abt. Arzt. Max-Planck-Institut fuer Metallforschung. Heisenbergstr. 3. D-70569 Stuttgart, Germany. Perez-Goodwyn@mf.mpg.de

The structure and function of the hemelytra-to-hindwing locking mechanism of the bug *Coreus marginatus* were analysed. The system consists of a cuticular protrusion in the ventral side of the hemelytra, which locks the subcostal border of the hindwing in flight. The speed and distance slid by both surfaces against one another during flight were assessed using a combination of high-speed video recordings and a 2D geometrical model. The friction coefficient between sliding surfaces was assessed using a micromanipulator, coupled with force transducers. This was done under three experimental conditions: freshly dissected, air dried and rehydrated ethanol preserved samples. The results showed a high speed of sliding, approximately 0.18 $m \cdot s^{-1}$, with a relatively low friction coefficient (0.2 μ). The surface morphology of this mechanism, namely outgrowths of one part having rounded edges, and completely flat surface on the counterpart, effectively aids in the reduction of friction at the microscopical level. The structure is effective even y, and after being preserved in ethanol, suggesting that no cuticle secreted lubrication substance is responsible for its effectiveness. The ultrastructure presumably confers mechanical stability to the system under the high load it is subjected to in flight.

Mandible movements: biting and prey capture

W Gronenberg
ARL-Neurobiology, University of Arizona, 602 Gould-Simpson Building, Tucson, Arizona, 85721, USA

In many insects, the mandibles are the most powerful mouthparts used for biting, chewing and prey capture. In ants, mandibles are involved in diverse tasks such as manipulating larvae or fungus gardens, grooming, carrying heavy loads, chewing, digging, biting, and predatory strikes. Mandibles generate a wide range of forces and velocities ranging from the softest touch to forceful seed cracking or super-fast strikes. Mandible closer muscles are the largest muscles in the body of ants and are composed of sets of muscle fibers that differ in their morphological and contraction properties. Force and speed output also depend on the arrangement of muscle fibers and apodemes (tendons) within the head capsule, which are reflected by the head shape (long heads = fast, broad heads = forceful). Mandible muscles are supplied by arrays of large motor neurons integrated into sensory feedback circuits that allow the required subtle force control. A particularly fast predatory mandible strike has independently evolved repeatedly in different ant taxa. These 'trap-jaws' are powered by a catapult mechanism and comprise some of the fastest reflexes known.

Respiratory response of insects to hypoxia and anoxia

VS Haritos, G Dojchinov,
GPO Box 1700, Canberra, ACT 2601, Australia, victoria.haritos@csiro.au

The respiratory responses in insects that are highly tolerant to hypoxia may contribute to their adaptation to these environments but are not well understood. We have investigated the respiratory response of individual insects to hypoxia using a sensitive, flow-through CO_2 and water analyser, coupled with an O_2 probe. Respiration rates and patterns in *Tenebrio molitor* larvae exposed to reduced O_2 for 10 min, then returned to normoxia, were monitored. In 10, 5 and 2% atmospheres the normal ventilation patterns of the larvae were completely disrupted although the output of CO_2 was maintained; this pattern suggests the larval ventilation rate had been greatly increased and the spiracles remained open during hypoxia. When the larvae were returned to normoxia, CO_2 release was significantly depressed in the larvae exposed to 5 and 2% O_2 and recovery was slow. Mild hypoxia (15% O_2) had little discernable effect on ventilation pattern or volume of CO_2 released. The respiration in highly tolerant *Sitophilus oryzae* larvae was strongly suppressed during 1 h of anoxia but had recovered to its normal pattern within 10 min of returning to normoxia. Respiratory water loss was minimal in both insects during short exposures to hypoxia despite the increased ventilation rate in *T. molitor*.

Rearing oxygen effects on body and tracheal morphology in insects

JF Harrison, J Henry, K Greenlee, S Hetz
Arizona State University, School of Life Sciences, Tempe, AZ USA 85287-4501

Normal development of the tracheal and body morphology of insects can be influenced by tissue oxygen levels. This oxygen-responsiveness provides a mechanism by which insects can compensate for variation in rearing oxygen level. Despite the many mechanisms of physiological compensation available, micro-electrode measurements in locusts indicate that tissue oxygen levels correlate with air oxygen content. Single-generation exposure of fruitflies to hypoxia or hyperoxia induces compensatory changes in the diameters of the dorsal longitudinal tracheae. Multi-generation exposure to hypoxia or hyperoxia (laboratory natural selection experiments) produces heritable changes in tracheal diameters, indicating that rearing oxygen level can influence the evolution of tracheal dimensions. Body size is positively correlated with rearing oxygen levels in fruitflies for both single-generation and multi-generational experiments, consistent with the notion that atmospheric oxygen can limit insect size. However, effects of atmospheric oxygen level on body size are inconsistent across insect species (mealworms, locusts), so perhaps responsiveness of body size to oxygen depends on phylogenetic history or ecology.

Gregarious development of a solitary endo-parasitoid in its habitual hosts

EM Hegazi, WE Khafagi
Faculty of Agriculture, Alexania University, Alexania, Egypt, eshegazi@hotmail.com

Microplitis rufiventris Kok. wasp attacks and can develop on earlier instars of *Spodoptera littoralis* (Boisd.) larvae with preference to third ones. All experiments were carried out using the newly moulted 6th instar larvae (reluctance hosts) at two different temperatures (20±1 and 27±1°C) to test the effect of variable ranges of superparasitization on the developmental interaction between the parasitoid and its host larvae. The effects seem to be dose (no. of eggs + parasitoid factors)-temperature-dependent. In all experiments, neither controls nor stung larvae underwent a larval/larval moult. The parasitoid eggs in singly parasitized host larvae invariably died. However, as the number of parasitoid eggs/host larvae increased, the rate of parasitoid's egg hatching and number of parasitoid larvae successfully reached to their final instar increased. This indicates that the parasitoid has become submissive to the others and stopped fratricide probably due to host's hormone and/or excessive dilution of factors injected with parasitoid eggs. The wasp larvae developed normally to the point of emergence but most did not successfully emerge from the host. The improvement of hatchability and normal post-embryonic development of parasitoid wasp were significantly ($P<0.01$) greater at low temperature (20°C) than at higher one (27°C).

Mechanisms for regulating oxygen delivery in pupae

SK Hetz
Dept. of Animal Physiology, Humboldt-University at Berlin, 10115 Berlin, Germany, stefan.k.hetz@rz.hu-berlin.de

Moth pupae are a useful model to investigate the regulation of oxygen uptake in insects. Due to their large size, the uptake of respiratory gases into the tracheal system can be studied directly by small electrodes inserted through single spiracles eventually combined with standard respiratory techniques. We investigated the regulatory capabilities in diapausing moth pupae showing a DGC both under normoxic, hypoxic and hyperoxic conditions. The main part of gas exchange takes place via the spiracles. In order to meet the aerobic metabolic demands of the tissues, moth pupae adjust spiracular conductance by modulation of opening frequency, area and duration. During "microopening", oxygen enters the tracheal system by two mechanisms: convection along a hydrostatic pressure gradient and diffusion, following an partial pressure gradient. We found that oxygen uptake by convection plays a role shortly after the constriction period whereas in the further stage of the fluttering period diffusion plays the main role. Modulating ambient oxygen partial pressure evoked a quick change in spiracular conductance despite of crucial changes in ambient oxygen partial pressure. Under hyperoxic conditions, pupae decreased spiracular conductance by restricting the number of microopenings. The morphological and physiological parameters used to regulate oxygen uptake are discussed in a model.

Contribution of dietary antioxidants (ascorbate and plant phenolics) and low O_2 to the powerful antioxidant capacity of *Manduca sexta* midgut fluid

KS Johnson
Dept. of Biological Sciences, Ohio University, Athens, OH USA 45701

Many folivorous caterpillars ingest large quantities of phenolics that can potentially produce reactive by-products, such as semiquinone radicals, hydroxyl radicals and superoxide when oxidized in the midgut. However, the extent to which these actually induce oxidative stress in insects is still debated. In some taxa, oxidative reactions may be minimized by the presence of endogenous or dietary antioxidants or low O_2 availability in the lumen. The midgut fluid of *Manduca sexta* has a powerful antioxidant capacity, and molecular O_2 is rapidly depleted to near-anaerobic conditions. We will present data on the biochemical mechanisms that underlie this phenomenon. We will also show that at least in *Manduca*, ingested phenolics (quercetin, catechin, chlorogenic acid and tannic acid) appear to retain their antioxidant properties (ability to quench a solution of ABTS radical) when mixed with midgut fluid or hemolymph. Caffeic acid exhibits only modest prooxidant properties when mixed midgut fluid. Overall, however, phenolics contribute relatively little to the total antioxidant capacity of the midgut fluid, as demonstrated by comparisons before and after their removal with polyvinylpyrrolidine. The powerful antioxidant nature of midgut fluid is also relatively insensitive to the availability of ascorbate in the diet.

Changes in the haemolymph proteome of the host *Spodoptera littoralis* (Noctuidae) if parasitized by the parasitic wasp *Chelonus inanitus* (Braconidae)

M Kaeslin, B Lanzrein
Institute of Cell Biology, University of Berne, Baltzerstrasse 4, 3012 Berne

Successful parasitism of many endoparasitic wasps depends on the supporting action of symbiontic polydnaviruses. *Chelonus inanitus* induces in its host a precocious onset of metamorphosis and a developmental arrest in the prepupal stage. The polydnavirus prevents encapsulation of the parasitoid and causes the developmental arrest, while the parasitoid is responsible for the precocious onset of metamorphosis. Here we report that substances in the haemolymph of polydnavirus/venom containing hosts must be responsible for the developmental arrest. To get an overview of the changes in the protein composition in the haemolymph of non-parasitized, polydnavirus/venom containing and parasitized larvae we analysed the haemolymph proteome by 2D-gel electrophoresis in various stages. In addition, proteins released by the parasitoid larva were analysed. We found that 8 proteins are due to polydnavirus/venom and are analysing them in more detail. 6 proteins are due to the parasitoid larva. Some of the parasitoid released proteins could already be N-terminally sequenced and might play a role in inducing the precocious onset of metamorphosis.

Endoparasitic Strepsiptera masquerade as self in host-derived epidermal bag

J Kathirithamby, L Ross, JS Johnston
Department of Zoology, South Parks Road, Oxford OX1 3PS

Stichotrema dallatorreanum Hofeneder (Strepsiptera: Myrmecolacidae) manipulates host epidermal tissue and wraps itself within it; which probably camouflages the endoparasitic stages; which probably camouflages the endoparasite and is recognized as ``self'' by the host. This mechanism is one of immune avoidance among parasitoid insects. The host-derived epidermal ``bag'' might have enabled Strepsiptera to radiate to disparate hosts compared with the relatively few taxa (596 species) described so far. They have been recorded as parasitizing 34 families belonging to seven orders of Insecta. While enclosed in the bag an unusual mechanism of insect ecdysis occurs between the first- and second-instar larval stages whereby the cuticle of the 1st instar breaks along the base of the head capsule instead of along the mid dorsal line, as in other insects. The endoparasitic stages undergo apolysis without ecdysis while enclosed within the "bag".

Polydnavirus genome sequencing: exploring polydnavirus structure and gene function through comparative genomics

JA Kroemer, SN Deborde, K Tanaka, WE Barney, A Makkay, W Rattanadechakul, K Bale, D Stoltz, MR Strand, BA Webb
U. of Ky, Dept. of Entomology, S-226 Ag. Sci.Ctr. N., Lexington, KY 40546, jakroe@uky.edu, bawebb@uky.edu

Polydnavirus (PDV) sequencing projects have provided novel insights into PDV genome organizations and unique opportunities for exploring viral gene composition and function. Comparisons between the *Campoletis sonorensis* Ichnovirus (*Cs*IV), *Hyposoter fugitivus* Ichnovirus (*Hf*IV) and *Microplitis demolitor* Bracovirus (*Md*BV) genomes have revealed consistencies in aggregate genome sizes and the presence of repetitive non-coding sequence, but have delineated distinct differences in gene composition, viral segment number and topology occurring both within and between the PDV genera. Comparisons between coding sequences within these PDVs indicate the presence of diverse genes and multi-gene families that are unique to individual viral species, conserved within viruses of a given genus, and conserved between viral DNA of both IV and BV origin. Database searches against viral ORFs indicate that many possess significant similarity to known insect genes suggesting that PDVs are accumulating and diversifying invertebrate host genes for pathogenic viral activity. Ongoing analyses of gene and protein expression patterns, sequences, and functions have begun to elucidate that variants within gene families, such as the *Cs*IV *cys-motif* family and the conserved *Cs*IV, *Hf*IV, and *Md*BV *viral ankyrin/I*kb families, may be evolving to play both redundant and unique physiological roles during parasitization.

Balancing oxygen uptake, CO_2 release and water loss in *Periplaneta americana* L.

P Kestler
University of Osnabrück, Faculty of Biology, Zoology, Germany, kestler@uos.de

An enhanced Krogh model reveals the limitations of continuous O_2 uptake, continuous CO_2 release and H_2O loss at changing oxygen demands: continuous exchanges would be limited by a hyperoxic tracheolar $^{TRL}P_{O2}$ of ca. 15 kPa due to the limited maximal $^{TRL}P_{CO2}$ of 6 kPa. Cockroaches utilize the dangerous $^{TRL}P_{O2}$ as a reserve during bouts of running, walking or preening by CO_2 retention in body buffers in a closing strategy (CS) which also prevents H_2O loss. At the minimal $^{TRL}P_{O2}$ of ca. 1 kPa the accumulated CO_2 is released irregularly by autoventilation. This maximises convective and diffusive O_2 and CO_2 fluxes over the H_2O fluxes as DP_{O2} and DP_{CO2} rise in contrast to the constant DP_{H2O} in a specifically water saving partial pressure strategy (PPS). Resting insects use a combined CS+PPS in CFB cycles where DP_{O2} is maximized in C (closed) periods, and DP_{CO2} is further maximized over DP_{H2O} between repetitive micro-openings in F (flutter) periods in which there is maximal O_2 influx. Adult insects, except ants, use the CS+PPS combination during active ventilation (V) even in the burst (B): in CFV cycles diffusive and convective CO_2/O_2 fluxes are confined to short expiratory/inspiratory openings of the spiracles to retain H_2O specifically.

Characterisation of the digestive system of grape phylloxera (Hemiptera: Phylloxeridae)

K Kingston, K Powell, P Cooper
Primary Industries Research Victoria - Rutherglen, Department of Primary Industries, RMB 1145 Chiltern Valley Road, Rutherglen, Vic 3685, Australia, kim.kingston@dpi.vic.gov.au

Grape Phylloxera, *Daktulosphaira vitifoliae* Fitch (Hemiptera: Phylloxeridae) feeds on the root system of European grapevine (*Vitis vinifera* L.) leading to the development of galls, vine decline and economic loss to the commercial vigneron. Despite being recognised as a significant pest since the late 1800s, the digestive physiology of phylloxera remains poorly characterised. Previous studies have suggested that the gut is blind ending, although both the presence and absence of an anus has been reported. The structure and function of the insects' digestive system was reinvestigated through the use of modern microscopic (light and scanning electron) and molecular techniques. Phylloxera has an atypical digestive system, with the hindgut emerging dorsal to the midgut. The reproductive system dominates the insects' internal structure. The hindgut intertwines with the ovary duct, emerging dorsal to the gonopore at the posterior end of the insect. Multiple egg development may block the function of the hindgut. Molecular analysis confirmed the absence of bacterial endosymbionts, suggesting that phylloxera is very efficient at converting a high protein diet from individual cells into energy. This research has improved our understanding of phylloxera's physiology. By understanding phylloxera's nutritional requirements, and interactions with grapevines, insect survival and development with changing vineyard management may be predictable.

Immune investment and sexual ornamentation

RJ Knell, JC Pomfret
School of Biological Sciences, Queen Mary, University of London, Mile End Road, London E1 4NS, UK R.Knell@qmul.ac.uk

The relationship between immune investment and sexual ornamentation is an important subject because insects may trade-off investment in these two costly aspects of their biology. I will describe how ornament size and immune investment covary in two very different systems, the horned dung beetle *Euoniticellus intermedius* and the stalk-eyed fly *Cyrtodiopsis dalmanni*. I will discuss the importance of the 'resource bottleneck' of pupation in these trade-offs, and I will review how our findings relate to sexual selection theory, and in particular immunocompetence handicap ideas.

Genetic dissection of oxygen response pathways and tracheole formation in Drosophila

E Johnson, SK Chiu, J Jarecki, V Sudarsan, MA Krasnow
Howard Hughes Medical Institute and Department of Biochemistry, Stanford University, Beckman Center B400, Stanford, CA 94305-5307 USA,
krasnow@cmgm.stanford.edu

We are using genetic and genomic approaches to elucidate the developmental program that governs branching morphogenesis of the *Drosophila* larval tracheal system, a network of ~10,000 interconnected epithelial tubes that transports oxygen to the tissues. These studies have begun to reveal the cellular and molecular processes that induce sprouting and guide outgrowth of tracheal branches and dictate tube size and stability. An FGF ligand (Branchless) guides the migrations of the tracheal epithelium as it grows out and assembles into primary branches. Cells at the ends of the primary branches are induced to express secondary and terminal genes, and go on to form secondary and terminal branches. Primary and secondary branching is highly stereotyped and controlled by a hard-wired developmental program, whereas terminal branch (tracheole) sprouting and outgrowth is highly variable and regulated by tissue oxygen need, as Wigglesworth showed for Rhodnius prolixus 50 years ago. Oxygen control of terminal branching is mediated by the same FGF ligand that controls the earlier, hard-wired stages of branching, but during terminal branching expression of the ligand is regulated by oxygen. We will describe the oxygen response pathway that senses cellular oxygen levels and induces expression of Branchless FGF in oxygen-starved (hypoxic) cells. Secreted Branchless protein activates the FGF receptor Breathless on nearby tracheal terminal cells, triggering a signal transduction cascade that induces expression of tracheole genes and directs cytoplasmic outgrowth to the hypoxic cell. A lumen forms within each cytoplasmic projection, creating new tracheoles that transport oxygen to the hypoxic cell and relieve the oxygen crisis. We will also describe how the same oxygen response pathway also induces a remarkable cellular phenomenon described by Wigglesworth that allows hypoxic cells to locate, capture, and rearrange existing air-filled tracheoles to enhance their oxygen supply.

Immunological adaptation in invertebrates

J Kurtz
Max Planck Institute Of Limnology, Po Box 165, 24302 Plön, Germany, kurtz@mpil-ploen.mpg.de

Immunological adaptations are central to our understanding of the coevolution between parasites and their hosts, such as invertebrate disease vectors. However, the immune systems of insects and other invertebrates are assumed to have no specific immunological memory, which characterizes acquired immunity in vertebrates. On the other hand, studies of ecological immunity, which demonstrated genotype-specific interactions between invertebrate hosts and their parasites, indicate that invertebrate immunity might be much more complex than is generally believed. We investigated the degree of specificity in the defence of the copepod *Macrocyclops albidus*, against a natural parasite, the tapeworm *Schistocephalus solidus*. We found that the degree of reinfection depends on the antigenic resemblance between consecutively encountered parasites. These results give evidence for specific immune memory in an invertebrate species. Given specific immunity of their hosts, parasites should benefit from antigenic heterogeneity. We are therefore now studying antigenic heterogeneity in *S. solidus*, using fluorescent lectins, which bind specific sugar residues on the parasite surface. We will relate these characteristics to infectivity and innate and adaptive immune activity in the two hosts, copepods and stickleback fishes, to investigate possible constraints for parasites that coevolve with both invertebrate and vertebrate immune systems.

Maternal spread of *Enterobacter agglomerans* and *Klebsiella pneumoniae* through populations of the Mediterranean fruit fly, *Ceratitis capitata* (Weidemann): another piece of the symbiotic puzzle

C Lauzon
California State University, Department of Biological Sciences, 25800 Carlos Bee Boulevard, Hayward, CA, 94542-3090, USA, E-Mail: clauzon@csuhayward.edu

Enterobacter agglomerans and *Klebsiella pneumoniae* have been associated with fruit fly pests within four genera of Tephritidae. The associations include aspects of fruit fly nutritional, chemical, and behavioral ecology. The role these bacteria play in the life history of pest tephritids is not fully understood, however recent findings suggest that these bacteria are important in maintaining a healthy and functional gut. Probiotic diet formulations containing *E. agglomerans* and *K. pneumoniae* have been shown to improve the gut of irradiated male *C. capitata* and *A. ludens* used for SIT. In addition, sterile *C. capitata* have demonstrated improved mating efficiency after feeding on particular probiotic formulations. Reports of horizontal and now vertical transmission of *E. agglomerans* and *K. pneumoniae* strongly link these two bacteria to tephritid fitness.

Tracheal capacity and oxygen delivery during flight of Dr*osophila*

F-O Lehmann
BioFuture Research Group, Department of Neurobiology, The University of Ulm, Albert-Einstein-Allee 11, 89069 Ulm, Germany,
fritz.lehmann@biologie.uni-ulm.de

The respiratory system of insects must maximize the flux of respiratory gases through the spiracles of the tracheal system. During flight the supply of oxygen becomes crucial when locomotor activity is increased during maximum aerodynamic force production. In Dr*osophila* most of the gas exchange is due to the 4 large thoracic spiracles that match their opening area to the metabolic need of the animal during flight. To estimate tracheal gas capacity in this insect and to understand the significance of spiracle opening behaviour for oxygen supply of flight muscles we have flown Dr*osophila* in a flight simulator in which we measured carbon dioxide release and locomotor performance during visually controlled flight. By blocking various spiracle openings for gas exchange we varied oxygen supply and measured the changes in muscle mechanical power output delivered to each wing including muscle efficiency. Data show that a reduction of spiracle gas exchange area impairs maximum locomotor capacity that results in a decrease in stroke amplitude and aerodynamic force production. The release of carbon dioxide tends to be more cyclic under these experimental conditions suggesting that the insect might employ discontinuous breathing patterns even at elevated locomotor activity.

Parasitoid wasp uses a venom cocktail injected into the brain to manipulate the behavior and metabolism of its cockroach prey

F Libersat
Department of Life Sciences, Ben-Gurion University, POB 653, Beer-Sheva, Israel 84105; e-mail: libersat@bgumail.bgu.ac.il

Parasitoid wasps incapacitate their prey to provide a food supply for their offspring. Because the wasp's goal is to provide a living meal for its newborn larva, the behavioral and metabolic changes in the host are brought about by manipulating the host behavior and metabolism in a way beneficial to the wasp and its offspring. To this end, these wasps have evolved venom-cocktails tailored to the wasp hunting and its larva feeding strategies. The two consecutive stings of the parasitoid wasp *Ampulex compressa* are unusual, as they induce a transient paralysis of the front legs followed by grooming behavior and then by a long-term hypokinesia of the cockroach prey. The first sting in the thoracic central nervous system causes a transient front leg paralysis lasting a few minutes. This paralysis is due to the presence of a venom component that induces a postsynaptic block of central cholinergic synaptic transmission. Following the head sting directly into the brain, dopamine identified in the venom appears to induce 30 minutes of intense grooming. During the long-term hypokinesia that follows the grooming, specific behaviors of the prey are inhibited while others are unaffected and the overall metabolic rate of the cockroach is modulated.

Insect midgut proteinases

AR Lopes, PT Cristofoletti, SR Marana, WRTerra
Dept of Biochemistry. Inst. of Chemistry. University of São Paulo.C.P.26077, 05513-970 S.P., Brazil. ilopes@iq.usp.br

Most initial protein digestion takes place at the endoperitrophic space in insect midguts and depends on three classes of proteinases: aspartic, cysteine and serine proteinases. Aspartic proteinases are described in some few insects and are preferentially active on substrates containing a Phe-Phe peptide bond. Cysteine proteinases occur in Hemiptera and some Coleoptera as *Tenebrio molitor* and are active on B-R-pNA, B-R-NA, Z-FR-MCA and e-amino-caproyl-leucyl-(S-benzyl)-cysteinyl-MCA are activated by DTT and cysteine and are inhibited by E-64. Five cysteine proteinase cDNAs were sequenced and cloned from a midgut cDNA library from *T. molitor* larvae: three lysosomal, one digestive and another probably digestive. A Neighbor-Joining (NJ) analysis of all cysteine-proteinase sequences from different insect species described in GenBank distinguish two main branches: one which contains typical digestive cysteine-proteinases presented by Coleoptera and another with Hemipteran cysteine proteinases closest to lysosomal ones. Serine endopeptidases are the main enzymes involved in protein digestion in insects, usually comprising trypsin and chymotrypsin. Purification and characterization of these enzymes from different insect species revealed enzymes with different specificities and physical properties. Sequence alignment, structure superposition, NJ analysis and molecular modeling allowed the identification of residues involved in resistance to plant metabolites like proteinase inhibitors and ketones. Supported by: FAPESP, CNPq and PRONEX.

Irritable bowel syndrome in insects: Plant defenses that disrupt the peritrophic matrix

T Pechan, PWK. Ma, S Mohan, S Ozkan, E Bassford, R Shivaji, WP Williams, DS Luthe
Dept of Biochemistry, Box 9650, Miss. State University, Mississippi State, MS 39762, dsluthe@ra.msstate.edu

We have demonstrated that a unique 33-kD cysteine protease (Mir1-CP) accumulates in the whorls of caterpillar-resistant corn genotypes in response to feeding by fall armyworm (*Spodoptera frugiperda*) larvae and other lepidopterans. The growth of fall armyworm larvae reared on transgenic Black Mexican Sweet (BMS) cells that ectopically expressed Mir-CP was retarded approximately 70%. Physiological indices suggested that this was due to impaired nutrient utilization. Scanning electron microscopy (SEM) of midguts from fall armyworm larvae reared on resistant plants or transgenic BMS indicated that peritrophic matrix (PM) was severely damaged. Because Mir1-CP binds chitin, we speculate that it might be tethered to the PM where it digests PM proteins. Proteomic analysis of PM proteins isolated from larvae reared on resistant and susceptible corn genotypes indicated that approximately three proteins were absent from the PM of larvae reared on resistant plants. This suggests that the protease may affect the integrity of the PM by attacking specific PM proteins. To test this Mir1-CP has been expressed in a heterologous expression system using a recombinant baculovirus vector and *Trichoplusia ni* larvae as hosts. Mir1-CP has been purified to homogeneity from the hemolymph and its affects on PM structure will be tested *in vivo* and *in vitro*.

Cellular differentiation and functional development of the organs responsible for sustained active water vapour absorption (WVA) in the firebrat, *Thermobia domestica* (Packard).

J Noble-Nesbitt
School of Biological Sciences, University of East Anglia, Norwich NR4 7TJ, England (UK). e-mail: j.noble-nesbitt@uea.ac.uk

WVA commences sporadically in the second instar but then develops rapidly, reaching its mass-specific peak in late-third and fourth instars before settling to a slightly lower plateau. The dorsal and two ventro-lateral posterior rectal (anal) sacs responsible for WVA develop as outpushings of the proctodaeal invagination. Functionally mature sac epithelial cells are characterised by a very regular, dense honeycomb-like array of elongated mitochondria closely associated with deep pleated infolds of the portasome-studded apical plasma membrane. In the first instar, the prefunctional single-cell thick epithelium convolutes, forming saccules. The epicuticle lifts away from the epithelial surface and traverses only the neck of each sac, with a faintly granular subcuticular matrix filling the expanding intervening space. Mitochondria are manufactured and packed very densely in mitochondrial factory cells. In the second instar, the apical association of mitochondria and plasma membrane begins to appear. By late in the third instar, the fully mature sac epithelium has developed, coinciding with peak WVA. During moults, WVA temporarily ceases as the sac cells dedifferentiate, divide and redifferentiate. A new cuticle is secreted. Mitochondria multiply. When WVA restarts immediately after ecdysis the functionally mature state of the sac cells has been fully re-established.

Cold tolerance and feeding behaviour in the Tasmanian scorpionfly *Apteropanorpa* Carpenter (Mecoptera: Apteropanorpidae)

CM Palmer
School of Botany and Zoology, Australian National University, Canberra ACT 0200, Australia, chris.palmer@anu.edu.au

The Apteropanorpidae is a small family of scorpion flies endemic to Tasmania, comprising two described species. The biology of the family is almost completely unknown. Adults of both species are found on shrubs in the alpine zone and can be active in winter, although the peak in adult abundance is autumn. Experiments cooling individuals from 3ºC to −10ºC at 1ºC/3 mins and measuring body temperature using infrared video thermography show that live *Apteropanorpa* freeze at an average temperature of −4.9ºC (n=20). However, stress response behaviour is triggered at an average temperature of −1.1ºC (n=20), and no individuals survived freezing to −10ºC. Combined behavioural and physiological data indicate that *Apteropanorpa* does not possess a physiological mechanism to survive freezing, and instead employs freeze avoidance behaviour as the insect seeks microhabitats with favourable temperatures. *Apteropanorpa* is apparently well-adapted to its natural environment; the maritime climate of the Tasmanian alpine zone is relatively warm and stable compared to that of mainland Australia. Adults are most likely saprophagous in nature, predominantly feeding on dead and decaying invertebrates. Thirty-three adults were included in a feeding choice experiment in which twenty-two adults showed a statistically significant preference for feeding on dead arthropods. A saprophagous feeding strategy in the Apteropanorpidae is supported by field observations, histological tests and gut contents analyses by light and electron microscopy.

Geographic variation in host selection behaviour in the *Drosophila* parasitoid *Leptopilina clavipes*

BA Pannebakker, N Garrido, BJ Zwaan, JJM. van Alphen
Institute of Biology, PO Box 9516, NL-2300 RA Leiden, The Netherlands, pannebakker@rulsfb.leidenuniv.nl

Coevolutionary processes between hosts and parasitoids are not simply the result from host-parasitoid interactions between two species, but rather are determined by the diffuse interactions between a number of biotic or abiotic factors. An important factor influencing this coevolutionary process is the predictability of the environment. Modelling studies show that in a stable predictable environment, the optimal strategy for the parasitoid is to specialise on the most frequently encountered species. In a fluctuating environment however, high temporal variation in the frequency of different host species do not favour the evolution of specific virulence in the parasitoid. To test this hypothesis, we compared survival probabilities of two strains of *Leptopilina clavipes* a parasitoid of *Drosophila* larvae breeding in fungi. One strain originates from northwestern Europe, where fungi are almost continuously available during the season, the other strain originates from southern Europe, where fungi are absent during an important part of the season. The availability of fungi presents European *L. clavipes* populations with environments that differ in their predictability. We tested survival and host selection behaviour on three different host species from different breeding substrates. Our results confirm the model predictions and show specialisation in northwestern, and generalisation in southern populations.

Host regulation by ***Toxoneuron nigriceps*** **bracovirus genes**

F Pennacchio, P Falabella, P Varricchio, C Malva
Department of Biology, University of Basilicata, 85100 Potenza, Italy, pennacchio@unibas.it

Toxoneuron nigriceps is an endophagous parasitoid of the tobacco budworm, *Heliothis virescens*. Parasitized host larvae show the suppression of the immune response and are unable to attain the pupal stage, becoming developmentally arrested as mature larvae. This complex syndrome is largely induced by a symbiotic bracovirus (TnBV), which is injected by the adult wasps at the oviposition. The sequence of TnBV genome is in progress and several genes expressed in parasitized hosts have been cloned and fully characterized. Among them, some code for members of interesting protein families, such as IκB-like and tyrosine phosphatases, while others do not show significant levels of sequence identity with known proteins. The current study of these TnBV genes provides new insights on the possible regulation mechanisms of host immune disruption and developmental arrest modulated by *T. nigriceps* parasitism, and shows the occurrence of interesting cellular and molecular pathways of host disguise which seems to occur also in other host-parasitoid systems.

Is reproduction of the silkworm parasitoid *exorista sorbillans* **(diptera: tachinidae) totally dependent on the endosymbiont** *wolbachia?*

HP Puttaraju, BM Prakash
Department of Sericulture, Bangalore University, Bangalore-560 056, India, (puttarajuhp@hotmail.com)

Several species of arthropods harbour endosymbiotic bacteria of the genus *Wolbachia*. These endosymbionts are transmitted vertically from one generation to the next and are facultative / obligatory in several Dipterans that have been studied to date. The tachinid uzifly, *Exorista sorbillans* known to cause extensive damage to silk industry by adopting obligate parasitic mode of life on its host silkworm, *Bombyx mori* L (Lepidoptera: Bombycidae). Further this pest is known that it harbour *Wolbachia* endosymbiont. Administration of 0.05 mg/ml oxytetracycline to the adult uzifly, removed *Wolbachia* endosymbiont and results in causing different invasive effects such as i) reduction in fecundity of aposymbiotic females ii). Cytoplasmic Incompatibility in the crosses between symbiotic male and aposymbiotic female. iii) Partial Genomic incompatibility in crosses between both sexes untreated and in crosses between aposymbiotic males and symbiotic females, as well as in the crosses between both males and females administered with antibiotics. It is hypothesised that, there is a driving force which causes partial genomic incompatibility in crosses between both sexes untreated (uncured) and in crosses between cured male and uncured female, is pronounced might be due to the lack of *Wolbachia*. However, the tetracycline has no much effect on longevity and survivability of uzifly. These results suggest that, *Wolbachia* present in the uzifly display obligate mutualism as it controls the overall development of reproductive physiology of its hosts.

Parasitoid-induced changes in gene expression patterns in *Ephestia kuehniella*

A Reineke, S Loebmann
University Of Hohenheim, Institute Of Phytomedicine, D-70593 Stuttgart, Germany, areineke@uni-hohenheim.de

Parasitism by endoparasitic wasps may significantly alter the host's physiology and ontogeny, including development, growth rates, and immune response. To understand the basic molecular mechanisms underlying these parasitoid-host-interactions and to obtain a first general idea on the genes involved in these processes we have analysed patterns of gene expression by cDNA-AFLP (cDNA-Amplified Fragment Length Polymorphism) in *Ephestia kuehniella* (Lepidoptera: Pyralidae) caterpillars after parasitization by the wasp *Venturia canescens* (Hymenoptera: Ichneumonidae). Comparison of expression patterns of approximately 1860 cDNA fragments in parasitized and unparasitized *E. kuehniella* caterpillars showed that about 1% of the transcripts were suppressed after parasitization, which was further confirmed by virtual Northern blot or RT-PCR analysis. Sequence analysis of the cDNA-AFLP fragments revealed that the putative translated proteins are associated with energy metabolism, protein synthesis, signal transduction, or are part of different membrane proteins. In addition a number of fragments were derived from novel genes not matching any database entries. Our transcriptomic approach therefore demonstrates that parasitization by an endoparasitic wasp changes key developmental processes as well as expression of new specific genes in the lepidopteran host caterpillar.

Genome sequencing of the *Cotesia flavipes* polydnavirus

MA Rodriguez-Pérez, T Kingan, M Hongskula, J Lenz, N Beckage
Centro de Biotecnología Genómica, Instituto Politécnico Nacional (IPN), Reynosa, 88710, México, mroiguez@ipn.mx.

Diatraea saccharalis is a key pest of sugarcane, but a minor pest of sweet corn, rice, and sorghum. Natural enemies of *D. saccharalis* have been reported to be important in reducing its populations, thus minimizing damage to crops. *Cotesia flavipes* is a gregarious parasitoid of *D. saccharalis*. The parasitoid injects polydnavirus (PDV) genes into *D. saccharalis*, which are transcribed into proteins that alter the physiology and suppress the immune system of the host. This paper reports the establishment of a *D. saccharalis-C. flavipes* colony, which is being used to construct a genomic library for the *C. flavipes* PDV. The genomic sequencing of *C. flavipes* PDV is under way using the shot gun strategy. The final goal is to identify potential opening reading frames of immune-suppressive genes and others with significant physiological functions.

Ecological adaptation of circadian activity rhythms: Phase shift and loss of rhythmicity with the altitude change in plusinae (Noctuidae) moths

M Sasaki, CP Kingenburg
Laboratory of Entomology, Faculty of Agriculture, Tamagawa University, Machida, Tokyo, 194-8610 Japan, sasaki@agr.tamagawa.ac.jp

Most of the Plusinae moths are nocturnal and the rhythms are driven by endogenous circadian rhythmicity. But it is also well known that the silver Y, Autographa gamma shows diurnal migration flight and Alpine species visits flowers in the daytime. We investigated the details of their rhythms using actographs. The Alpine Syngrapha nyiwonis was found to be essentially nocturnal but some, especially mated females, take flights in the daytime. Interestingly, their nocturnal activity is strictly limited in a few hours right after sunset, and they show no circadian component in the free-running state under DD or LL condition. Both of these natures seem to be adaptive to cool and unstable alpine weather. Rhythms of non- and sub-Alpine species are also discussed.

On the immunological memory of insects

P Schmid-Hempel
ETH Zurich, Ecology & Evolution, ETH-Zentrum NW, CH-8092 Zurich, Switzerland (psh@env.ethz.ch)

There are several hypotheses as to why insects should not have evolved an immunological memory comparable to that found in the higher vertebrates. Nevertheless, a number of studies suggest that a memory exists - with properties not unlike those of vertebrates. In the light of evolutionary ecology, the issue of a memory cannot be addressed without taking into account the problem of specificity in the immune response. Here, the existing evidence concerning these two questions is discussed and structured within a more general defence framework. Finally, a look at the temporal dynamics of the immune response hints at "solutions" that insects may have found for the problem of immunological memory.

Lectin-induced immune-suppression in insects

R Glatz, S Asgari[1], O Schmidt

Insect Molecular Biology, University of Adelaide, Glen Osmond, SA 5064, Australia. otto.schmidt@adelaide.edu.au, [1]University of Queensland, School of Life Sciences, St Lucia QLD 4072, Australia.

Many insect parasitoids that deposit their eggs inside immature stages of other insect species inactivate the cellular host defence to protect the growing embryo from encapsulation. Suppression of encapsulation by polydnaviruses-encoded immune-suppressors is correlated with specific alterations in hemocytes that include cytoskeletal rearrangements, and the loss of ability to spread on foreign surfaces. We have previously shown that the *Cotesia rubecula* polydnavirus gene product CrV1 is sufficient to cause immune suppression when injected into the host hemocoel, where CrV1 is taken up by hemocytes. Uptake is dependent on dimer formation, which is also a prerequisite for lipophorin binding, an indication that CrV1-lipophorin complexes are involved in hemocyte uptake. Since CrV1 resembles oligomeric lectins regarding interaction with lipophorin and uptake in resting cells, we examined the cytoskeleton during lectin-mediated uptake reactions and observed F-actin depolymerization resembling cytochalasin D inactivation. These observations suggest that some oligomeric adhesion molecules, which may include immune-suppressors, internalise receptors from the cell surface and in the process depolymerize actin-cytoskeleton. Although other more complicated mechanisms are possible, cellular immune inactivation in insect parasitoids may involve massive uptake reactions driven by lipoprotein complexes, which destabilize actin-cytoskeleton. Since recycling of membrane-vesicle to the periphery requires actin-cables, consecutive uptake reactions deplete receptors from the cell surface.

Variation in tracheal and spiracle morphology among insects

A Schmitz
Institute for Zoology, Rheinische Frieich-Wilhelms-University Bonn, Poppelsdorfer Schloss, 53115 Bonn, Germany, ankeschmitz@uni-bonn.de

Tracheal systems enable insects to support high aerobic metabolic rates by a direct transport of oxygen to the mitochondria. But organs differ in oxygen demand and the high-capacity respiratory system may cause water loss and excess tissue oxygen levels. Physiology and morphology of tracheae and spiracles must therefore be finely regulated. Thus it can be hypothesized that gross morphology and ultrastructure of tracheal systems and spiracles correlate with the metabolic demands of a species, a developmental stage or a single organ. This hypothesis is tested looking at the tracheal systems and spiracles of insects of different environments and with different metabolic rates. Two examples of quantitative studies of tracheal systems are presented: (i) The tracheal system of the stick insect *Carausius morosus* is an example for a simple system in which air sacs are lacking and organs are hardly penetrated. Nevertheless, the distal fine tracheae are most important in oxygen delivery. (ii) The tracheal gills of the aquatic larvae of the dragonfly *Aeshna cyanea* are an example for the adaptation of tracheal systems to water as respiratory medium. The tracheolar supply of the respiratory epithelia is designed for effective oxygen uptake, supported by ventilation of the respiratory chamber.

Friendly-fire on the battlefield: how important is autoimmunity in insects?

B. Sadd, MT Siva-Jothy
Dept. of Animal & Plant Sciences, University of Sheffield, Sheffield S10 2TN, UK. m.siva-jothy@sheffield.ac.uk

Insects express a range of immune effector systems in their haemocoel during systemic immune insults. Some of these effector systems function by generating generic cytotoxins in the haemolymph in the vicinity of the pathogen. In theory expression of these effector systems should have autoimmune consequences, and such consequences are a major assumption in many studies of immune costs in ecological immunity. We present the results from experimental tests of this notion and document the autoimmune consequences of expressing the phenoloxidase cascade in response to a controlled immune insult.

Suppression of host cellular defense responses by *Microplitis demolitor* bracovirus

MR Strand
Department of Entomology, University of Georgia, Athens, GA 30602, USA. mrstrand@bugs.ent.uga.edu.

Host insects often kill parasitoids by a cellular immune response called encapsulation. During an encapsulation response, insect blood cells (hemocytes) attach to the target and form a multilayered sheath. Since hemocytes normally circulate freely in the insect's body cavity (hemocoel), encapsulation requires that hemocytes recognize the target as foreign and change from nonadhesive cells to adhesive cells that attach to the target and one another. Polydnavirus-carrying parasitoids often evade encapsulation by disrupting the host's encapsulation response. Our studies have identified several key factors that regulate capsule formation by the moth *Pseudoplusia includens* and have also determined that *Microplitis demolitor* bracovirus (MdBV) blocks encapsulation by inhibiting infected hemocytes from adhering to foreign surfaces. The MdBV genome encodes several gene families expressed in host hemocytes and other tissues. In this presentation, we discuss the role of selected MdBV genes in suppression of encapsulation and other host immune responses. We also discuss the use of RNA interference (RNAi) and gain of function methods in studying PDV gene function.

Controlling flapping flight: lessons from locusts, dragonflies and *Aedes* mosquitoes.

GK Taylor
Zoology Department, South Parks Road, Oxford, OX1 3PS, UK, graham.taylor@zoo.ox.ac.uk

To a flying insect, unsteadiness is everything. With wings flapping tens or hundreds of times every second, the airflow changes continually, but despite – or perhaps because of – this complexity, insects are able to control manoeuvres with greater finesse than even the highest performance fighter aircraft. By adopting and adapting techniques used by engineers to analyse aircraft stability and control, it is possible to predict an insect's response characteristics to accidental disturbances and deliberate control inputs. By analysing the insect's natural modes of motion, we can then make quantitative predictions about the operating bandwidth of the nervous system and even the preferred directions and temporal resolution of its sensors. Besides yielding integrative physiological insight, analysing the insect as a miniature flying machine is instructive for the engineer seeking to mimic aspects of insect flight. In this talk I will illustrate some of the lessons we can learn from behaviours as diverse as the cruising flight of locusts, the take-off manoeuvres of dragonflies, and the mating flights of *Aedes* mosquitoes. Finally, I will show how an understanding of flight control can even contribute to pest control, by helping us select the most successful male mosquitoes for use with the sterile insect technique.

Molecular cloning and expression patterns of the molt-regulating transcription factor, Hhr3 from *Helicoverpa armigera*

X-F Zhao, J-X Wang, X-L Xu, Z-M Li, C-J Kang
School of Life Sciences, Shandong University, Jinan 250100, China, Email: xfzhao@sdu.edu.cn

A 1668 bp cDNA encoding a molt-regulating transcription factor, hormone receptor 3 (HHR3) was cloned from *H. armigera,* which deduced a protein with 556 amino acids. The isoelectric point of this protein was pI 6.52 and the molecular mass was 62 kDa. A DNA-binding region signature of nuclear hormone receptor was found from No. 107 to 133 amino acids. A possible transmembrane helice from outside to inside was found from No. 72 to 90 amino acids. Five bands of HHR3 were detected from the larvae by northern blotting. Among of them, band 1 and 2 were the dominant populations. The expression patterns of HHR3 *in vivo* were variable upon developmental stages and tissues. Results suggested that bands of 1 4 of HHR3 was only shortly expressed during molting which suggested that they were involved in the regulation of molting cascade, whereas, band 0 was observed in both molting and feeding larvae. Band 1 and 2 of HHR3 could be inducted from epidermis by RH-2485. The cDNA of HHR3 was expressed in *E. col.* A reconstructed HHR3-NPV was prepared and the efficacy to pest insect was studied. The work was supported by grants: 3008002,30330070 and 2001AA214031-1-2.

Immune-related genomics and proteomics of the lepidopteran *Galleria mellonella*

A Vilcinskas
Institute of Biochemistry and Biology, University of Potsdam, Lennestr. 7a, 14471 Potsdam, Germany, vilcinsk@rz.uni-potsdam.de

Screening for and characterization of immune-related proteins from the greater wax moth *Galleria mellonella* resulted in the identification of antimicrobial peptides which have been conserved in bilaterian evolution and in the discovery of novel proteinase inhibitors contributing to innate immunity of this insect. Using the subtractive hybridization in combination with suppressive PCR, we analysed genes that are differentially expressed in haemocytes in response to injected microbial elicitors such as LPS. Among the differentially expressed transcripts we identified homologues of pattern recognition molecules, antibacterial peptides and a novel member of the defensin-like peptides exhibiting antifungal activity which was named Gallerimycin. Application of proteomic methods in targeted screening for immune-related proteins in the haemolmph of preinjected *G. mellonella* larvae resulted in characterization of three inducible serine proteinase inhibitors (ISPI-1-3) which are active against the serine proteinases produced by the entomopathogenic fungus *Metarhizium anisopliae*. In addition, we discovered a specific inhibitor of microbial metalloproteinases (IMPI) which represents the first non-TIMP-like inhibitor of metalloproteinases reported from animals. Our research focussed on non-self recognition and immune-related signal transduction in *G. mellonella* provides evidence that pattern recognition of microbial characters in this insect comprises recognition and regulation of thermolysin-like metalloproteinases associated with invading pathogens.

Intratracheal pressure gradients and oxygen supply in resting and flying hoverflies

LT Wasserthal
Institut of Zoology 1, Staudtstrasse 5, D 91058 Erlangen. ltwthal@biologie.uni-erlangen.de

Hoverflies were chosen as extremely steady and rapid fliers in expectation of a very effective respiratory mechanism. The Syrphidae *Eristalis*, *Volucella* and *Sericomyia* were analyzed using non-invasive sensor techniques. At rest, the tracheal system is ventilated by hemolymph shift due to periodic heartbeat reversal causing fluctuations in intratracheal pressure and oxygen content. During shivering and flight, rate of pressure pulses in the thoracic tracheae is identical with wingbeat frequency. While during shivering oxygen content decreases dramatically, during flight oxygen content increases and reaches almost concentrations of ambient air. This reminds of the unidirectional air supply by the flight apparatus in hawkmoths (Wasserthal JEB 204, 2001): During full flight, a pressure gradient arises with a mean negative pressure at the anterior spiracles and a mean positive pressure at the second thoracic spiracles. Downstroke of the wings coincides with inspiration through the first spiracles, upstroke with expiration through the 2nd spiracles. As a unique feature for forced expiratory air flow the 2nd spiracles of *Eristalis* possess a motile filter apparatus combined with the inner valve.

Applications of atomic force microscopy for entomological studies

JA Watson
School of Science, Griffith University, Nathan, QLD, 4111, Australia, J.Blach@griffith.edu.au

The atomic force microscope (AFM) is a relatively new form of microscopy based on the detection of small forces acting between a sharp probe and a surface. The microscope has a spatial resolution of less than a nanometre and can provide a 3 dimensional interaction profile of the probe and sample at the pico-newton level in real time and space. In its most common form of operation the AFM will provide a topographical view of a surface from the micron down to the nano-metre scale. On flat well-ordered surfaces atomic and molecular scale resolution is possible. Unlike the traditional forms of high resolution microscopy (e.g. Scanning electron microscopes) the samples can be good conductors or insulators and thus sample coating is not a requirement. Moreover the samples can be examined in ambient conditions. As the instrument operates effectively in vacuum, air and liquid environments the samples in many cases can be viewed in-situ in a living and functioning state.

Sex-biased immunity and parasitism in insects

K Wilson, SL Moore
Department of Biological Sciences, Lancaster University, Lancaster LA1 4YQ, England, ken.wilson@lancaster.ac.uk

Recent studies of vertebrates, especially mammals and birds, have indicated that males generally have weaker immune systems and are generally more heavily parasitised than females. One mechanistic explanation for sex-biased immunity and parasitism involves the immunodepressive effects of androgen, testosterone. Since insects lack this hormone, they provide a suitable taxon for examining the ubiquity of sex differences in parasitism and immunity, without the confounding influence of testosterone. Here, we report the results of a comparative analysis aimed at determining the direction and magnitude of sex-biased parasitism and immunity in insects and examine some of the proximate mechanisms underpinning the observed relationships.

Tolerance of *Drosphilla melanogaster* to very low levels of oxygen.

G Haddad
Albert Einstein College of Medicine, Bronx, NY, USA, ghaddad@montefiore.org

Paper not available at time of production.

Effect on native *Pieris* Butterflies in New England, USA, by *Cotesia glomerata* and *C. rubecula* (Braconidae), Introduced Biological Control Agents of *Pieris rapae*.

RG Van Driesche,
Department of Entomology, University of Massachusetts, Amherst, MA, 01003, USA ph 513-545-1061, email: vandries@nre.umass.edu

In New England (northeastern USA), *Pieris rapae* is an invasive butterfly (ca 1860), against which two braconid parasitoids were introduced: *Cotesia glomerata* (1884) and *Cotesia rubecula* (1988). Neither introduction was preceded by formal host range estimation. Two butterfly species are at potential risk in the region: *Pieris virginiensis* and *Pieris napi*. Recent studies have shown that both are physiologically acceptable hosts for both parasitoids. Field studies showed that the univoltine woodland nature of *P. virginiensis* protects it from attack by either parasitoid. In contrast, a range reduction of *P. napi* appeared to occur shortly after the *P. rapae* invasion. Currently, critical host plants are abundant in both areas retaining *P. napi* (northern New England) and areas now lacking the species (southern New England), and host plants do not explain this range change. Parasitism by *C. glomerata* is high (66-100%) in the summer generation of *P. napi* in both areas retaining and areas lacking the butterfly. The critical difference appears to be a higher rate of commitment to first generation pupal diapause by caterpillars in wooded habitats in northern New England and absence of these parasitoids in wooded areas has protected northern *P. napi* populations, which has avoided parasitism by effectively becoming univoltine in a parasi

The genetic components of community structure and ecosystem processes: conservation implications

TG Whitham, JK Bailey, JA Schweitzer, RK Bangert, GM Wimp, SM Shuster, EV Lonsdorf, RL Lindroth and P Keim
Department of Biological Sciences & Merriam-Powell Center for Environmental Research, Northern Arizona University, Flagstaff, AZ 86011 USA.

The heritable genetic variation within individual species, especially dominant and keystone species, has community and ecosystem consequences. These consequences represent extended phenotypes, i.e., the effects of genes at levels higher than the population. Using diverse examples from microbes to vertebrates, the extended phenotype can be traced from the individuals possessing the trait, to the community, and to ecosystem processes such as leaf litter decomposition and N mineralization. Common garden experiments show a heritable component to community structure and ecosystem processes. Our studies also argue that there are genetic based assembly rules that can be used to predict community structure. These findings have important basic and applied implications. For example, the loss of genetic diversity in a dominant tree can result in the loss of community members that are dependent upon specific tree genotypes for their survival. Also, the extended phenotypes of genetically modified organisms can have unexpected community and ecosystem consequences.

A modern metaphor for island biogeography of SW Pacific Simuliidae - the Indiana Jones Zone.

DA Craig.
Department of Biological Sciences, University of Alberta, Edmonton, Canada T6G 2E9, d.craig@ualberta.ca

The simuliid subgenus *Hebridosimulium* from Vanuatu and Fiji, originally thought to be a taxonomically isolated taxon, can now be related to *Wallacellum*, a subgenus sporadically distributed west of New Guinea, but mainly in the Philippines. Simuliid taxa on New Guinea and the Solomon Islands are apparently not closely related to *Hebridosimulium*. The paleogeology of New Guinea, the Solomon Islands, Vanuatu and Fiji shows the region to be of a geological complexity second-to-none in the world. In Fiji, Viti Levu has been dated to some 40 Mya, but other islands only of 7-2 Mya. While some islands of Vanuatu may have been emplaced for some 30+ My, all appear to have been submerged at one time and some more than once, albeit all are presently rising. Colonization of islands that may, or may not, become submerged is similar to the problem presented to Indiana Jones crossing the floor of the Temple of the Holy Grail. Step on (colonize) the wrong tile (island) and Indy falls through the floor (submerges) and cannot move on to reach the Holy Grail (Fiji).

The fine-scale physical attributes of coarse woody debris associated with utilization by ants (Hymenoptera: Formicidae).

RJ Higgins, BS Lindgren.
University of Northern British Columbia, 333 University Way, Prince George, BC, Canada, V2N 5A4, rhiggins@cariboo.bc.ca

"Coarse woody debris (CWD) is increasingly recognized in Canada for its contribution toward biodiversity. [U1]It is a particularly vital resource in sub-boreal forests as nesting habitat for ants (Formicidae). Wood, which has low specific heat, provides a thermally favourable environment in this cool climate. Ants contribute to physical breakdown of wood, and colonies are a significant food source for vertebrates like grizzly bears and woodpeckers. Where CWD retention has been a management objective, volume is usually used as the sole indicator. However, CWD differs greatly in quality between non-harvested and harvested sites. Pieces remaining after harvest are shorter, thinner, lacking in bark, and missing decay classes typical of non-harvested sites. This has led to the concern that post-harvest CWD may not be biologically functional. In this study, conducted in cool moist sub-boreal forests, we are examining the fine-scale physical attributes of CWD utilized by ants, in non-harvested and harvested sites (8-10 years post-harvest). Results to date indicate significant effects of stand structure and climate on ant ulitization of CWD, with only a few species tolerating cool interior stand conditions. The possible significance of regional climate, insolation, temperature, and moisture will be discussed.
"

Indicators, Flagships and Predictor Sets: Insects as Surrogates

R Kitching
Griffith University, Brisbane, Australia

Invertebrates have been used as indicators of environmental qualities for over fifty years. There remains a lack of clarity of their use in this connection which may lead to inappropriate choices of what to use as an indicator or even of the state of the quantity being indicated. Single species may indicate the quality of their chemical environment when they interact physiologically with that chemistry. In contrast complex ecological changes are unlikely to be reflected by the state of single species. A whole biota will respond to such changes and an indicator for such a complex entity will be, inevitably, a set of species. How we choose such a set is also an issue that requires careful thought. A predictor set acts as a surrogate for the complete biota. Such a set is better chosen for its ecological variability and representativeness than simply for taxonomic convenience. A predictor set of insects is more likely to be effective if it spans different feeding guilds. Examples will be presented and discussed. Flagship species, in contrast, are chosen and used for socio-political purposes and may indicate nothing more than a particular place, time or mind-set.

The concept of effective community size for furthering the development of community genetics

EV Lonsdorf, TG Whitham, S Schuster, GM Wimp and R Bangert

Community genetics represents the union of community ecology with population and quantitative genetics. This unique perspective emphasizes investigating the influence of genetic variation on interactions between species. Determining when this perspective is important is the subject of ongoing research. In this light, we introduce the concept of "effective community size," the fitness relevant community that an individual experiences. This value represents the weighted number of species' genomes that influence fitness of an individual, and is determined the frequency and strength of interaction of an individual with all other species in its community. We apply this concept to explore two major conditions that are crucial for broad application of a community genetic approach: (1) fitness in one species must covary with genes in a second species and (2) the community context is appropriate such that the effective community size of each interacting species is low. Using simulated communities with controlled, genetically determined species interactions, a community genetic framework breaks down as we increase the effective community size of the participants. We use a well-studied, cottonwood-arthropod system to show that a constant, strong selective influence of dominant or keystone species greatly reduces effective community size of many other species in a community and enhances the need for a community genetics perspective. Recent analyses of community webs from other systems indicate that a large proportion species interact with relatively few other species in a community. Applying the concept of effective community size to these analyses suggests that community genetics is an important perspective in many communities.

Genetic variation in leaf chemistry influences ecosystem processes during decomposition.

MD Madritch, MD Hunter, RL Lindroth.
Department of Entomology, University of Wisconsin, Madison WI.

Many tree species display large variation in genetically-mediated leaf chemistries important to insect herbivore defense. These secondary compounds, especially polyphenolics, are also important to ecosystem level processes during decomposition. As natural plant population sizes decrease, genetic diversity within a single species also declines, yet the importance of this loss in genetic variation to ecosystem processes is relatively unknown. We use two model species, *Quercus laevis* and *Populus tremuloides* to demonstrate the ecosystem level effects of intraspecific genetic variation in leaf chemistries. In a three-year field experiment, we varied the intraspecific leaf litter composition of *Q. laevis* in an oak sandhills community and monitored ecosystem responses. Intraspecific variation affected carbon and nitrogen cycles during decomposition through genetically-mediated litter chemistries. Mass loss, changes in litter carbon and nitrogen content, as well as soil ammonium availability were all affected by intraspecific litter composition. In a parallel laboratory microcosm experiment, we tested the effects of intraspecific litter diversity and nitrogen deposition on ecosystem processes. Intraspecific diversity increased soil respiration overall, with the greatest increases in respiration occurring under high nitrogen deposition. In a second field experiment, we also varied the genetic composition of *P. tremuloides* litter grown under different nutrient availability regimes. Decomposition rates varied two-fold within identical nutrient treatments, depending upon the genetic identity of the leaf litter and corresponding litter chemistry, and strong gene by environment effects were evident. While leaf secondary chemistries have traditionally been known to be important to insect herbivore ecology, it is becoming increasingly apparent that they also play important roles in ecosystem level carbon and nitrogen cycling. Our results demonstrate that genetic variation within a single species can have independent, and interactive effects with nutrient availability, to influence terrestrial nutrient cycles.

Conservation of species at the edge: Hybrid zone dynamics and cryptic mountain species impacteded by changing thermal landscapes.

JM Scriber and GJ Ording
"Department Of Entomology, Michigan State University, East Lansing, MI 48824,USA scriber@msu.edu"

Hybrid animals may harbor significant genetic novelties, and provide valuable genotypes needed for rapidly changing environments. Recently (and probably directly related to extensive regional global warming in the region since 1998) considerable northward and rapid interspecific introgression (150-350 km in 6 years) into historical *P. canadensis* populations has been observed for several autosomal species-diagnostic traits of *P. glaucus* such as detoxification of tulip tree leaves, morphological wing traits, and *Hk*-100 allozymes. In addition, some X-linked traits such as *Pgd*-100 alleles and tulip tree oviposition preference behavior have moved extensively northward. However, there has been little introgression of certain other sex-linked *P. glaucus* traits (such as facultative diapause, dark morph females, and LDH-100 allozymes). We have determined that recombination and strong selection on *Ldh*-100 alleles (or some undetermined trait on the X-chromosome with very close linkage) seem to limit gene flow North of this interspecific hybrid zone wherever fewer than 2700 degree-days accrue. We have created recombined/introgressed hybrids that largely match the morphological and delayed post-diapause emergences of the new mountain swallowtail species, *P. appalachiensis* (Pavulaan & Wright 2002). The new species expresses an extensive introgressed mix of both *glaucus* and *canadensis* diagnostic traits and may represent the high altitude version of our high latitude northern "false second generation" populations. This neospecies may represent a rare example of an animal "hybrid species". Detailed GIS mapping of thermal accumulations allows prediction of the geographic location of the purportedly new mountain species in West Virginia as well as for Georgia in the southern Appalachian Mts. The exceptionally warm 2002 and 2003 seasons may extirpate the neospecies as genetic swamping from *P. glaucus* may occur from lower elevations.

Eucalypt hybridisation and heteroblasty affect biodiversity of dependent communities

BM Potts, R Lawrence, PR Minchin and T Whitham
School of Plant Science and CRC for Sustainable Production Forestry, University of Tasmania, Australia

The relative effects of host hybridisation and ontogeny on the composition and diversity of dependent communities was examined using manipulated hybrids between two heteroblastic forest tree taxa, *Eucalyptus nitens* and *E. globulus.* The abundance of 44 dependent arthropod and fungal taxa was assessed on 3 year old trees of *Eucalyptus globulus*, *E. nitens* and their hybrids (F_1, F_2, and backcrosses) growing in a replicated field trial on the island of Tasmania. Half of the trees of each cross type had undergone the transition to adult foliage (heteroblastic) while the remainder still retained juvenile foliage (homoblastic) at the time of assessment. The ontogenetic change was shown to have an enormous impact on the composition of the dependent community, far exceeding the effect of genetic differences between the pure species and their hybrids. Dependent taxa exhibited a variety of responses to host hybridisation, however consistent with our other studies with eucalypts there was a clear trend for hybrids to support a greater number of dependent taxa than either pure species host. This study shows how the effects of genetic and ontogenetic variation in a forest dominant may extend beyond the individual and population to affect biodiversity at the community level. Our findings also argue that plant ontogeny can be a major mechanism driving community structure, which is deserving of much greater research emphasis in the study of biodiversity.

The importance of type (logs, snags or the top of trees) and treatment (shading or burning) of dead wood for its attractiveness to saproxylic beetles.

J Hjältén and T Johansson
Department of Animal Ecology, Swedish University of Agricultural Sciences, SE-90183 Umeå, Sweden. E-mail: Joakim.hjalten@szooek.slu.se

Intensive forest management resulting in reduced fire frequency, the dramatic decrease of dead wood and changes in tree species composition in boreal forests is probably the main reason for the dramatic decrease of many saproxylic species in Fennoscandian boreal forest. This has lead to changes in forestry practise, including dead wood retention, which value not yet has been rigorously evaluated. To evaluate the value (from a conservation perspective) of different types of dead wood (logs, snag or remaining top of the tree) and find ways of improvement (burning and shading of logs) we performed a large-scale field experiment in northern Sweden. Species richness and the abundance of saproxylic coleopterans were higher on logs than on snags and tops but the different types of dead wood also attracted different beetle communities. Some red-listed species as the endangered *Monochamus urussovi*, was most common on tops and also found on snags, but not on untreated logs. Treatment of logs also influenced their suitability for red-listed species. Eleven, seven, five and four red-listed species was found on burned, control, shade net and naturally shaded logs, respectively. The implication of these findings for conservation strategies is discussed.

Herbivory alters plant litterfall dynamics: contrasting "afterlife" effects due to genetic diversity in susceptibility to herbivory

SK Chapman, JA Schweitzer, TG Whitham

Arthropod herbivory can alter forest ecosystem processes by changing litterfall chemistry and dynamics. Specifically, herbivores in different systems have been shown to 1) accelerate leaf abscission and thus, stunt nutrient resorption, and 2) elicit secondary chemical defenses from plants, both effects which alter litter chemical quality. Litterfall is an important input of carbon and nutrients; thus, any factor that alters the quality of plant litter can profoundly alter the decomposition rate of that litter and the subsequent rate of nutrient release. Plant defensive chemicals, which persist in litterfall, are manifestations of biochemically-based allocation tradeoffs. The balance of these tradeoffs is in large part genetically determined; therefore, plants inherit defense strategies against herbivores to a great extent. Using two experimental test systems, we illustrate how the contrasting influences of herbivore-induced changes in plant litter dynamics can contribute differently to the long-term dynamics of nutrient cycling in two different types of ecosystems, coniferous and broadleaf deciduous forests. Within a species, and population, variation in ecosystem processes may arise from genetic variation as expressed in susceptibility and resistance to herbivory. Among different species, within a community, the net ecosystem effect of herbivory may depend largely on plant phylogeny.

Estimation of conservation areas in the light of historical biogeography

H Abe
Nihon Univ., 1866 Kameino, Fujisawa, 252-8510 Japan; acari@brs.nihon -u.ac.jp

A method for estimating protect areas for biological conservations is newly introduced in the light of historical biogeography. Biological conservation is achieved in part by establishing protect areas for particular organisms. So far ecology has greatly contributed to the establishment of such nature reserves. Generally, ecological research only deals with synchronic biological phenomena. Biological conservation, however, should be made referring to historical events through evolutionary transition. In this respect, historical biogeography will play an important role in conservation biology. The vicariance model of historical biogeography is utilized to explain the present distribution of organisms. Under this model the distribution of particular species is most likely established through the process of extinction and/or fragmentation. The dispersal vicariance analysis (DIVA) used in the historical biogeography is applicable to detect highly fragmented species by using parameters of habitat fragmentations in spatio-temporal scale. The analytical procedure of the method is illustrated in the case of marine mite genus *Isobactrus* (Acari: Halacaridae). As the result of the protect area analysis, the south western and middle eastern parts of the Pacific were nominated as the most desirable areas for biological conservation of the mites.

Diversity of *Aegialites* - an intertidal rock dwelling genus (Coleoptera: Salpingidae: Aegialitinae)

L Zerche, D Ahrens
Deutsches Entomologisches Institut (DEI) im ZALF, Eberswalder Str. 84, D-15374 Müncheberg, Germany; zerche@zalf.de

Aegialites Mannerheim, 1853 is an intertidal rock dwelling genus of amphi-Pacific distribution, which comprises 17 species in Asia and 13 in America. Its range includes the coasts of California, British Columbia, and Alaska, inclusive of islands, and Honshu, Hokkaido and 17 islands in the Far East of Russia. The range of *Aegialites* is largely congruent with that of north Pacific auks (Alcidae), also with that of seal species (Pinnipedia). The wingless *Aegialites* species are highly adapted to their special habitat by morphological, ethological, and presumably also physiological characters. The restricted range of the genus, the adaption to a cold climate (subarctic, cold currents) and an amphipolar vicariance with its sister group *Antarcticodomus* (subantarctic islands, Chatham Islands) imply a high phylogenetic age. Apparently, all the species are local endemics; non-adaptive radiation is hypothesized. 24 species, all from rocky seashores of the northern Pacific, are described as new. The genus requires further investigation: special physiological adaptions are still unknown and our current knowledge of the true diversity of the genus is far from complete.

The importance of conducting regional faunal surveys: a case study involving velvet ants in Wisconsin. (Hymenoptera: Mutillidae)

CM Brabant
1630 Linden Drive, Rm. 445, Madison, WI, 53706, USA, brabant@entomology.wisc.edu

Regional insect faunal surveys can be invaluable to taxonomic and ecological studies. Such surveys fill gaps in the existing distributional and biological knowledge for many taxa. Generally, trapping materials are inexpensive and trapping techniques are relatively low-effort, yet they often yield an abundance of new specimens for examination. Regional insect surveys are also critical for identifying and prioritizing areas targeted for conservation. Considering that insects typically constitute the majority of animal species for a given habitat, conducting surveys to identify which species are present is an important first step in any conservation effort. This case study illustrates the importance and value of regional insect surveys. Relatively simple, inexpensive survey techniques were utilized in Wisconsin to look for members of the family Mutillidae. Results of this study will include: 1) the publication of 25 new state species records (only four species had been reported prior to the study); 2) a sex association resulting in a new synonym for one species; and 3) a description of the previously unknown female of another species. Although this study focused on mutillids, the described survey techniques and materials are taxon-independent, and thus can be used by researchers anywhere who wish to study a variety of insects.

The arthropods of Morelos State: a preliminar synthesis

A. Burgos-Solorio, TL Aiana.
Laboratorio de Parasitología Vegetal, Centro de Investigaciones Biológicas Universidad Autónoma del Estado de Morelos. Av. Universidad 1001. Col. San Lorenzo Chamilpa, Cuernavaca, Morelos, México. CP. 62210; burgos@cib.uaem.mx

Morelos, one of the smallest states in central Mexico (4 958.22 km^2), is located between two important biogeographic regions, neartic and neotropical. Climate conditions, physiography, and plant diversity make it an important zone in terms of species biodiversity. The purpose here was to compile information about all arthropod species recorded for the region. As many as 700 papers (from Mexican and foreign journals) were scanned. Up to date, 4,108 species are recorded included in 387 families and 40 orders within several classes: Arachnida, Acarida, Crustacea, Chilopoda, Entognatha, and Insecta. The Insecta grouped 3596 species (1509 of those were coleopterans). This information represents part of all the species potentially existing in Morelos. New investigations and revision of additional bibliographic material will surely increase the count.

Saproxylic beetle diversity & the cumulative ecological effects of wildfire & forest harvesting in boreal mixedwood forests.

TP Cobb, JR Spence, DW Langor, BE Kishchuk
Department of Renewable Resources (442 Earth Sciences Building), University of Alberta, Edmonton, AB, T6G 2E3, Canada; tcobb@ualberta.ca

"Along with industrial forest harvesting, natural disturbances such as wildfire continue to play dominant roles in shaping the boreal forest landscape. Therefore, to achieve goals for biodiversity conservation and sustainable forest management, the individual and combined effects of natural and anthropogenic disturbances need to be better understood. In this study, we examined the effects of wildfire and forest harvesting on saproxylic beetle species diversity and composition to test the hypothesis that the combined effects of these two disturbances are greater than either disturbance alone. Specifically, we conducted a replicated, stand-level experiment in and around a large-scale (120,000ha) wildfire that occurred during the spring of 2001 in northern Alberta, Canada. Using flight-intercept traps, we compared saproxylic beetle assemblages from four stand treatments: (1) undisturbed; (2) burned; (3) clear-cut harvested; and (4) post-fire salvaged. Preliminary results suggest that fire and harvesting differentially affect saproxylic beetle assemblages and the combined effects of these two disturbances are cumulative for many (>20%) species. Moreover, our results demonstrate a link between the effects of disturbance, the breakdown of coarse woody material, and soil nutrient status, suggesting that alteration of saproxylic species diversity may have implications for soil nutrient dynamics in burned stands.
"

Mites as ecological indicators of sustainability in Michigan tree fruit

D Nortman, A Coombs, M Whalon
Department of Entomology, Michigan State University, East Lansing, MI, 48824, USA; biasiand@msu.edu

An ecological indicator is a tool that can be used to detect disruption in the environment. In agricultural landscapes, it can be used to determine the relative sustainability of an ecosystem exposed to various combinations of management strategies. Mites are a rapid measuring tool of orchard health and its ability to cope with pest infestations, fertility, mulching, pruning, ground cover management, and many other orchard phenomena. Mites essentially integrate a wide range of management practices, environmental occurrences and surrounding habitat influences in and around the orchard. Monitoring is used to determine mite species presence and their relative abundance. These simple measurements, combined with seasonal ratings, are plugged into a mite index model. The mite index value is used to characterize the orchard along a continuum of orchard ecology classifications. An immediate goal of developing ecological indicators of sustainability is for tree fruit growers to use this information to make ecologically sound orchard management decisions. A more long term goal is for tree fruit growers to understand if their orchards are progressing positively toward a more sustainable and healthy system or negatively toward a disrupted system that will negatively effect yield, nutrient availability, pest populations, and non-target impacts.

Effects of conventional & integrated crop production on Collembola (Arthropoda: Hexapoda) communities in the soil of papaya orchards in Espírito Santo, Brazil

MP Culik, JA Ventura, D dos S Martins
Instituto Capixaba de Pesquisa, Assistência Técnica e Extensão Rural – Incaper, Rua Afonso Sarlo 160, CEP 29052-010, Vitória, Espírito Santo, Brasil; markculik3@hotmail.com

Collembola have significant influences on soil microorganisms and fertility but information on these ecologically important arthropods is lacking, especially in agricultural and tropical environments. This research was conducted to identify species present and determine effects of agricultural practices on Collembola in Espírito Santo, Brazil. Soil samples (4.8cm diameter, 10cm deep) were collected in Feb, May, Aug and Nov 2003 from papaya orchards under conventional (traditional management and pesticide application) and integrated production (selective pesticide application only when necessary based on pest monitoring) in one experimental site with 3 treatments (conventional, integrated with drip irrigation, integrated with microsprinkler irrigation) and 4 commercial orchards (2 with conventional, 2 with integrated production). Berlese-Tullgren funnels were used to extract Collembola from samples. In initial results (February-August) collembolan density ranged from 13,000-187,000 Collembola/m^2. In the experimental site, *Willemia brevispina*, *Arlea* sp., *Folsomina* aff. *onychiurina*, *Folsomides* aff. *centralis*, *Folsomides* aff. *parvulus*, and *Cyphoderus* aff. *similis*, were more abundant with integrated versus conventional production. However, this difference was not observed in commercial orchards sampled. Results indicate that relatively high populations and diverse communities of Collembola occur in papaya orchards in Espírito Santo. However, no collembolan species were apparent as consistant biological indicators of conventional or integrated production.

Biogeography of butterflies (Lepidoptera: Papilionoidea) of the east slope of the Colombian Cordillera Oriental: their use in definition of priority conservation areas

GA Pérez, G Fagua
Carrera 7ª No 43-82, Pontificia Universidad Javeriana, Edificio 53; Bogotá, Colombia; fagua@javeriana.edu.co

The study was made to propose priority conservation areas in the east slope of the Cordillera Oriental, based on a biogeographical analysis of butterflies (Papilionoidea); records from biological collections and literature were gathered to that end. Presence-absence matrixes were made using records and 341 quadrants of 7′ 30″ x 7′ 30″ resulting from the division of the study area. Cluster analysis and parsimony analysis of endemicity analysis were applied to them, and biogeographic units were defined and evaluated according to priority criteria for conservation. 8145 records of 1269 species were obtained, belonging to 62 municipalities of 10 departments that comprise the east slope of the Cordillera Oriental. Records were found only in 83 quadrants where 1098 butterfly species with specific geographic information were registered. The butterflies of the east slope these follow a distributional pattern determined by the influence of the transinterandean and cisandean biogeographical regions, differentiating two areas: the middle and south parts of the east slope, besides of being segregated by an altitudinal gradient. These areas were defined too as coincident with humid refuges and centers of endemism. The regions that gather the municipality of Mocoa (Putumayo), Piamonte (Cauca) and Ipiales (Nariño) were to be considered of priority in conservation efforts.

Detecting canopy insect fauna in a tropical rain forest

K Fukuyama, K Maeto, AS Sajap
Matsunosato 1, Ibaraki 100-8952 Japan; fukuchan@affrc.go.jp

A comparative study of trap systems for flower visiting beetles was carried out at Pasoh Forest Reserve, West Malaysia, in the canopy of a lowland tropical rain forest. We compared a balloon system (traps hung by balloon), a hanging system (traps hung by rope from a branch of an emergent tree) and a tower system. Abundance of scarabaeid beetles caught by traps was highest in the balloon system and lowest in the hanging system. The species composition of Scarabaeidae caught by the balloon system was quite similar to the tower system but was relatively different from the hanging system. *Dasyvalgus dohlni* and *D. pyrrhopygus* were absent in catches from the hanging system. *D. dohlni* and *D. pyrrhopygus* were therefore distributed in a relatively higher part of the forest canopy. This suggests that the hanging system was not so effective in catching beetles acting in the upper canopy and that the balloon system was useful in collecting these beetles because we were able to elevate the trap above the canopy layer.

Are endemic Curculionoidea (Coleoptera) good bioindicators of high biodiversity areas in the Iberobalear region of the southwest Europe?

P Gurrea, MJ Sanz
Fac. Biología. Universidad Autónoma de Madrid, Cantoblanco, 28049 Madrid, Spain; pilar.gurrea@uam.es

Endemic species represent a way to quantify the richness, diversity and habitat conservation status of geographic areas. In this way, the Ibero-Balear region occupies an outstanding position in Southwest Europe as it has a high concentration of endemic species and is considered as the origin point of a great number of other species that actually have a wider distribution. The results showed in previous works, allowed us to elaborate the Book of the endemic Curculionoidea from the Iberian Peninsula, Balearic and Canary Islands. In the Iberobalear region over 2000 curculionoidea species are known, from which more than 25% have been recorded as endemic of this region In the present work we have analized the distribution of these endemic species in the Iberian Peninsula and Balearic Islands, and we have compared it with the distribution of other arthropod groups, amphibians, reptiles and monocotyledonous plants. Although the studied groups differ in the levels of endemicity and in the width of the distribution ranges, almost in all of them distribution patterns of high endemicity areas are similar. There is a significant correlation between most groups and we also discuss if the endemic Curculionoidea are good bioindicators of high diversity areas.

Distribution map of genus *Exapion* (Coleoptera, Curculionoidea, Apionidae) in Spain

MJ Sanz, P Gurrea
Dep. Biología. Universidad Autónoma de Madrid, Cantoblanco, 28049 Madrid, Spain; pilar.gurrea@uam.es

Genus *Exapion* includes nearly 30 palaearctic species, although today its range of distribution has been increased due to the introduction of certain species (*E. fuscirostre* (F.) and *E. ulicis* (Forst.)) in other parts of the world as Australia, New Zealand and Northamerica. These introduced species have been largely used as control agents of also introduced weeds as *Ulex europaeus* L. and *Cytisus scoparius* (L.) Link. In Spain, is represented by 15 species that belong to two subgenus: *Exapion* with 10 described species and 4 subspecies, and *Ulapion* with 5 described species. Almost half part of these, are Spanish endemic species (six species), some of them restricted to small areas as *E. oblongulum* (Desbr.), *E. wagnerianum* (Schatzm.), *E. breviusculum* (Rosenh.) and *E. laufferi* (Schils.). The *Exapion* species more widely distributed is *E. fuscirostre* known from great part of the Spanish mountain range, due to its association with certain Genisteae species that belong to the genus *Cytisus* (*C. scoparius, C. multiflorus* (L'Hér.) Sweet, *C. oromediterraneus* R. Mart.) that are widely spread in the mountains of Spain. Distribution maps show that the Spanish province that have more species of this genus is Leon (in the north), with most of the records associated to the mountain systems (Montes de Leon and Cordillera Cantábrica)

Do summertime temperatures form hotspots of jumping spider endemicity?

NA Guthrie
Wildlife Research Centre, Department of Conservation and Land Management, PO Box 51, Wanneroo, 6946 Western Australia; nadineg@calm.wa.gov.au

Previous sporadic and opportunistic collecting of jumping spiders (Salticidae) indicated that the southern and central-western regions of Australia are centres of endemicity. Recent broad-scale biogeographic surveys in Australia have revealed many new undescribed forms of jumping spider, indicating the presence of a very rich and diverse fauna. A broad-scale biogeographic survey of the jumping spider fauna (Salticidae) of the Western Australian Wheatbelt was carried out to determine the levels of diversity and their relationships with environmental gradients on a regional scale. A total of 41 genera and 121 species, of which 17 genera and 106 species are undescribed, were collected. Patterns in the species composition of assemblages across the survey area were broadly correlated with environmental gradients, particularly 'Maximum Temperature in the Warmest Period'. High proportions of apparently localised endemic species dominated the geographical patterns in species composition. Speciation in these 'hotspots' may be driving broad-scale biogeographic patterns in this area, but more detailed taxonomic and ecological studies are required to test this hypothesis.

Saproxylic invertebrates & wood decay fungi in living trees in Tasmania's southern forests

KS Harrison, AJM Hopkins, SJ Grove, TJ Wardlaw, CL Mohammed
Co-operative Research Centre for Sustainable Production Forestry, University of Tasmania, Private Bag 12, Hobart, Tas 7001; Kate.Harrison@ffp.csiro.au

Mature trees are an important part of a forest ecosystem providing a range of unique habitats that are utilised by both vertebrates and invertebrates. In the southern hemisphere little is known about the saproxylic organisms associated with living trees. However, in Europe many species of invertebrates and wood decay fungi associated with old trees are threatened, due to a severe decline in habitat availability. A long-term impact of current native forest management in Tasmania's wet eucalypt forests will be to alter stand age structure across the managed forest landscape, resulting in the decline of old-growth features. The effect this will have on the saproxylic communities is unknown due to a lack of knowledge of both the species involved and their habitat requirements. This poster describes two ongoing interrelated ecological studies of saproxylic communities that should put ecologists in a better position to advise on ways of sustaining the full spectrum of biodiversity in managed wet eucalypt forests. One is an investigation of the invertebrate assemblages found in living *Eucalyptus obliqua* trees of different ages (young regrowth to oldgrowth), and the other explores the relationships between fungal communities, stages of stem decay and increasing stem age.

Bear necessities: myrmecophagy of grizzly bears in north-central British Columbia.

RJ Higgins
University of Northern BC, 3333 University Way, Prince George, BC, Canada V2N 5A4; rhiggins@cariboo.bc.ca

The grizzly bear (*Ursus arctos*) is a species of special concern in central British Columbia. Little is known regarding grizzly bear ecology in the Sub-boreal spruce biogeoclimatic zone, so a multi-year study was conducted between 1998 and 2002. As part of the larger study, we investigated bear myrmecophagy by direct and indirect assessment. Up to 62 radio-collared grizzly bears were located twice per week. Randomly selected bear locations were visited within 1-14 days, and a habitat-plot survey was conducted. Foraging was the primary activity identified at 385 of the 538 sites visited. Of 9 food-related activity categories, foraging for ants was the 4th most common. Myrmecophagy was infrequent in spring, but relatively significant in summer and fall.

Grizzly bears appeared to forage opportunistically for ants, and showed little preference for any particular species. Half of the bear scats with ants had a high proportion of ant remains of many species, indicating targeted "anting". The most prevalent species eaten were *Camponotus herculeanus*, *Formica neorufibarbis*, *Formica aserva* and *Lasius pallitarsis*, all of which are very common in the study area. This study shows that ants are an important food source for grizzly bears. Promoting ant habitat is recommended for grizzly bear management.

The rediscovery and captive breeding of the "extinct" Lord Howe Island stick insect, *Dryococelus australis* (Phasmatidae)

D Priddel, P Honan, S Fellenberg, M Humphrey, N Carlile
Macleay Museum, University of Sydney, NSW, 2006, Australia; margaret@macleay.usyd.edu.au

Dryococelus australis was a large, impressive stick insect, abundant in the forests of Lord Howe Island until it was exterminated following the introduction of rats in 1918. In February 2001 three live specimens of *D. australis* were discovered feeding on the tea-tree, *Melaleuca howeana*, on Ball's Pyramid, a desolate, volcanic spire, 25 km SE of Lord Howe Island. Although about 30 bushes of *M. howeana* and other low vegetation were growing on Ball's Pyramid, the stick insect was found on only one *M. howeana* bush that was growing below a small water seepage. When Ball's Pyramid was visited again in 2003, 17 individuals were counted and two pairs were removed for captive breeding in Sydney and Melbourne. Both pairs have successfully bred, resulting to date, in over 200 eggs that have so far yielded 12 nymphs in late instar and two adults.

A comparison of insect assemblages associated with macrofungi in native & exotic New Zealand woodlands

S Hodge, I Andrew, J Marris
Dept. of Agricultural Sciences, Imperial College London, Wye, Kent, TN25 5AH, UK; s.hodge@imperial.ac.uk

The fruiting bodies of macrofungi attract a specialist guild of fungivorous arthropods, along with their associated parasitoids and predators. The aim of this study was to compare the Coleoptera and Diptera found on decomposing fungi in four classes of New Zealand woodlands: native beech, native mixed deciduous, restoration/conservation sites and exotic plantations. Seventeen woodlands across the South Island were examined and, to standardize sampling, insects were collected using traps baited with commercially produced *Agaricus* mushrooms. In total, 9 families and 36 species of Coleoptera were collected, along with 14 families and 47 species of Diptera. As expected, the native beech and deciduous woodlands had the most diverse coleopteran faunas, with the restoration/conservation sites having the poorest. However, Diptera where most diverse in the exotic conifer plantations, with the mixed deciduous woodlands having the least rich faunas. The results indicate that conclusions regarding the diversity of woodland faunas can be dependent upon which taxa or functional guilds are considered. The results also suggest that monoculture plantations of exotic tree species need not necessarily contain less diverse faunas than native woodlands. The use of a 'site score' based on this specialist guild may have potential use as an indicator of conservation success.

Change in a butterfly community with forest growth in a cool temperate region of central Japan

T Inoue
Forestry and Forest Products Research Institute, PO Box 16, Tsukuba, Ibaraki, 305-8687, Japan; taisei@ffpri.affrc.go.jp

Transect counts of butterflies were conducted in the northern part of Ibaraki, central Japan at 22 census sites, composed of successive stages of forest growth (natural deciduous forest series and coniferous plantation series). The species richness, abundance and diversity indices of butterflies were high in the early stages of forest growth in both the natural forest and plantation series. In the natural forest series, typical natural forest species increased with the progress of secondary succession, and the old secondary forests and old-growth natural forests had similar species composition. Almost no typical natural grassland species were recorded in the young secondary forests. In the cutover land, the number of individuals of grassland species considerably decreased from the first to the second year after clear cutting. Thus, the suitable stage for grassland butterfly species lasts for only 1–2 years after clear-cutting because the regrowth closes over the ground vegetation after 3-4 years. Old secondary forests may be able to give refuge to the forest butterfly species, including typical natural forest species. In the plantation series, only a few typical natural forest species were recorded in the older stages, but the species richness and abundance of grassland species (incl. typical natural grassland species) were very high in the young plantations (up to 7th-8th year) because of frequent clearings by humans.

Effects of volcanic ash on insects in a tropical forest canopy

KA Marske, MA Ivie
Department of Entomology, Montana State University, Bozeman, MT 59717 USA; mivie@montana.edu

The effects of volcanic ash on insects have been proven repeatedly in the laboratory, but field studies are few, and have utilized temperate-zone ground-dwelling species or colonial Hymenoptera. Our research focuses on an entire arthropod community in the tropical forest canopy, and at a still-intact habitat affected by volcanic activity rather than a devastated blast zone requiring recolonization. We investigated the impact of ash deposition levels on canopy arthropods from the West Indian island of Montserrat, which has been subject to ongoing volcanic eruption since 1995. Arthropod samples were obtained using canopy fogging at four sites regularly receiving different levels of ash deposition, and foliar ash was measured during each sampling. We compared our findings from Montserrat with samples from the neighboring island of St. Kitts, which has not been subject to recent volcanic activity. Based on analysis of 44,290 specimens in 34 samples from 4 sites on Montserrat and 3684 specimens in 3 samples from 3 sites on St. Kitts, volcanic ash appears to have a limited impact on the forest canopy insects of Montserrat. We explore potential environmental and evolutionary implications for these results.

Genetic diversity & phylogeography of endemic beetles on oceanic islands: examples from the Canary archipelago

C Juan, O Moya, HG Contreras-Díaz, P Oromí
Departament de Biologia, Universitat de les Illes Balears, 07122 Palma de Mallorca, Spain; cjuan@uib.es

The Canary Islands constitute one of the 25 "hot spots" of worldwide biodiversity. Seven main volcanic islands, 110 km northwest Africa, form the island belt. They have a large diversity of habitats, including a low altitude xeric scrub, cloud and pine forests plus high altitude alpine areas. A fifth of the about 7000 species of the terrestrial invertebrates in the archipelago, are endemic Coleoptera. The effect of habitat fragmentation on the genetic variation levels of Canaries beetles varies among species with different life history traits and time since fragmentation. We focussed into two genera with quite different life histories; the endemic species of the genus *Pimelia* (Coleoptera, Tenebrionidae), present in arid and semiarid regions of all islands, and the carabid species-pair *Eutrichopus gonzalezi* and *E. canariensis*, occurring in the cloud laurel forest of the island of Tenerife. We have obtained COII mitochondrial sequences of *Pimelia* taxa and populations from several islands, and in *E. canariensis* and *E. gonzalezi* to study phylogeographic and demographic patterns. There are clear associations between volcanic events and genetic differentiation within and between taxa. The aim is to provide useful information helping in conservation management of the beetle populations and the island habitats they inhabit.

Diversity, biogeography and ecology of the insects of Australian rainforests– an overview

N Lenz
Aquazoo – Löbbecke Museum, D-40200 Düsseldorf, Germany; orbert.dr_lenz@stadt.duesseldorf.de

Australian rainforests have been the subject of numerous studies since the late 1950s, mostly devoted to defining 'rainforest', mapping the distribution of rainforests and classifying them, based on structural and physiognomic features, and climatological parameters. The insects of Australian rainforests have only come into focus more recently, and the available information on them is reviewed in this study. Although rainforest covers only 0.3 % of Australia´s land area, it is particularly biologically diverse. Maps depicting the geographic distribution of Odonata, Cicindelinae, Rhopalocera and Formicidae show that these taxa are most species-rich in high rainfall areas, particularly those in the tropics. This distribution pattern, however, does not apply to all insects, Isoptera and Tettigoniinae being examples of taxa more species-rich in drier areas. Australian rainforests are well known for their evolutionarily conservative plants but are also home to several families of 'ancient' insects, such as the Peloridiidae, Xylophagidae, Micropterigidae and Agathiphagidae. Insects play many roles in rainforest ecosystems, as herbivores, decomposers, pollinators, seed dispersers, predator or prey. Rainforest insects represent textbook examples for camouflage and mimicry, but for many species it is still unknown how restricted their habitat requirements, and how host specific they are – information needed to protect their diversity.

Biogeography of the Australasian genus *Melobasis* (Coleoptera:Buprestidae)

B Levey
Department of Biodiversity & Systematic Biology, National Museum & Galleries of Wales, Cathays Park, Cardiff CF10 3NP, U.K; brian.levey@nmgw.ac.uk

Melobasis is a primarily Australasian genus with around 200 known species in Australia, and around 40 known species from Papua. Within Australia the distribution patterns of species and subspecies suggest that speciation has been primarily the result of allopatric speciation at times of increased aridity. Only a few widespread species occur in the regions having less than 400mm of rainfall a year. A number of species from the less arid areas of S.W and S.E. Australia exhibit geographical variation, with the subspecies having distributions suggestive of differentiation in less arid refugial areas during drier periods, and in some cases more recent geographical overlap and introgression. The S.W. of Australia is the region of highest species richness. Within this region the transitional rainfall zone is much richer in species than the high rainfall zone and most of the endemic species occur in the former zone. Humid and sub-humid areas of S.E. Australia to S. Queensland, sub-humid central Queensland and the rainforest areas of Queensland south of Cape York Peninsula are also areas with many endemic species.

Discriminant analysis of the disruptive impacts of a horticultural mineral oil and two synthetic pesticides on citrus ecosystems

WG Liang, GAC Beattie, R Spooner-Hart, A Meats, L Jiang
NSW Agriculture, Locked Bag 26, GOSFORD, NSW 2250, Australia; weiguang.liang@agric.nsw.gov.au

The disruptive impacts of an *n*C24 horticultural mineral oil (HMO) and two synthetic insecticides (carbaryl and methidathion) on citrus ecosystems were evaluated in Peats Ridge and Kulnura on the central coast of New South Wales, Australia. At Peats Ridge, the impact of HMO was compared with carbaryl and methidathion in single trees, while at Kulnura, HMO was compared with methidathion in blocks of trees. Discriminant analysis was used to distinguish between the impacts of the different pesticide applications. Parameters representing scale pests and their natural enemies, as well as soil fauna, were included in the analyses. The model clearly distinguished the treatments into groups with a greater difference between the synthetic pesticide groups and the unsprayed control than between the HMO treatment and the unsprayed control. Results indicated that the HMO only had a minor and transient impact on the citrus ecosystems, while carbaryl and methidathion had significant and long-term disruptive impacts on the arthropod communities within these ecosystems.

Geographic variation in the water-based defence system of plants in the genus *Adriana*.

DA Mackay, MA Whalen
School of Biological Sciences, Flinders University, GPO Box 2100, Adelaide. S.A. 5001, Australia; duncan.mackay@flinders.edu.au

Adriana (Euphorbiaceae) is an endemic genus of dioecious shrubs widely distributed in Australia. Extra-floral nectaries (EFNs) occur at the base of the leaves in the stipular position and are frequently visited by several species of ants. A survey of geographic variation in the size of EFNs of adrianas was conducted. Nectary sizes on plants collected from sites across Australia were matched with climate data from the nearest climate station. Data from three plant taxa were analyzed using multiple regression to relate gland widths to a series of climatic variables. Stipular gland widths exhibit significant geographic variation which is correlated with climatic factors, particularly the amount and variability of rainfall. Functional EFNs are found on plants of all three taxa and EFNs tend to be smaller on plants from areas of low rainfall. A droughting experiment was conducted in the glasshouse to examine the effects of water stress on extra-floral nectaries and nectar production. Numbers of active or functional nectaries on water-stressed plants did not decline more rapidly than numbers on watered plants. Reasons why water-based defences may still be effective for plants in arid regions are discussed.

Tube-renting wasps and bees monitored with nesting traps in Japanese forests

S Makino
Forestry and Forest Products Research Institute, Tsukuba, 305-8687 Japan; makino@ffpri.affrc.go.jp

"Nesting traps, which are typically made of drilled wooden blocks, reeds, or bamboo shoots, have widely been used to monitor hunting wasps or bees. This is because many of those species preferentially or exclusively nest in pre-existing tubelike structures, and because the nesting trap is easy to apply to various environments. We studied the tube-nesting hymenoptera with the nesting trap in cool-temperate forests of varying ages in Japan (36°N, 140°E) in order to learn how their species composition differ with forest conditions. A single trap was composed of 20 bamboo shoots and reeds, 4 to 16 mm in diameter, which were fastened together. We installed nine traps in each of six secondary deciduous broad-leaved stands, varying from 2 to >100 yr in age after clear-cutting, and in two conifer plantations, 5 and 70 yr-old. About 30 aculeate species utilized the traps in the 8 stands. The number of species recorded and the proportion of traps utilized were larger in younger than older stands both in broad-leaved and conifer stands. Spider wasps (Pompilidae) remarkably occurred in every stand in contrast with mason wasps (Eumenidae) or bees which only nested in young stands.
"

Macroinvertebrate diversity of isolated wetlands: are wetland quality and size important factors?

MD McIntosh, RW Merritt, V Lougheed, CA Parker, RJ Stevenson
243 Natural Science Building, Department of Entomology, Michigan State University, East Lansing, Michigan, USA, 48824; mcinto57@msu.edu

Recent attention has focused on the conservation of isolated wetlands due to changes in the federal wetland regulatory program. In order to protect these isolated wetlands, more scientific information is needed to understand the ecology and function of these ecosystems. Our research focused on the role of different biological communities within isolated wetland ecosystems and how these communities change with environmental stressors (e.g., human disturbance). Specifically, the objective of this study was to compare macroinvertebrate diversity among isolated wetlands of variable quality (impacted or non-impacted) and size (large or small). Four depressional marshes were sampled from each possible combination of treatments (large impacted, large non-impacted, small impacted, and small non-impacted) from the Muskegon River watershed, Michigan, USA, during July 2002. Preliminary results suggest differences in macroinvertebrate diversity among wetlands of variable quality; however differences due to wetland size were not as defined. Knowledge of the association between macroinvertebrates and environmental stressors can be utilized in the assessment of wetland health, predicting change in wetland structure, and in the establishment of biocriteria for the regulation and protection of isolated wetland ecosystems.

Evolution of behavioural & ecological diversity: Australian *Acacia* thrips as model organisms

LA Mound, BJ Crespi, DC Morris
L.A. Mound, CSIRO Entomology, Canberra ACT Australia 2601; laurence.mound@csiro.au

A single lineage of phytophagous thrips has radiated on Australian *Acacia*, resulting in over 250 species in 30 genera. This radiation has generated four ecological suites of species: gall-inducing species (some of which have defensive 'soldier' castes), species that create a domicile by glueing together two or more phyllodes, parasitic species of these two, and opportunistic species that use old domiciles or other microhabitats. This study integrates ecology, behaviour, molecular phylogenetics and taxonomy, including the description of 140 new species. The driving force behind the system is the arid and unpredictable Australian climate that leads to intense competition for small protected spaces. These ecological pressures have generated a positive feedback mechanism, such that adoption and modification of host-plants by some thrips species create further niches for additional species. The causes and consequences of this behavioral-ecological diversification are explored through a novel, 'model clades', approach that provides insights into the evolution of social behaviour, host-plant use, and exploitative behaviours. The remarkable morphological, behavioural and ecological variation exhibited by these insects means that they can be considered a microcosm for understanding the processes that generate biodiversity among all phytophagous insects, and indeed among all animals.

Temporal and spatial variation of arboreal beetles diversity in an Amazonian rain forest

MC Pimienta, OE Murillo, TL Erwin
Calle 13 No 41 A 24, Cali, Valle del Cauca, Colombia, Suramérica; cleopim@hotmail.com

Tropical communities are rich in diversity; however, many species have very local or patchy distributions, so that a complete understanding of species diversity requires comparison of species turnover at local scales. We assess the patterns of coleopteran diversity on different spatial and temporal scales at two 10 ha plots in western Amazonian forests. At each plot, we sampled diversity of seven groups of arboreal beetles by fumigation at 100 stations. During the sampling period, there was significant temporal variation in species richness due to the effects of El Niño Southern Oscillation and significant spatial variation amongst stations influenced by the architecture of the forest canopy within the two plots. Spatial autocorrelation analysis revealed that the richness and composition of this coleopteran assemblage was significantly patterned at distances below 1000 m for herbivores, fungivores and predators beetles, while dung beetles do not display any spatial structure. Such variation can strongly affect overall patterns of diversity and contribute to the high diversity characteristic of tropical coleopteran communities. Knowing the temporal and spatial patterns of distribution may be a fundamental step toward understanding basic patterns of species richness, hence achieving knowledge crucial to the evaluation of conservation effectiveness among conservation strategies.

Conservation of Galapagos Lepidoptera: a preliminary analysis of the endangerment status and factors affecting the Galapagos endemic Lepidoptera

L Roque-Albelo, B Lany
Charles Darwin Foundation, Galapagos Islands, Ecuador, P.O. 17 01 3891 & Biodiversity and Ecological Processes Research Group, Cardiff School of Biosciences Cardiff University, PO Box 915, Cardiff CF10 3TL, United Kingdom; lazaro@fcdarwin.org.ec

The Galapagos Lepidoptera fauna is characterized by poor diversification, high level of endemism and prolonged geographic isolation. These characters, because of their scientific importance, constitute unique attributes that emphasize, as a priority, their study and conservation. These unique attributes have been the foci of our research and conservation efforts for 15 years. So far, 310 species of Lepidoptera are known to occur on the archipelago and 52 % of the native component of this fauna is endemic. This study investigates the factors affecting the conservation of the endemic species and presents preliminary data on their endangerment status. The introduction of exotic species and the transformation of native forests into agricultural or urban areas are the main factors affecting the conservation of the endemic species.

The effects of human impacts on cave arthropod biodiversity: Thailand component

W Sakchoowong, C Hutacharern, D Smart, R Cunningham, P Sawai, P Vichitbandha, R Phukthair
Department of National Parks, Wildlife and Plant Conservation. 61 Phaholyothin Road, Chatuchak, Bangkok, 10900, Thailand; wsakchoowong@yahoo.com

Cave ecosystems are widely regarded as being one of the most vulnerable ecosystems on earth. They are remarkably fragile and subject to intense pressure from human activities. One of the most prevalent of these activities is the human utilization of caves for recreation and tourism. These activities are detrimental to the cave ecosystem is based largely upon the collective results of numerous, piecemeal observations. These observations have shown clearly that specific events and situations caused by people have an effect on the occurrence, absence or distribution of certain species. However, whilst useful at micro-management levels, this evidence can only be regarded as circumstantial when trying to establish links between cave use and the ecosystem as a whole, as required in macro-management. This study was carried out by conducting a replicated, natural experiment examining the overall effects of cave visitation and disturbance on the ecosystems of seven stream caves in southern Thailand, Meso and macro terrestrial arthropods were sampled in January, March and May 2003. A total of 4079 specimens were collected representing 519 species from 24 orders in 5 classes, showing the effects of disturbed areas having greater abundance than undisturbed areas and the highest diversity occurs near the entrance.

Geographical structure of morphological characters and mitochondrial DNA in *Semanotus japonicus* (Coleoptera: Cerambycidae) in Japan

E Shoda-Kagaya
Forestry and Forest Products Research Institute, Tsukuba, Ibaraki 305-8687, Japan; eteshoda@ffpri.affrc.go.jp

The sugi bark borer, *Semanotus japonicus*, occurs naturally in Honshu, Shikoku, Sado Is., and Oki Is. in Japan, and its main host tree is the Japanese cedar, *Cryptomeria japonica*. After intensive establishment of cedar plantations occurred during the 1960-70's, this borer has become a serious forest pest. To assess the geographical structure of *S. japonicus* populations, I used morphological and molecular information. Multivariate analyses were performed based on external morphological characters of the borer in Honshu and Shikoku. Comparing populations along the Pacific coast and populations by Wakasa Bay (on the Japan Sea), the reverse morphological features were indicated. Populations in the northeast and the southwest Honshu showed intermediate conditions. The patterns of morphological variations in *S. japonicus* are approximate to the distribution of the refugia of *C. japonica* throughout the glacial maximum. It is suggested that the geographical structure of the present *S. japonicus* population was caused by isolation during the last glacial period. Then I used partial sequences from mitochondrial DNA genes, the COI, tRNA$^{\text{Leu-UUR}}$ and COII to elucidate processes in the geographical structuring of *S. japonicus* populations. Two distinct lineages were detected, which probably represented the Pacific coastal and the Japan Sea side lineages.

Biodiversity of scarab beetles in Himalayan region of India & its correlation with weather parameters

SN Sushil, JC Bhatt, M Mohan, HS Gupta
Vivekananda Insitute of Hill Agriculture, (Indian Council of Agricultural Research), Almora-262 601 Uttaranchal, INDIA. E-mail : snsushil@yahoo.co.uk

Scarab beetles, commonly called as White grubs, are the major limiting factor in agricultural crop production particularly during the months of April to October in the Himalayan region of India. Upland rice, finger millet, barnyard millet, French bean, black gram, chilies, tomato, brinjal, ladies finger, apple, pear, plum, pomegranate and forest trees such as *Quercus* sp., *Grevia optiva*, *Toona ciliata*, *Alnus nepalensis*, *Celtis australis* are severely damaged by the grubs. Due to changes in cropping pattern and profuse deforestation coupled with reduction in the population of predatory birds and other natural enemies, the white grub problem became alarming in the region. More than 40 species of white grubs belonging to subfamilies viz., Melolonthinae, Rutelinae, Dynastinae, Cetoniinae, Troginae, Scarabinae and Aphodinae of family Scarabidae have been recorded from the region. Attempt has been made to correlate white grub beetle population with the climatic factors *viz.,* maximum temperature, minimum temperature, relative humidity and rainfall. Data of light trap catches of white grub beetles of 13 years revealed significant correlation of weather parameters with beetle emergence. The present paper discusses species diversity and critically analyses impact of climatic factors on beetle population in the region.

Biology and distribution of the sugarcane planthopper genus *Eumetopina* (Hemiptera: Auchenorrhyncha: Delphacidae)

MR Wilson
Department of Biodiversity & Systematic Biology, National Museums & Galleries of Wales, Cardiff, CF10 3NP, UK; mike.wilson@nmgw.ac.uk.

Sugarcane has a very interesting Auchenorrhyncha (Hemiptera) (leafhopper and planthopper) fauna and among them the planthopper genera *Perkinsiella* and *Eumetopina* are of special significance. *Eumetopina* species are confined to SE Asia (although two African species are currently placed in the genus) and distributed from the pacific islands to Vietnam, but the greatest number of species seem confined to Papua New Guinea, the origin of commercial sugarcane. *Eumetopina* species live exclusively on sugarcane and are found in the growing shoot of the cane. When found they may be very common (hundreds per plant) and are frequently attended by ants of various genera. Around nine species have been described from SE Asia- mostly from Papua New Guinea but perhaps another ten species remain undescribed. One species, *E. flavipes* Muir is known to spread a phytoplasma disease of sugarcane (ramu stunt) in PNG and is found quite widely distributed on some Pacific islands. The biology, taxonomy and distribution of the known and undescribed species will be reviewed.

What wasp is that ? An interactive key to the identification of Australian & New Zealand ants, bees, sawflies & wasps.

A Austin, J Jennings, N Stevens
The University of Adelaide, Centre for Evolutionary Biology & Biodiversity, School of Earth & Environmental Sciences, S. Aust, 5005. Australia.
andrew.austin@adelaide.edu.au

The Hymenoptera is one of the largest terrestrial invertebrate groups and can be found in most habitats including intertidal and freshwater environments. They perform important functional roles in natural and agricultural communities as herbivores, pollinators, and as predators and parasitoids. This interactive key provides an easier alternative to traditional dichotomous keys for enthusiasts and professionals to identify families of Hymenoptera occurring in Australia and New Zealand. The CD also provides comprehensive information about the order. The morphological characteristics and the biological traits for each family are well illustrated and clearly explained. In addition, a review of past and present phylogenetic classifications of the Hymenoptera is concisely laid out. A thorough bibliography is also included which allows users to easily access the major titles in the study of the Hymenoptera.

The cicadas of central eastern Australia

LW Popple
Dept Of Zoology & Entomology, University Of Queensland, Brisbane QLD 4072, Australia. l.popple@uq.edu.au

This website is designed as an interactive identification guide to the cicadas of central eastern Australia. It covers an area extending from the Wet Tropics in northern Queensland south to the south coast of New South Wales and west to approx. 144°E. General information is provided on cicada endemicity, feeding, life histories, common names, biology, phenology, sound production and reception mechanisms, sexual communication, calling songs, habitats, defining species limits, species of economic importance, collection and literature. Specific information is given for the two families, Tettigarctidae and Cicadidae, 33 genera and 230 species within the region. Text detailing the appearance, size, distributions, habits and songs is provided for all species illustrated, along with photos, distribution maps and sound recordings, where available.

The distribution & conservation status of gall-forming midges from acacias in southern Australia

RJ Adair
"Department Of Primary Industries, Po Box 48, Frankston, VIC 3199, Australia; robin.adair@dpi.vic.gov.au"

Acacias of southern Australia support a species-rich fauna of gall-forming Cecidomyiidae that utilise inflorescences for their development. Most taxa are undescribed but can be identified using insect morphology, DNA sequences, gall morphology and biological characteristics. Eight broad groups of Australian midges were recognised based on gall and life history characteristics that encompass 22 species of *Dasineura* and eight species of *Asphondylia*. The conservation status of gall-forming cecidomyiids of *Acacia* was determined by scoring four host related factors (abundance, reservation status, host-organ availability, horticultural utility) and five insect related factors (abundance, specificity, temporal constraints, spatial constraints, reproductive capacity). Using insect-related factors alone, eight cecidomyiids had low score values, and when combined with host-related factors, four species had low total scores indicating potential for conservation concern. Surveys in 400 km grid squares indicate eastern Australia has a higher species richness of gall-forming cecidomyiids than Western Australia with most species (16) recorded from the northern New South Wales-southern Queensland region. There was a strong segregation in the faunal distribution between eastern and western Australia, with only two species shared between the two regions. Two eastern Australia species, *D. rubiformis* and *D. pilifera* were found naturalised and abundant in Western Australia.

Himalaya: evolution of a "hot spot" area - insight from phylogenies of sericine chafers (Coleoptera: Scarabaeidae: Sericini)

D Ahrens
"Deutsches Entomologisches Institut (DEI) im ZALF, Eberswalder Str. 84, D-15374 Müncheberg, Germany; ahrens.dirk_col@gmx.de, dahrens@zalf.de"

Due to extent in width and height, the Himalaya has an outstanding position within the tertiary orogenetic belt at the southern margin of the former Cretaceous Asian continent. In the present study phylogenies were generated for ten genera/species' groups of sericine chafers (Coleoptera: Scarabaeidae) with different patterns of vertical and horizontal distribution. The cladistic analyses were based on morphology, mainly characters of external skeleton and genitalia. These hypotheses of phylogeny provide evidence to predict multiple events of radiation which may be regarded as a main source of the high diversity within this region. The occurrence of numerous basal lineages in the Himalaya, additionally, lead to assume that the Himalaya was in historical framework a „refugium", too, being able to buffer fluctuations of climate by "orobiom-shifting". The phylogenies found show a congruent pattern in groups with similar vertical and/or horizontal distribution. Patterns of vertical and/or horizontal distribution are shown to be of crucial importance for gene flow, dispersal capacity, and for the opportunity to occupy new habitats. Hence, in framework of evolutionary process they should have influenced not only patterns of diversification but they determined recent faunal composition (obviously, beside the influence of recent climate) of the Himalaya, too.

Diversity of arthropod fauna associated with rice ecosystem in Nagaland, India

A Zhimomi, M Alemla, Imtionen, HK Singh
Department of Entomology, School of Agricultural Sciences and Rural Development, Nagaland University, Medziphema Campus, Nagaland – 797106, India; alemla2000@yahoo.com

Large numbers of diverse arthropods are associated as pests and beneficial with rice ecosystem in Nagaland. Rice is the staple food, which is traditionally cultivated under jhum, terrace and low wetland farming depending on the topographic conditions. For an effective pest management, identification of key pests and their natural enemies is very important. The present investigation was therefore, conducted during 2002 to 2003 under terrace farming located at Jotsoma area (1070 MSL) to find the qualitative and quantitative composition of arthropod faunas.Twenty-one families of seven orders were recorded as aerial arthropods with maximum number in Anisoptera and Zygoptera. Twentyfive families of eleven orders represented the nightactive arthropods where Muscidae followed by Blattidae and Meloidae were recorded maximum. The terrestrial arthropods were represented by eighteen families of ten orders with Collembolla and Formicidae being dominant. Few groups of Cryptostigmata, Collembola and immature Scarabaeidae were recorded from soil inhabiting arthropods with Collembola as dominant group. It also showed that terrestrial arthropods were most abundant followed by aerial arthropods with different group dominating different faunas. Besides, natural enemies such as *Cicindella sp. Coccinella septumpunctata, C. sexmaculata, C. transversalis, Agriocnemis pygmaea, A. femina femina, Tetragnatha sp., Oxyopes sp., Agriope sp,* and Theridid spiders were abundantly found.

Evolutionary radiations of ants in arid Australia

AN Andersen
"CSIRO Tropical ecosystems Research Centre, PMB 44 Winnellie, NT 0822, Australia; Alan.Andersen@csiro.au"

Ants are undoubtedly one of the biggest biological success stories in Australia, and their story is played out primarily in the arid zone. Ant species richness, productivity and behavioural dominance are all far higher in arid Australia than in climatically comparable regions elsewhere in the world. Semi-arid southern and northern Australia support by far the richest communities of epigaeic ants known on Earth, with over 100 species commonly occurring within 0.2 ha. However, ant genus richness is only moderate, with its extraordinary species richness due to exceptional speciation within a relatively few genera. The most important genus ecologically is *Iridomyrmex*, whose species exert a level of behavioural dominance unparalleled elsewhere in the world outside the canopies of lowland tropical rainforest. The three richest genera, *Melophorus*, *Meranoplus* and *Monomorium*, each with huneds of species in arid Australia, possess remarkable adaptations that indicate a long evolutionary association with behaviourally dominant species, pointing to unusually high ant productivity over evolutionary time in arid Australia. A range of historical and ecological factors is likely to contribute to the remarkable ant diversity in arid Australia, but there is emerging evidence that carbohydrate supply might be the key driving force behind exceptional productivity and behavioural dominance.

Natural enemies & the evolution of resistance to Bt crops in herbivorous insects

DA Andow
Department of Entomology, 219 Hodson Hall, University of Minnesota, St. Paul, MN 55108 USA; dandow@umn.edu

Some recent theoretical research has suggested that natural enemies can retard or accelerate the rate of evolution of resistance to Bt crops in an herbivorous insect. Other theoretical results imply that natural enemy induced mortality may have little influence on the rate of evolution. I provide an overview to the various theoretical approaches to the problem of resistance evolution and focus on the role of natural enemies in modifying evolutionary patterns. I suggest some conditions where natural enemies could exert considerable selection pressure on an herbivorous insect to adapt to Bt crops.

Indicators of climate change: insect herbivore colonisation of a novel host plant in a warmer climate

NR Andrew, L Hughes
"Key Centre for Biodiversity and Bioresources, Department of Biological Sciences, Macquarie University, North Ryde, Sydney, NSW 2109, Australia; nanew@bio.mq.edu.au"

Rapid climatic warming over the next few decades will affect the distribution and abundance of many species. We conducted a transplant experiment to investigate the potential colonisation of a plant species by insect herbivores under a warmer climate. Plants were transplanted to two sites, 280km north of the host-plants current coastal range; the transplant sites were 1.2 and 6.5^{0}C warmer than the northernmost and southernmost boundaries of the species' current range respectively. We compared the structure and composition of the herbivorous Hemiptera and Coleoptera communities on *Acacia falcata* transplants to that of *A. falcata* within its current distribution and to a closely-related *Acacia* species that naturally occurred at the transplant sites. Guild structure of this herbivore community did not significantly differ between the transplants and that found on *A. falcata* within its natural range, but did differ between the transplants and *A. leptostachya*. Host plant identity was apparently more important than climate in influencing the structure of the colonising herbivore community. If this result holds for other plant-herbivore systems, we might expect that under a warmer climate, broad patterns in community structure may remain similar to that at present, even though species composition may change substantially.

Endemic radiations within the megadiverse fauna of Australian Hymenoptera

AD Austin, J La Salle, JT Jennings
Centre For Evolutionary Biology & Biodiversity, School Of Earth & Environmental Sciences, The University Of Adelaide, SA 5005 Australia; anew.austin@adelaide.edu.au

The Australian hymenopteran fauna is huge, poorly studied, and probably 5-10 times larger than the currently described 8400 species. Because of its long post-Gondwanan isolation, a large proportion of the fauna is endemic, although numerous groups share species with New Guinea and other islands to the north. Although detailed assessment of the level and degree of endemic radiations is hampered by a lack of supporting phylogenetic information, several groups are recognised for their remarkable explosive radiations into particular unique austral habitats or host groups in the case of parasitoids. Further, a number of little known, poorly studied taxa have been shown recently to have speciated far more in Australia than on any other continent. Here we use a number of examples, mostly from the parasitic Hymenoptera, to examine the extent, uniqueness and nature of these radiations in Australia. These examples come from the superfamilies Evanioidea, Platygastroidea, Ichneumonoidea and Chalcidoidea and will focus on parasitoids of native bees and wasps, Coleoptera, Lepidoptera, the spider fauna, and importantly 'parasitoid' groups associated with galls of *Eucalyptus*.

Relevance of edge & riparian effects to conservation of litter beetles in streamside reserves

SC Baker, AMMR Richardson, LA Barmuta
School of Zoology, University of Tasmania, Private Bag 05, Hobart, Tasmania 7001, Australia; bakers@utas.edu.au

Streamside reserves in the form of unlogged strips of forest 20-30 m either side of streams, are a component of the reserve network within Tasmanian logging areas. Although primarily protecting aquatic values, these reserves have the potential to provide habitat and landscape connectivity for terrestrial litter-dwelling beetle species unsuited to conditions in coupes or young regeneration forest. Narrow reserve areas are prone to edge effects, which could limit their effectiveness for some species. Preliminary results indicate that edge effects on litter beetles usually extend for approximately 10 m or less from coupe edges in wet eucalypt forest. Litter beetles also respond to the riparian zone, with generally lower abundance and species richness and changing community composition for 5-10 m from streams. The combined effects of these riparian and edge zones may render streamside reserves unsuitable for some species. 100 m wide wildlife habitat strips appear to have greater potential than streamside reserves for protection of terrestrial invertebrate fauna.

The relationship between crown structural attributes & the canopy invertebrate fauna of 100 year-old & old-growth Tasmanian *Eucalyptus obliqua* trees

YD Bar-Ness
University of Tasmania Geography and Environmental Studies, Private Bag 78, Hobart, Tasmania 7004, Australia; ybarness@utas.edu.au

Invertebrates were collected in the crowns of 100 year-old and old-growth Stringybark *Eucalyptus obliqua* to compare the composition of invertebrates associated with specific regions within younger and older tree crowns. The aims of the research are to test the hypotheses that: a) older trees are inhabited by a different invertebrate community than younger trees; and that b) older trees are quantitatively more structurally complex than younger trees. Rope techniques were used to access the crowns of 16 trees near the Huon River at Warra LTER in Southern Tasmania, Australia. Spatially explicit trapping methods (sticky traps, omnidirectional flight intercept traps, and bark crawl funnel traps) were selected to compare live branches, dead branches, and the trunk surfaces in the upper and lower crowns. Structural measurements on branching structure and special habitat location were used to record the exact position of the traps in the tree crown, and processed into 3-dimensional virtual tree models to aid other researchers and the general public in visualizing these arboreal habitats.

A plethora of ants, a paucity of ant pollination systems

AJ Beattie
"Key Centre for Biodiversity and Bioresources, Macquarie University, NSW 2109, Australia; abeattie@bio.mq.edu.au"

While the Hymenoptera are among the most important pollinators worldwide, the ants, although abundant in most terrestrial ecosystems, and frequent flower visitors, are rarely involved. I briefly review the reasons for the scarcity of ant pollination and the few cases in which ant pollination has been documented. Two very different kinds of ant pollination system have evolved. The first, limited to two highly specialized interactions involving complex floral traits and insect behaviour, occur only in y, grassy or shrubby habitats in southern and eastern Australia. By contrast, the second kind s relatively unspecialized, with easily accessible floral rewards that ants share with a variety of small winged or flightless insects. These systems occur chiefly in harsh habitats where selection for plants with low, accessible growth forms favour visits by ants. The discovery of more plant species with varying levels of dependence on ants for seed set seems likely. Moreover, the apparently unspecialized ant pollination systems may reveal behavioural, morphological, physiological, chemical or colony traits that predispose particular ant species for pollination.

Phylogeography of two genera of funnel web spider (*Haonyche* & *Atrax*) from the saproxylic habitat in Tallaganda State Forest (NSW)

AS Beavis
Division of Botany & Zoology, Australian National University, ACT, 0200, Australia; amber.beavis@anu.edu.au

Decomposing logs are habitat to invertebrate species occurring across a spectrum of ecological niches. A collaborative research project is examining patterns of genetic endemism among saproxylic (log-dwelling) invertebrates across Tallaganda State Forest (NSW). Previous study of the onychophoran *Euperipatoides rowelli* revealed strong population structuring, identifying five areas of local endemism. Subsequently, *E. rowelli* has been used as a base-line study species for a comparative phylogeographic study of saproxylic invertebrates. To date, analysis of the mitochondrial gene Cytochrome Oxidase I (mtCOI) has revealed that a number of taxa display phylogeographic congruence with *E. rowelli*, suggesting that the saproxylic habitat has been a major factor in the evolution of these invertebrate species. *Haonyche* and *Atrax* are two ecologically similar genera of funnel web spider found across Tallaganda State Forest, however, *Haonyche* species are log-dwelling whereas *Atrax* species are ground-burrowing. The niche partitioning of unnamed species within these genera allows the separation of species and habitat as contributing factors to the patterns of local endemism found in this system. The resolution of this question is central to defining the impact of habitat on the evolution of log-dwelling invertebrates and critical to the establishment of conservation priorities for invertebrate species in Tallaganda State Forest.

Biogeography of the coffee berry borer *Hypothenemus hampei* **(Ferrari 1867; Coleoptera: Scolytidae) and design of molecular markers**

P Benavides, J Stuart, F Vega, J Romero-Severson, A Bustillo, D Hawthorne.
4112 Plant Science Bldg. University of Maryland. College Park, MD 20742, USA; pbenavid@mail.umd.edu

Hypothenemus hampei, **the most destructive insect pest of coffee, reproduces as matrilineal lines ensuring low genetic variability. To examine the biogeography of this pest, AFLP was performed to generate DNA fingerprints from a worldwide collection. The greatest genetic variability was found in the presumed center of origin. Samples collected from West Africa and Asia were more closely related to samples collected from the Americas than to samples collected in East Africa. The greatest amount of variation in the Americas was discovered in Brazil, and the distribution of that variation suggested that these lines spread from Brazil throughout Latin America. The presence of all American lines in Colombia was used in order to understand the distribution of** *H. hampei* **throughout the Americas. Furthermore, this examination revealed the origin of** *H. hampei***'s latest introduction, as well as the possible pattern and manner in which this insect was distributed in the Americas. We found at least 3 introductions of** *H. hampei* **in Colombia; however, a main line was found in every coffee producing area. Hypothesis for this dispersion will be presented. The development of molecular markers and their use in population genetics, biology, and ecology studies will be discussed.**

Lepidopteran diversity hotspots in Canada: use of Biodiversity World virtual laboratory for predicting past & future patterns

S Bhagwat, P Williams, Mr T Sutton, N Caithness, M Scoble, F Bisby
Biogeography & Conservation Laboratory, Department of Entomology, The Natural History Museum, Cromwell Road, London, SW7 5BD UK;
S.Bhagwat@nhm.ac.uk

British Columbia (BC) has the most diverse Lepidopteran fauna in Canada. Its postglacial origin makes butterflies ideal candidates for time-slice bioclimatic modelling. If adequate and precise distribution data were available, it would be possible to model the Lepidopteran diversity at various times – from the arrival of this group in BC (*c.* 15,000 yr BP) to its future distribution under changing climate. Canadian specimen information network held by the Canadian Biodiversity Information Facility provides a Lepidoptera data set (*c.* 100,000 point records) from which to create bioclimatic envelopes of butterfly species. Climate Space Model, which uses past and future climate scenarios and a set of point observations to capture a model environment, is used for building bioclimatic envelopes for each of the species in the data set. Many such envelopes are superimposed to generate species richness maps in Worldmap (http://www.nhm.ac.uk/science/projects/worldmap). The Biodiversity World project is developing a problem solving environment (PSE) to bring all these components together in a GRID setting. As an exemplar study of the PSE, the species richness maps, generated based on the distributions of butterfly species, are used for prediction of past and future hotspots of Lepidopteran diversity and for their comparison with the present hotspots.

Biogeographic connections between Australia & New Caledonia

DJ Bickel
"Australian Museum, 6 College Street, Sydney, NSW 2010, Australia; danb@austmus.gov.au"

Two genera of Dolichopodidae (Medeterinae), *Atlatlia* and gen. nov., are sister groups known only from Australia and New Caledonia. In Australia both display a classical "Bassian" distribution pattern (Tasmania, eastern Australia to SE Qld., and southwestern Australia), typically associated with Gondwanan taxa, while in New Caledonia, they occur above 500 m. These two genera have radiated on both landmasses, but are unknown from New Zealand, New Guinea, Solomon Islands and Vanuatu. These taxa are highly unlikely to have dispersed between Australia and New Caledonia. Possibly some of these genera will be found in montane New Guinea, where the Highlands often hold old Australian elements of Gondwanan affinity. However, they are unlikely to occur in the tropical Solomons and Vanuatu, and would not have reached New Caledonia via island "stepping-stones". The Australia and New Caledonia pattern suggests a relictual Gondwanan distribution. Were these genera once widely distributed in eastern Gondwana? Or did certain groups have Australia and New Caledonia as a center of origin? The absence of the two genera from New Zealand is more puzzling. However, during the Tertiary, New Zealand underwent major climactic and tectonically induced extinction events, losing much of its ancestral flora, and probably associated insects as well.

Insect diversity on tree trunks

DJ Bickel
"Australian Museum 6 College Street, Sydney, NSW 2010,Australia; danb@austmus.gov.au"

Tree trunks have a characteristic but little studied invertebrate fauna. Sticky traps (plastic strips coated with Tanglefoot) were placed on eucalypt trunks in forests of northeastern N.S.W., at 12 sites over four seasons. Approximately 103, 000 arthropods were collected, representing some 180 families. Diptera comprised 85% of the total catch and the top nine family ranks, Sciaridae being first at 49%, the most abundant family on all traps, all seasons. This data is discussed with respect to taxonomic richness, trap bias, seasonality, and site history. The importance of soil fauna, hidden larvae, and "orphan taxa" are discussed. Artificial sticky traps and naturally exuded tree resins are similar biotic "traps", and therefore taphonomic analogues. Relative taxonomic abundances from modern trunk sticky traps and early Tertiary Baltic Amber collections are briefly compared, which suggest similar arthropod communities are associated with tree trunks through time.

Ant assemblage structure in the CFR: Investigating patterns across altitude

A Botes, SL Chown
Spatial, Physiological and Conservation Ecology Group, Department of Zoology, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa

Climate-modeling exercises have demonstrated that the fynbos in the Cape Floristic Region is likely to be highly sensitive to climate change and it is thought that this vegetation type will be wholly replaced with a different, unknown vegetation type. It is thus crucial to collect baseline data on taxa that are critical for ecosystem functioning in this biome. Therefore, we investigated ant assemblage structure across an altitudinal gradient ranging from sea level (Lambert's Bay) to approximately 2000 m above sea level (Sneeukop, Cederberg) and down again to 500 m above sea level (Wupperthal) in the Western Cape, South Africa. Sampling was undertaken during October 2002 and March 2003 at 17 altitudinal bands, stretching over three vegetation types (Strandveld, Mountain Fynbos and Succulent Karoo). Ant assemblages differed significantly with regard to altitude, geology and vegetation type. Four ant species were specific to the Succulent Karoo biome, and one species each to Strandveld and Mountain fynbos. Furthermore, one ant species was specific to the summit. Mean daily temperature, available area and the proportion of sand in the soil were the most important environmental variables explaining assemblage structure. These results suggest that the ant assemblages might also be influenced by climate change.

Distribution of invasive/endemic cockroach species on two oceanic islands

S Boyer, C Rivault
"stephane.boyer@univ-rennes1.fr"

Establishment of invasive species is one of the major factors causing decline of native faunas. Their impact is more severe on oceanic islands where faunas are more sensitive to environmental changes and more prone to extinction. Our study was centred on two oceanic islands: Mayotte and La Réunion. We describe the distribution areas of nine invasive and four endemic cockroach species. Our aim was to evaluate the impact of invasive cockroach species on the distribution and maintenance of endemic species. Interference between invasive and endemic species was evaluated by comparing their distribution areas, their habitat selection and their co-occurrence. Habitats occupied by invasive species highlight their colonizing capacities and their wide tolerance with regard to environmental parameters. Their distributions overlap greatly and many sites are colonized by guilds. Their presence is related to low elevation, presence of water and strong anthropization. Thus, irrigated sugar-cane fields on La Réunion are the most suitable habitat for invasive species, harbouring guilds of up to seven species. On the other hand, distributions of endemic species never overlap, although two of them co-occurred with invasive species. Their distribution areas emphasize their reliance on their original habitat and the threat that anthropization represents for their conservation.

Role of planted forests as habitat for the endangered *Holcaspis brevicula* & other ground beetles

EG Brockerhoff, LA Berndt, H Jactel
"Forest Research, P.O. Box 29237 , Christchurch, New Zealand; eckehard.brockerhoff@forestresearch.co.nz"

The Canterbury Plains in the eastern South Island is one of the most modified regions of New Zealand with less than 2% of indigenous vegetation remaining. From 2000-2004 we surveyed ground beetles using pitfall traps in several remnants of the formerly extensive *Kunzea ericoides* shrubland, a 7000 ha plantation forest, grassland and pasture areas, exotic shrubland, and the nearest mountain beech forest in the foothills of the Southern Alps. A total of 5985 carabids representing 43 species were collected, including two specimens of the critically endangered *Holcaspis brevicula*, a local endemic thought to be threatened by habitat loss and fragmentation. Catches per trap were lowest in *Kunzea* shrubland and highest in pasture and young pine plantations both of which had a large proportion of introduced species. By contrast, virtually all carabids trapped in shrubland, beech forest and old pine plantations were indigenous. All known specimens of *H. brevicula* were caught in the plantation forest. The small and fragmented *Kunzea* shrubland remnants may not be sufficient to maintain populations of all forest carabid species. We propose that the pine plantation provides an important substitute habitat for forest carabids.

Improving management for the Eltham copper butterfly (*Paralucia pyrodiscus lucida*) in Victoria, Australia

AA Canzano
"Department of Zoology, La Trobe University, Kingsbury Drive, Bundoora Vic 3086, Australia; A.canzano@zoo.latrobe.edu.au "

The Eltham Copper Butterfly *Paralucia pyrodiscus lucida* (Lepidoptera: Lycaenidae) was widely considered extinct until its rediscovery in 1987. Public campaigns promoted the establishment of reserves to protect known colonies, and since 1988 the relevant management authorities have been involved in maintaining viable habitat for the butterfly. *P.p.lucida* is a widespread but isolated sub-species, with remnant populations in suburban Melbourne, Castlemaine (central Victoria) and Kiata (North-West Victoria). The butterfly was one of the first insects listed as Threatened under the Flora and Fauna Guarantee Act. All known colonies are managed individually by their local management authorities. Contrasting attitudes both of management agencies and funding bodies have had both positive and negative outcomes by maintaining interest of independent agencies, but not allowing for holistic state-wide management of the butterfly. The Eltham copper is an important flagship species for conservation in Victoria. Thus an integrated management regime has the potential to provide a framework for other potentially threatened species in Australia. This paper highlights the weaknesses in current contrasting management schemes and offers tentative solutions to strengthen management through promoting more effective liaison and coordination between all agencies involved.

Biodiversity & biogeography of Lord Howe Island: an answer in the Pacific

G Cassis, CAM Reid
"Centre for Biodiversity and Conservation Research, Australian Museum, 6 College St, Sydney, 2010, Australia; gerryc@austmus.gov.au"

In the 1950s the dipterist Paramonov labelled Lord Howe Island as "a riddle in the Pacific". It has remained both an enigma and an attraction to entomologists because of its great species richness and endemicity. The Australian Museum has had a long scientific association with the island, with surveys dating back to the 1860s. Over the past four years we have undertaken an All Taxa Terrestrial Invertebrate Inventory, including a synthesis of historical information. Although the Lord Howe Island fauna is predictably disharmonic, there is considerable representation of higher taxa, with 28 orders, 306 families and 903 genera recorded. At present, about 1600 species have been recognised, with overall endemicity estimated at about 40%. This endemicity reflects considerable within-island diversification, which is partly correlated to habitat types and altitudinal gradients. The origins of the fauna of the island are complex in that numerous biogeographic area relationships are recognised for Lord Howe Island, including: i. Indo-Pacific; ii. Gondwanan; iii. temperate Australia; iv. tropical North-east Queensland; v. New Caledonia; and, vi. New Zealand. These patterns are partly explained by classical biogeographical theory, namely proximity to source areas. However, the area relationships are also a reflection of Lord Howe Island's refugial nature and its geological history.

Species richness & abundance of ant-like litter beetles (Staphylinidae: Pselaphinae) in three forest types of northeastern New South Wales

DS Chandler, H Recher
"Dept. of Zoology, University of New Hampshire, Durham, NH 03824 USA; dsc1@cisunix.unh.edu"

The species richness and abundance of ant-like litter beetles is examined for the fauna of three forest types in northeastern New South Wales, with a total of 229 species taken. Sampling was conducted for over a year in both managed and old growth stands of dry sclerophyll, wet sclerophyll, and temperate rainforest in the Styx River State Forest. Biweekly samples were taken of rotten wood and leaf litter, and from two flight-intercept traps (FIT's) at each site. The FIT's produced over 90% of the species taken, and half of the specimens. Species overlap between FIT's and the faunas characteristic of leaf litter and rotten wood was low, and these traps are productive in sampling for those species living in habitats that were apparently overlooked. Old growth sites usually produced larger numbers of species and abundances, and often were not strongly marked. The rotten wood fauna is characterized by high diversity and low numbers, while abundance of the leaf litter fauna is much higher.

Endemic insects of Andaman & Nicobar Islands

K Chandra
"Zoological Survey Of India, New Adarsh Colony, Kamala Nehru Nagar, Jabalpur-482 002, India; Crszsijb@Sancharnet.In"

This is the first comprehensive study on endemic insects of Andaman and Nicobar Islands, studied by the author during the long stay of eight years in these islands. Andaman and Nicobar Islands comprised of an arcuate chain of more than 500 islands, islets and rocks spreading in more than 1100 km in Bay of Bengal. The long isolation of these islands from the sub-continent has resulted in high endemism particularly in terrestrial faunal elements. Due to the sea barrier, the distribution of fauna in these islands varies from island to island. Some species are restricted to certain areas in Andaman's, some to Nicobar, while others are common to both the group of islands. Sometimes, a species is even confined to a particular island. These islands with 0.25% of the geographical area of India harbor about 4.2% of all known species of insects in the country. Presently, 2506 species of 1552 genera under 20 orders of insects have been recorded, of which 604 (24%) are endemic to these islands. At species level endemism is being recorded highest, in Trichoptera (70.8 %) and least in Blattaria (6.6%) percent, while in sub-species level, more than 70% endemism is recorded among the butterflies.The study indicates that the endemism may be more if the species are studied up to subspecies level with the molecular techniques.

Pacific voyagers: the diversification & decline of *Rhyncogonus* (Curculionidae: Coleptera) in the Pacific

EM Claridge, GK Roderick, RG Gillespie
Insect Biology Division, U.C. Berkeley, 201 Wellman Hall, Berkeley, CA 94720, USA; claridge@nature.berkeley.edu

Surprisingly, large, flightless weevils constitute a conspicuous element of many oceanic island faunas. The genus *Rhyncogonus*, for example, occurs across Polynesia, on some of the most remote islands in the world. Multiple *Rhyncogonus* species occur on many oceanic islands, often sympatrically, which could represent independent colonization events or *in situ* diversification, linked with geographic isolation, morphological changes and host shifts. Studying the phylogenetic relationships within this genus provides an interesting opportunity to investigate diversification and colonization processes. Recent collections of *Rhyncogonus* from French Polynesia are compared with historical collections made by the Pacific Entomology Survey, over 70 years ago, highlighting the general plight of endemic island biotas and the need for further survey work in this region. Phylogenetic analysis of 2,000 b.p of nuclear and mitochondrial sequence data, for over 60 ingroup species, and numerous outgroup taxa, reveal that *Rhyncogonus* has affinities in the western Pacific, and would have had to colonize the eastern Pacific against prevailing ocean and wind currents. The long branches and deep splits in the phylogeny reveal a long history for this group in the Pacific region, colonizing new islands long before the first Polynesian canoes, and probably before the emergence of some oceanic island chains.

Ant functional group responses to perennial shrub loss & recovery in a xeric environment

SG Clarke, AD Austin, JM Facelli, AN Andersen
"Environmental Biology, School of Earth and Environmental Science, University of Adelaide, SA, 5005, Australia; sylvia.g.clarke@adelaide.edu.au"

Habitat recovery within chenopod shrublands in South Australia, as in most arid environments, is extremely slow. Arthropod communities may be able to provide an indication of small scale recovery in these habitats because of their rapid turnover and close ties with ecosystem function. In bluebush (*Maireana* sp.) dominated chenopod shrublands, ants are one of the most abundant and species rich arthropod groups. Although this group has been touted as the quintessential indicator of ecological change, the evidence for their applicability in arid environments is so far unconvincing. Ant functional group composition within wetter, forested habitats appears to be largely controlled by shade and litter cover. However within ier, more open environments where access to sunlight is not limited, factors such as access to food resources are likely to be of greater importance. In this study, patterns within the bluebush shrubland ant community are therefore correlated with environmental variables, and habitat manipulations of shade and structure are used to provide insight into the mechanisms iving functional group level responses. This project will develop a greater understanding of the role of ants as bioindicators in arid environments and provide land managers with suitable tools to monitor habitat recovery.

Evolutionary radiations: what they are & how we can test for them

LG Cook
School of Botany and Zoology, The Australian National University, Canberra, ACT, 0200, Australia; Lyn.Cook@anu.edu.au

A radiation results when the rate of generation of new taxa is greater than the extinction rate. Thus, any lineage comprising more than one taxon has undergone a detectable radiation. Most interest is centred on radiations that contribute to our understanding of evolutionary processes such as speciation, adaptation and biogeographical change. Typically, these include radiations that are characterised by changes in the rate of speciation, including rapid increases associated with innovations, ecological shifts or climatic change, and radiations that generate or assess biogeographic hypotheses. An emerging feature of phylogenetic studies is that the rate of origin of species does not appear to be constant across all taxa or through time. Some lineages appear to have undergone radiations in which taxa diversified by rapid speciation, interspersed with periods of extinction or relatively slow diversification. Comparative methods and the inclusion of a time dimension in phylogenetic studies allow increased understanding of evolutionary radiations.

Estimating biodiversity: a case study on true bugs in Argentinian wetlands

MC Coscarón, Lic PM Dellapé, Lic MC Melo, J Coddington
Facultad de Ciencias Naturales y Museo, UNLP, Paseo del Bosque s/n, 1900 La Plata, Argentina; coscaron@netverk.com.ar

Measures of biodiversity provide the base-line information on distribution, richness, and relative abundance of taxa required for conservation decisions, studies of ecosystems ecology, cladistic biogeography, and phylogenetic measures of conservation value. Species richness in particular is an increasingly important statistic in conservation evaluation. This work aims to improve knowledge of the Ibera complex (Corrientes, Argentina), one of the most important but least known South American wetlands, and of terrestrial heteropteran biodiversity. We use quantitative measures of inventory completion and statistical analyses to critique our results and to elucidate the effects of inventory design parameters, with a view towards increasing the efficiency and effectiveness of biological inventory.

Seven collectors sampled the fauna of true bugs in the Iberá watershed (Col. Pellegrini, 28º 32´ S 57º 09´ W) during early spring, summer, and late summer of one year. Sixteen families, 225 spp. and 4,688 adults were found. The lower bound of annual heteropteran species richness at Pellegrini was about 250-300 species. Among heteropteran families, the particular inventory methodology was especially efficient in sampling Miridae.

Aquatic wood – an insect perspective

PS Cranston, B McKie
Department of Entomology, University of California, Davis, CA 95616, USA; pscranston@ucdavis.edu

Aquatic immersed wood (snags) provide major substrate for macroinvertebrates and refugia for fish, turtles and amphibians. The effects of human intervention such as wood removal for navigation and angling on fluvial geomorphology is well-known, but biotic responses of insects remain poorly known. Investigation of experimentally-immersed wood in Australia shows native timber supports enhanced biomass compared to alien woods in open riverine areas or alien pine forests. Structural modifications of immersed wood by grooving and tunnelling of elmids encourage proliferation of surface-dwelling invertebrates. A diverse 'mining' fauna develops within immersed wood, including specialist caddis, beetles, and especially chironomid midge larvae. Recent discoveries of unusual midges in Australia and south-east Asia allow speculation about the evolution of immersed-wood mining. The subfamily Orthocladiinae contains many unrelated taxa with larval mouthpart modifications associated with mining. In contrast, in the subfamily Chironominae, wood-mining has not been associated with morphological differentiation and is restricted to fewer clades, but radiation is evident in several early-branching clades. Wood mining in each subfamily is inferred as ancestral and may be associated with differential survival from cataclysmic extinction events.

Grazing effects on arthropod distribution & abundance mediated by habitat structure & consequences for meadow pipits in the Scottish uplands

P Dennis, J Skartveit, DI McCracken, R Pakeman, A Kunaver, DM Evans, D Elston
Macaulay Institute, Craigiebuckler, Aberdeen, Ab15 8qh, Scotland, UK; p.dennis@macaulay.ac.uk

Bird populations have significantly declined in upland landscapes of Britain in recent decades. The progressive increase in grazing herbivores has been implicated. The mechanism is uncertain, whether habitat structure indirectly affects birds via arthropod abundance and distribution or directly affects breeding birds in terms of nest site suitability or restricting the access of foraging birds to arthropod food. The GRUB (GRazing and Upland Birds) project is using an experiment located in the Southern Highlands of Scotland to investigate the effects of different grazing regimens on plant-insect-bird interactions. Vegetation, arthropods and Meadow pipit populations are being studied in a grazing experiment (4 grazing treatments replicated in 6 blocks) located in the Southern Highlands. Here we focus on the distribution and abundance of arthropods prior to the experiment and their short-term response to the varied grazing regimens of the experiment. We hypothesise that initial responses of arthropods in the wet, heterogeneous biotopes will be to structural changes in vegetation and that these will be related to the foraging preferences of sheep and cattle. We also explore how the distribution and abundance of arthropods relates to the position of nest sites of Meadow pipits.

The effects of stand age & silvicultural treatment on beetle biodiversity in coniferous stands in south west Nova Scotia

P Dollin, PN Duinker and C Majka
1322 Robie St, Halifax, NS, B3H 3J5, Canada; pdollin@dal.ca

Old-growth forest (OGF) in Nova Scotia typically has uneven-aged, multi-layered stand structure and contains much coarse woody debris. These traits provide microhabitats that support a large proportion of Nova Scotia's biodiversity. Many species, including invertebrates, depend on the deadwood substrates typical of OGF. Saproxylic beetles (family Coleoptera) depend on dead or decaying wood. They play a large role in nutrient cycling and decomposition in forest ecosystems. The goal of this study is to determine the relationships between forest stand age, silvicultural treatment, dead wood, and beetle diversity. Saproxylic specimens were gathered using four methods: pitfall traps, funnel traps, sweep-netting and manual grubbing. For the pitfall and funnel traps, effort and time were controlled; however, the sweep-netting and manual grubbing were only controlled for time. At present, we have completed a simple analysis of variance for both forest stand age and silvicultural treatment and have found that only silvicultural treatment has an effect on species richness. As well, we have identified several beetles previously unrecorded in Nova Scotia. The study is still underway; by August 2004, however, all results will be ready for presentation at the conference.

The systematics, biogeography & evolution of Tasmanian cave fauna

SM Eberhard, RS Eberhard
"Department of Conservation and Land Management, Woodvale Research Centre, PO Box 51, Waneroo, WA 6065, Australia; stefane@calm.wa.gov.au"

The Australian island of Tasmania is richly endowed with caves in numerous isolated karst areas. These harbour diverse faunas including obligate subterranean terrestrial and aquatic species. Located at the southern latitudinal limits of the Australian continent, and mountainous over much of its area, Quaternary climate change has profoundly influenced geomorphic, hydrologic and biologic processes within the karst and caves. Many karst areas were directly affected by glacial ice and other cold climate processes, during multiple phases of Pleistocene glaciation. This paper presents a broad overview of the systematic composition and biogeography of the Tasmanian cave fauna, and critically examines the influence of Pleistocene climatic changes and glaciation in shaping the evolution of the fauna. The terrestrial obligate cave fauna is derived from lineages associated with cool and moist temperate forest habitats, including Coleoptera (Carabidae), Arachnida (Araneae, Opiliones, and Pseudoscorpionida), Diplopoda (Dalodesmidae) and Isopoda (Oniscidea). Cave-limited species within these groups have restricted distribution ranges that are often limited to a single karst area. Isolation of ancestral populations in caves, and their subsequent speciation, may have occurred during periods of cold glacial climate when forest cover retreated from karst areas.

Australian cave-dwelling planthoppers: relics or explorers?

P Erbe, H Hoch
"Museum für Naturkunde, Institut für Systematische Zoologie, Humboldt-Universität Berlin, Invalidenstr. 43, 10115 Berlin, Germany;
petra.erbe@museum.hu-berlin.de"

The Australian planthopper taxon *Solonaima* contains epigean as well as cave-dwelling species. Hence it is an ideally suited model system to study cave-adaptation. Assumably cave-inhabitation happened within *Solonaima* several times. This would support the adaptive-shift hypothesis after Howarth 1986, which regards cave-adaptation as an active process driven by the exploitation of a previously unused habitat and/or food resource. In case of the cixiid genus *Solonaima* this means feeding on roots in the adult stage, even though this feeding strategy is in epigean Cixiids only known for nymphs. The allopatrical distribution of *Solonaima* (epigean species occur in coastal rainforest habitats while cavernicolous species are restricted to Queenslands Outback) on the other hand supports another hypothesis. This relict hypothesis after Barr 1968 postulates that cave-adaptation is due to decreasing conditions on the surface, though that populations could have only survived in caves. Current data based on phylogenetic reconstructions make a synthesis of the two hypotheses plausible. The most likely evolutionary scenario is that some *Solonaima* species have undergone an adaptive-shift, though that they spent their whole life cycle in caves. During the desertification of Australia in the Miocene the surface-dwelling species in the dry areas became extinct. Only those who there switched to a permanent life underground survived.

A survey of biodiversity in Siahkal forests North Of Iran

MM Fallahchay
Islamic Azad University (Lahijan Branch) Lahijan, PO Box 1616 Iran; mir_mozaffar@yahoo.com

The forests of north of Iran are of the most important broad leaf trees of the word. The purpose of this study is to investigate tree diversity in the forests of Siahkal (north of Iran) with an area of about 13000 hectar. For this purpose, 18 sample plots 0.5 hectar have been randomly chosen and surveyed in different altitudes of Siahkal forests . The results indicated that with increas in altitude from sea level, species richness decrease while species diversity and evenness continue to rise. Using the statistical test of chi-square, a comparison of the observed and expected frequencies of different characteristics of the trees indicated that the difference was highly significant as far as dominant trees and the quality of their trunks in a cylenic position is concerned. As for the suppressed trees, different tree crowns, as well as curved trunks no significant difference was observed. From a regeneration point of view, the best case was observed at the middle altitudes (1300-1600 meter).Besides, because of existence of wandering animals at the altitude range of 1300 meter below sea level and 1600 meter above, the regeneration of trees are not considered to be desirable.

Emergence collection – a trial of biodiversity composition & longitudinal patterns of aquatic insects emergence in small rivers in Palawan, the Philippines

H Freitag
Martin-Luther-Univ., Inst. of Zool., Animal Ecol., Dompl. 4, D-06099 Halle, Germany; henik.freitag@gmx.de

This study presents results of the first emergence trap samples from streams in the Philippines and Greater Sunda. It compares aquatic insect emergence of two 4th order rivers and describes longitudinal patterns including estuaries. A decline of total emergence with increasing stream order was observed, affecting all major orders. Diptera, namely Chironomidae, dominated all sites. High abundances in Ceratopogonidae, Odonata, and Coleoptera were found, compared to other emergence studies from tropical and temperate latitudes. Ephemeroptera displayed a highly variable contribution to the emergence from Palawan either supported by the appropriate conditions for certain functional groups or limited by environmental variables such as pH. Trichoptera were likely to tolerate a wider range of environmental conditions and are consequently able to fill further niches where Ephemeroptera are under-represented. Except for the scarce abundance of Plecoptera no substantial differences in emergence composition at order level existed between temperate and tropical rivers, however, with a remarkable local variation. The results obtained with emergence traps which were modified for the tropics displayed high species richness for the most insect orders. This fact and general characteristics of emergence trap samples suggest a high potential of this method for qualitative-ecological, taxonomic, and biodiversity studies in the tropics.

East meets west: phylogeny & biogeography of the Polynesian thomisid spiders

JE Garb, RG Gillespie
Department of Biology, University of California, Riverside, CA 92521 USA; jessicaga@ucr.edu

Spiders of the family Thomisidae are ambush predators that mimic the coloration of different substrates. Thomisid spiders occur on a number of remote archipelagos across the Pacific, having attained their highest diversity in the Hawaiian Islands. The twenty Hawaiian species are exceptionally diverse in coloration, reflecting mimicry of different substrate types. In contrast to the high species diversity exhibited by Hawaiian thomisids, a single species is known from each of three neighboring Polynesian archipelagos. Though relationships among different Hawaiian lineages have been extensively studied, the evolutionary history of biotas occurring on other Polynesian archipelagos and their relationship to the Hawaiian biota is poorly known. Here we reconstruct phylogenetic relationships among thomisid spiders occurring across Polynesia, including multiple islands from the Hawaiian, Marquesan, Society and Austral archipelagos, and outgroups based on mitochondrial and nuclear DNA sequences. Our results indicate that the Hawaiian thomisids are closely related to species in the genus *Misumenops* occurring in the nearest island archipelagos of the Marquesan and Society Islands as well as those that occur in North America. However, thomisids from the Austral Islands appear more closely related to those occurring in Western Polynesia, suggesting that thomisids colonized Polynesia from two opposing directions.

Comparative phylogeography of saproxylic invertebrates

R Garrick, C Sands, M Blacket, D Rowell, N Tait, P Greenslade, P Sunnucks
Dept of Genetics, La Trobe University, Melbourne 3086, Australia; r.garrick@latrobe.edu.au

To conserve evolutionary processes within taxa as well as local co-evolutionary associations among taxa, habitat reservation needs to take account of natural genetic-geographic patterns. While vertebrates tend to have at least moderate dispersal and gene flow on a landscape scale, there are good reasons to expect many small invertebrates to be strongly subdivided. Saproxylic (rotting log) invertebrates are particularly likely to exhibit fine-scale population structures owing to their ecological specialisation and limited dispersal. It is a major challenge in conservation biology to develop efficient tools and model systems to understand genetic and evolutionary spatial patterns in less mobile, habitat-specific organisms. Further, it is necessary to investigate the relative importance of local adaptation and historical differentiation. Comparative phylogeography provides a framework for differentiating species-specific and habitat-specific processes, yielding insights into forces driving the geographic distribution of biodiversity in individual species and regional biota. I present an overview of collaborative research into an exciting model system centred at Tallaganda State Forest NSW. In this system, velvet-worms, springtails and terrestrial flatworms show unexpected levels of local genetic subdivision and highly congruent phylogeographic breaks. These animals offer a fine-scale benchmark against which co-distributed animals can be compared. I outline our current and future investigations.

The effects of forest type & dead wood composition on saproxylic beetle assemblages on logs placed in boreal forests

H Gibb, J Hjältén, T Johansson, JP Ball, O Atlegrim, J Hilszczanski, R Pettersson, K Danell
Department of Animal Ecology, Swedish University of Agricultural Sciences, SE-90183 Umeå, Sweden; heloise.gibb@szooek.slu.se

Natural old-growth boreal forests contain large volumes of the coarse woody debris (CWD) and management practices have led to a reduction in both the volume and quality of CWD. Saproxylic beetles, many of which are red-listed, are dependent on such habitats. We tested the effect of forest management on assemblages of saproxylic beetles on logs placed in ten clear-cuts, managed forests and reserves in northern Sweden. Sites were surveyed to determine the volume and quality of CWD habitat available to saproxylic beetles in the surrounding area. Clear-cuts and managed forests clearly differed from reserves in most aspects of CWD composition and quality, in particular tending to have less wood in the later decay and larger size classes. While beetle assemblages in clear-cuts differed from those in reserves, assemblages in managed forests did not. In the first year of the experiment, assemblages in reserves and managed forests were dominated by the bark beetles *Trypodenon lineatum* and *Hylurgops palliatus* and other species dependent on the early stages of wood decay, and it is likely that any differences between the older forest types will become more apparent when the logs reach a later stage of decay.

Conserving Queenslands invertebrates

JA Greenland, J Playford, G Lundie-Jenkins
"PO Box 155 Brisbane Albert Street, QLD 4002, Australia; julia.playford@epa.qld.gov.au"

The Queensland entomological community has been making a very important contribution to the conservation of invertebrates within the State. A range of programs has been developed to allow for formal cooperation between Queensland Environmental Protection Agency and entomologists, both essional and non-essional. BugCatch is one of our major programs. Volunteers from the entomological community assist us with surveys on National Parks and State Forests. Products from these surveys include species lists as well as important recommendations for fire and other management regimes that will assist in conserving the species within protected areas. Scientific purposes permits have been a long-term issue for entomological collecting due to their non-specific nature and difficulties with assessment by people without adequate knowledge of invertebrates. The permit assessment has been significantly improved with issue of Scientific Purposes Permits to representatives of the Entomological Society of Queensland. The permits are endorsed for members of the Society. The Queensland entomological community has assisted the Queensland EPA because we have been able to engage them in our conservation activities. This has occurred as a result of enthusiasm of a number of staff in he Department and the leadership provided by Don Sands.

Detecting the effects of environmental change above the species level using beetles in a fragmented upland tropical rainforest landscape

PS Grimbacher, RL Kitching, CP Catterall
Australian School of Environmental Studies, Griffith University, Nathan 4111, QLD, Australia; P.grimbacher@griffith.edu.au

Significant changes to invertebrate communities resulting from environmental change have been widely documented at the species level. However, measuring environmental changes at the species level requires significant taxonomic expertise and time. Using classifications above the species level such as family, or trophic group could fast track this process. However, questions remain whether such data possesses the required sensitivity. The Atherton Tableland landscape in northeastern Queensland, Australia, is composed of numerous rainforest fragments of varying size surrounded by cleared habitat (pasture), thus representing two scales of environmental change. The extreme, habitat loss, and the more subtle change associated with habitat fragmentation. We sampled almost 20,000 beetles from six replicate sites of pasture, small rainforest remnants, and both edge and interior from large rainforest remnants. We then compared beetle species, family, and trophic group patterns. Not surprisingly all datasets showed significant differences in community composition between pasture and all rainforest sites (ANOSIM $P<0.001$). Within rainforest sites, species data showed a complex pattern consistent with climatic variation of sites and a microclimate mediated edge effect, affecting small remnants. However, these same patterns were only weakly evident for the family and trophic group data. It is suggested that data above the species level may not have the sensitivity required to detect subtle environmental changes.

Arthropods in Tasmanian ***Eucalyptus obliqua*****: how unique is the canopy fauna?**

S Grove, R Bashford, Y Bar-Ness, K Harrison, M Yee, C Mohammed.
Division of Research and Development, Forestry Tasmania, GPO Box 207, Hobart, Tasmania 7001, Australia; simon.grove@forestrytas.com.au

Tasmanian native eucalypt forest canopies are host to numerous arthropod species, but most of what we know about this fauna relates to the minority of species, particularly leaf-feeders, liable to cause economic damage. Sustainable management of these forests requires understanding how associated biodiversity is partitioned in space and time. For instance, how important for arthropod biodiversity conservation is it to maintain old living trees in a forestry landscape dominated by younger trees; and how distinct is the fauna of living trees when compared with that of coarse woody debris? A series of studies at the Warra long-term ecological research site in southern Tasmania is beginning to address this knowledge gap for the commercial species Eucalyptus obliqua. This paper discusses these studies, and presents some preliminary findings about the degree of overlap in arthropod faunas among different strata and microhabitats from the canopy to the forest floor, with particular emphasis on saproxylic species.

A research agenda for insects & dead wood

SJ Grove
"Division of Research and Development, Forestry Tasmania, GPO Box 207, Hobart, Tasmania 7001, Australia; simon.grove@forestrytas.com.au"

In recent years, great advances have been made in our knowledge of the ecology, evolutionary biology, biogeography and management of saproxylic insects and their dead wood habitat. There is now a greater level of awareness of the need to cater for their requirements in today's managed forest landscapes. However, having raised the profile of saproxylic insects, we are now being called upon to translate our knowledge gains into management principles. This throws up new research challenges, many of which can only be addressed through adaptive management. This paper outlines and prioritises some of those challenges.

Scale insect radiations on eucalypts

PJ Gullan, LG Cook
Department Of Entomology, University Of California, 1 Shields Avenue, Davis, CA 95616-8584, USA; Pjgullan@Ucdavis.Edu

At least 200 species from more than 50 genera belonging to a total of 10 families of scale insects (Hemiptera: Coccoidea) feed on species of *Eucalyptus sensu lato* (including *Corymbia*) in Australia. Most (about 60%) of these species belong to the Eriococcidae and approximately 80% of these eucalypt-feeding eriococcid species induce complex galls on their host plants. Molecular phylogenetic analysis of the Eriococcidae reveals two unrelated, speciose clades of gall-inducing taxa associated with eucalypts. One clade comprises the genera *Ascelis*, *Cystococcus*, *Lachnodius*, *Opisthoscelis* and relatives, and the second is the extraordinary genus *Apiomorpha*. Gall-inducing eriococcids are more host-specific than their non-galling relatives and, at least in *Apiomorpha*, appear to be cospeciating with their hosts.

Maculinea Butterflies of the Habitats Directive & European Red List as Indicators & Tools for Habitat Conservation and Management

S Gwillym, E. Kuehn, PDJ Settele.
"Dept. of Community Ecology, Umweltforschungszentrum (Environmental Research Centre), Theodor-Lieser-Str. 4, 06120 Halle/ Saale, Germany; Sarah.gwillym@ufz.de"

Insects have declined far more rapidly in modern European landscapes than any other known taxa. As agricultural intensification and abandoned hay meadows threaten European grassland biodiversity, we are assessing the suitability of *Maculinea* butterflies as bioindicators. The EU-funded project MACMAN (EVK2-CT-2001-00126) aims to develop standards for monitoring the 5 species of *Maculinea* butterflies as indicators and tools for grasslands and their management. With partners from 19 countries (including Associated partners) research is being conducted throughout the entire European range of each species, encompassing different biogeographical conditions and population structures. Trophic and functional relations and genetic biodiversity of the *Maculinea* are being investigated, population structures (from isolated to metapopulations) are being analysed, MVP and MVM thresholds established, co-occurrence data analysed and habitat models derived. The scientific questions answered during the project should provide guidelines on the management of grasslands for high biodiversity for land users and managers. We will provide users in EIA (Environmental Impact Assessment) with simple robust tools for assessing the effect of land use changes on the persistence of endangered communities of wildlife, which will involve a unique standardisation of approaches and applications across Europe. Subcontractors (i.e. National Parks and EIA consultants) will test our recommendations.

The role of dead wood in maintaining forest diversity

JL Hanula
"USDA Forest Service, Southern Research Station, 320 Green St, Athens, GA 30602-2044 USA; jhanula@fs.fed.us"

Dead wood is one of the major components of forests that contribute to overall diversity primarily through insects that feed directly on or in it. Likewise, a variety of organisms benefit by feeding on those insects. What is not well known is how or if dead wood influences the composition of the arthropod community that is not solely dependent on it as a food resource and whether woody debris influences prey available to generalist predators. One group likely to be affected by dead wood is ground-dwelling arthropods. We have studied the effect of adding large dead wood to unburned and frequently burned pine stands to determine if dead wood was used more when the litter and understory plant community are removed. We have also studied the effect of annual removal of dead wood from large (10 ha) plots over a 5 year period on ground-dwelling arthropods. In related studies, we have examined the interrelationship of an endangered woodpecker that forages on live trees, its prey, and dead wood in the forest. The results of these and other studies show that dead wood can influence the abundance and diversity of the ground-dwelling arthropod community, and prey available to generalist predators not foraging directly on dead trees.

Effects of two genetically controlled chemotypes on the community structure of herbivorous insects

T Hayashi, T Ohgushi
"Center for Ecological Research, Kyoto University, Kamitanakami, Otsu, 520-2113, Japan; tamano@ecology.kyoto-u.ac.jp"

Salix sachalinensis Fr. Schm (Salicaceae) has two distinct chemotypes: one biosynthesizes ampelopsin as a major component of low molecular weight phenolics in their leaves (A-type), and the other biosynthesises -D-glucopyranose 1-*trans*-*p*-coumarate and -D-glucopyranose 1-*trans*-cinnamate in addition to ampelopsin (AP-type). These two chemotype are genetically controlled. We investigated the effects of these chemotypes on the community structure of herbivorous insects. We placed potted clones of two chemotypes at a field study site located in the flood plain of Ishikari river in Hokkaido, northern Japan, and examined the plant leaf traits and herbivore communities of the cloned chemotypes. There were significant differences in leaf phenolics between the two chemotypes. Total abundance, species richness, and species composition of herbivorous insects did not differ significantly between the chemotypes, whereas the relative abundance of herbivores differed significantly. In particular, the density of the willow leaf beetle, *Plagiodera versicolora*, was significantly higher on the A-type than on the AP-type, In contrast, the density of leaf galls was significantly lower on the A-type than on the AP-type. This distribution pattern may indicate a potential ecological cost of leaf phenolics production in *Salix sachalinensis*.

The fine-scale physical attributes of coarse woody debris associated with utilization by ants (Hymenoptera: Formicidae)

RJ Higgins, BS Lindgren
University of Northern British Columbia, 333 University Way, Prince George, BC, Canada, V2N 5A4; rhiggins@cariboo.bc.ca

Coarse woody debris (CWD) is increasingly recognized in Canada for its contribution toward biodiversity. Wood, which has low specific heat, provides a thermally favourable environment in this cool climate. Ants contribute to physical breakdown of wood, and colonies are a significant food source for vertebrates like grizzly bears and woodpeckers. Where CWD retention has been a management objective, volume is usually used as the sole indicator. However, CWD differs greatly in quality between non-harvested and harvested sites. Pieces remaining after harvest are shorter, thinner, lacking in bark, and missing decay classes typical of non-harvested sites. This has led to the concern that post-harvest CWD may not be biologically functional. In this study, conducted in cool moist sub-boreal forests, we are examining the fine-scale physical attributes of CWD utilized by ants, in non-harvested and harvested sites (8-10 years post-harvest). Results to date indicate significant effects of stand structure and climate on ant ulitization of CWD, with only a few species tolerating cool interior stand conditions. The possible significance of regional climate, insolation, temperature, and moisture will be discussed.

The importance of type (logs, snags or the top of trees) & treatment (shading or burning) of dead wood for its attractiveness to saproxylic beetles

J Hjältén, T Johansson
Department of Animal Ecology, Swedish University of Agricultural Sciences, SE-90183 Umeå, Sweden; Joakim.hjalten@szooek.slu.se

Intensive forest management resulting in reduced fire frequency, the amatic decrease of dead wood and changes in tree species composition in boreal forests is probably the main reason for the amatic decrease of many saproxylic species in Fennoscandian boreal forest. This has lead to changes in forestry practise, including dead wood retention, which value not yet has been rigorously evaluated. To evaluate the value (from a conservation perspective) of different types of dead wood (logs, snag or remaining top of the tree) and find ways of improvement (burning and shading of logs) we performed a large-scale field experiment in northern Sweden. Species richness and the abundance of saproxylic coleopterans were higher on logs than on snags and tops but the different types of dead wood also attracted different beetle communities. Some red-listed species as the endangered *Monochamus urussovi*, was most common on tops and also found on snags, but not on untreated logs. Treatment of logs also influenced their suitability for red-listed species. Eleven, seven, five and four red-listed species was found on burned, control, shade net and naturally shaded logs, respectively. The implication of these findings for conservation strategies is discussed.

Effects of urbanization on insect-plant interactions on dominant & invasive plant species in Sydney, Australia: testing enemy release & plant stress hypotheses

DF Hochuli, LM McIntosh
School of Biological Sciences, Heydon-Laurence Building (A08), The University of Sydney, NSW 2006, Australia; dieter@bio.usyd.edu.au

Declines in dominant native vegetation in urban remnants are often associated with the establishment of invasive species beyond their natural range. The "enemy-release" and "plant stress" hypotheses are often offered to explain these patterns; the former reflecting the loss or absence of natural enemies in urban environments and the latter reflecting high levels of nutrient enrichment caused by urbanization. We examined the interactions between soil nutrients, plants and the arthropods associated with them in urban forest remnants in Sydney, Australia. *Angophora costata*, the dominant tree in these remnants, supported a different assemblage of arthropods and suffered higher levels of herbivory in urban areas where soil nutrient levels were high. Manipulative experiments also showed that *A.costata* seedlings could not establish in high nutrient soils, supporting the contention that enemy-release and plant stress contributed to its decline in urban remnants. A major native weed *Pittosporum undulatum* showed contrary patterns, suffering less herbivory in urban areas and no response to nutrient enrichment, suggesting that its success in new environments may be partially attributed to release from natural enemies. By driving biodiversity loss and the modification of soil properties, urbanization disrupts fundamental ecological processes and the ecological integrity of urban remnants.

Ecological comparisons within the arid zone

WF Humphreys
Western Australian Museum, Francis Street, Perth, WA 6000, Australia; bill.humphreys@museum.wa.gov.au

The subterranean life on the eastern seaboard of Australia is often closely coupled with surface relatives and influenced by quite recent events, such as Pleistocene glaciation. In contrast, the subterranean fauna of the Australian arid zone is characterized by relictual faunas in which surface relatives are now far distant in space and time. Still living in subterranean ecosystems, they comprise samples of the fauna 'snatched' from those of various geological Periods. Within the subterranean realm of Australia are clear signs of past connections with the various supercontinents and the Tethys ocean, and clear signals from major marine transgressions, as well as from the spread of aridity during the Tertiary. As such the subterranean realm has preserved ancient biodiversity of extraordinary richness and still largely in a pristine state. Three distinct faunas are discussed a) the terrestrial cave fauna of northwestern Australia dominated by relictual rainforest faunas having both temperate and tropical elements; b) the aquatic fauna of the northwestern near-coastal (anchialine) groundwater dominated by a fauna with Tethyan affinities whose closest relatives inhabit similar ecosystems on either side of the North Atlantic; c) an aquatic fauna inhabiting isolated 'island' aquifers in the desert.

Evolutionary diversification of an ant-plant-scale insect tripartite symbiosis in Southeast Asia

T Itino, SP Quek, S Ueda, T Kondo, PJ Gullan, T Itioka
Department of Biology, Faculty of Science, Shinshu University, 3-1-1 Asahi, Matsumoto, Nagano 390-8621, Japan; itinot@gipac.shinshu-u.ac.jp

Many tropical plants house ants and thereby gain protection from herbivores. Most of these myrmecophyte-ant systems include scale insects as the third associate. Scale insects live inside the plant hollow stem, suck the plant sap, and provide honeydew to the ants. We investigate the evolution of the three-way interaction among myrmecophytic *Macaranga* plants, their inhabitant *Crematogaster* (*Decacrema*) ants, and the trophobiont *Coccus* scale insects. Previous studies show that these three genera have a tight association although a few other genera are sometimes involved. The mtDNA COI phylogenies of comprehensively-sampled ants and scales reveal ten and five well-supported lineages, respectively. Comparisons of the two phylogenies and a published *Macaranga* phylogeny indicate an absence of cospeciation. Whereas the ant-scale and plant-scale interactions are diffuse, the ant-plant one is specific in the sense that host shifts have been constrained by plant stem traits that are themselves correlated with *Macaranga* phylogeny. Applying COI divergence rates of 1.5% per My, the *Decacrema* ants and the *Coccus* scales from *Macaranga* are inferred to be at least 12, and 10 My old, respectively, indicating that they have been diversifying contemporaneously since the mid-Miocene in the wet forest community of Southeast Asia.

Endemicity rates in the West Indian hotspot

MA Ivie, KA Marske, S Meano Cabral, LL Ivie
"Department of Entomology, Montana State University, Bozeman, MT 59717 USA; mivie@montana.edu"

The islands of the West Indies have recently been recognized as a Hotspot of global biodiversity, but the size and distribution characteristics of the insect fauna remain poorly documented. The view of regional vs. single-island endemism is greatly effected by lack of collecting, misidentification, and inadequate revisionary studies. Using beetles as an exemplar taxon, island faunal inventories as well as single-taxon revisions show the endemicity rates on small islands to be far higher than currently expected. Although rates are highest between island groups separated during the Pleistocene, even islands that have had an independent identity only since the eustastic rise at the end of the Pleistocene harbor endemic elements. Discovery rates on islands in the Northeastern Caribbean document the lack of comprehensive knowledge of the regional fauna and the underestimation of both total species and endemicity that result from this ignorance. Concentration on the faunae of large islands may significantly under-estimate total biodiversity in insular faunae.

Ethological interaction between whiteflies (Aleyrodidae : Hemiptera) & ants in certain locales along the Eastern & Western Ghats of India

RWA Jesudasan, MA Claver
Department of Zoology, Maas Christian College (Autonomous), Chennai 600 059, Tamil Nadu; India, alexjesu@vsnl.net

The Eastern and Western ghats of India are considered to be rich in biodiversity in India and the latter is recognized as one of the eighteen biodiverse hot spots of the world. During a survey for whiteflies in these regions a number of species of this group of insects have been collected and identified. Exudation of honey dew by whitefly nymphs attracts several ant species. Of the many species of whiteflies recorded along the ghats of India, the genera *Rhachisphora, Tetraleurodes* and *Aleuromarginatus* have been found to be having mutualistic interaction with 16 ant species. The number of ants tending whitefly on a leaf is positively related to the number of whitefly on that leaf. The activity pattern of each species of ants had its own time period and the activity time varied at different time intervals. Ants took more time for antennal grooming on the whitefly compared to palpating the honey dew with its mandibles. Large sized ants attended to more number of whitefly nymphs and spent longer time for feeding while smaller ones shared the exudation with its own members and also with other species. The ant attended whiteflies faced minimum parasite attack compared to non-ant attended whiteflies.

Beetle attraction to volatiles from fruit bodies & mycelium of wood decaying fungi

T Johansson, J Olsson, J Hjältén, BG Jonsson, L Ericson
Dept. of Animal Ecology, SLU, S-901 83 Umeå, Sweden; therese.johansson@szooek.slu.se

The interactions between beetles and wood-fungi are important for conservation of saproxylic beetles. Beetles living in fruit bodies of fungi are known to be attracted to volatiles from the fungi but it is not known if some beetles also are attracted to smell from the mycelium. The aim of this experiment was to test the attraction effects of volatiles from fruit bodies, mycelium and burned wood on beetles. In a randomized block design, nine substrate types - burned, *Fomitopsis pinicola* fruit body, *F. pinicola* mycelia, *Fomitopsis rosea* fruit body, *F. rosea* mycelia, Control, *Phellinus chrysoloma* fruit body, *Phlebia centrifuga* mycelia and wood - were attached separately to window traps in four old growth spruce forests in northern Sweden. Substrate type influenced both abundance and species richness of beetles and mycelium and fruit bodies attracted different species assemblages. Highest abundance of beetles occurred on mycelia of the red-listed *F. rosea* and fruit bodies of *F. pinicola*. The bark beetle *yocoetes autographus* preferred mycelia of *F. rosea* and the rove beetle *Lordithon lunulatus* showed preference for fruit bodies of *F. pinicola*. The results indicate that conservation of rare fungi species is important for many beetle species and beetles seem to be able to find suitable substrate using volatiles emitted from the mycelium.

Conservation of beetles, coarse woody debris & Natura 2000 in Europe – Slovenian experience

M Jurc
"University of Ljubljana, Biotechnical Faculty, Department of Forestry and Renewable Forest Resources, Večna pot 83, 1001 Ljubljana, Slovenia;
maja.jurc@bf.uni-lj.si "

The author presents the inclusion of elements of nature protection based on the European network Natura 2000 in the university education programme of forestry and in forestry practice. With the entrance into EU Slovenia is accepting, in the field of nature protection, the relevant legislation of the Community. Nature protection is based on Council Directive 92/43/EEC (the Habitat Directive) and Council Directive 79/409/EGS. In Slovenia the definition of potential Sites of Community Interest for the species of Coleoptera listed in Annex II of the Habitat Directive is nearing the end. 13 species from Annex II and another three from the list proposed by the candidate member states are present in Slovenia. 11 of the listed 16 species are saproxylic, two are water living species, one is a hygrophylic species, one is a cave dweller and one is a soil dwelling species. All except one live in forest habitats. They are mostly stenotopic species, dependent on old trees, above all on conifers or deciduous coarse woody debris. The characteristics of particular species, the methods of their protection and the role of particular species in the forest ecosystem are presented.

Endemism of dragonflies & damselflies (Order: Odonata) in Western Ghats of Kerala, India, & the constraints in their conservation

FK Kakkassery
"Research & Post-Graduate Department of Zoology, St.Thomas' College, (University of Calicut) Trichur, Kerala, India; kakkassery@yahoo.com"

India contributes about 500 species of dragonflies and damselflies to the total of 5600 species of world population. And 115 species are endemic to this country. Fraser (1924,1933-1936) who had extensively studied the Odonata fauna of this region, made a base line data of dragonflies and Damselflies of this area. A good number of Odonates are endemic to Western Ghats and neighbouring states (67 out of 177). Western Ghats is an array of mountains with evergreen tropical rain forests. Moreover, as far as biodiversity is concerned, Myers *et al* (2000) described Western Ghats as one of the "Hottest hot spots" of the world. But, high human population density (819 people/sq.km) in Kerala state leads to various anthropogenic activities such as migration of people to mountain/forest side for housing, construction of hydroelectric projects, change in land use for plantations such as Tea, Coffee, Rubber, Cardamom etc. Besides, the usage of very high quantity of insecticides and fertilizers in these plantations not only pollute the aquatic ecosystems in the mountain regions, which seriously affect the breeding of rare odonates, but also destroy the lower water bodies through riverine systems which carry high rate of these organic matter, and results in threatening the very existence of the rare endemic species of dragonflies and Damselflies of this region.

Ants as indicators in the quest for landscape thresholds in southern Queensland poplar box woodlands

J King, V Debuse, D Taylor, S Swift
Department of Primary Industries and Fisheries, Agency for Food and Fibre Sciences, Forestry Research, PO Box 631, INDOOROOPILLY, QLD, 4068, Australia; judy.king@dpi.qld.gov.au

Broad scale clearing of remnant vegetation for agricultural development can lead to habitat loss, fragmentation and disruption of important ecosystem processes. To investigate these issues, this project, funded by LWA Australia and Queensland Department of Natural Resources and Mines, aims to define and quantify ecological thresholds for habitat retention and management of poplar box woodlands in southern Queensland. A suite of environmental markers of ecological condition, genetic diversity and vegetation and soil health is being utilised to determine indicators of status and condition, measures of viability and, where possible, threshold values. The study area extends across 4.5 million hectares in the Queensland Murray Darling Basin. Data were collected from sixty *Eucalyptus populnea* remnants and regrowth patches, of which twenty were studied intensively. Data were analysed against landscape metrics reflecting different management regimes. Land use of the surrounding matrix, distance to neighbouring remnants and historical disturbance (1988 to present) were also determined. Ants are recognised as significant indicators of habitat condition. Pitfall trapping for ants took place three times at the intensive sites. Differences in ant assemblages, in terms of diversity and functional groups composition, were compared across sites and against changes in landscape pattern using multivariate analyses.

The arthropod fauna of cool temperate *Nothofagus*-dominated rainforests in Australasia: the first site

RL Kitching, SL Boulter, S Lassau, G Cassis
Rainforest CRC, Australian School of Environmental Studies, Griffith University, Brisbane, Qld 4111, Australia

A transect of one-hectare reference plots is proposed within the chain of remaining patches of microphyll and notophyll fern forests dominated by *Nothofagus moorei* and *N. cunninghamii* in Australia. These forests are relictual and considerably simpler than the contiguous warm temperate and subtropical rainforests of the east cost of Australia. The transect will be extended beyond Australia as the opportunity presents itself. The first, developmental, plot has been established in Lamington National Park, south-east Queensland. Following a total botanical inventory and establishment of permanent botanical subplots, wet season arthropod surveys using pitfall, interception, and yellow pan traps, plus litter, tree bark and canopy knockdown samples have been carried out. Early results will be presented. Even at the ordinal level the samples show amatic differences from otherwise comparable samples from subtropical forests at the same latitude. Explanations for these differences include physical differences in forest structure, altitude-related climatic contrasts, and the biogeographic history of insect/plant associations in these relictual ecosystems. Family and morpho-species results for the Coleoptera and Heteroptera are also presented. Exactly comparable surveys will be carried out at three more southerly, NSW locations, plus sites in Victoria and Tasmania. Comparisons with existing results from New Zealand and Chilean forests will be made.

The effects of fire severity & post-fire logging on boreal ground beetles (Coleoptera, Carabidae)

MJ Koivula, JR Spence, FKA Schmiegelow
Department of Renewable Resources, Earth Sciences Building, University of Alberta, Edmonton AB, T6G 2E3, Canada

Fire is one of the most important natural disturbance forces in boreal forested ecosystems. Yet, post-fire logging and fire-severity effects on beetles are poorly studied. We collected ground beetles by pitfall traps in 2003 in central Alberta, Canada, from 384 mixed-wood (Aspen, White Spruce) sites at House River, a ca. 3000-km2 area burned in May 2002. The sampling sites varied in burn severity and logging intensity. We present preliminary results of our study, with a general aim to determine the effects of post-fire logging and fire severity on ground-beetle assemblages.

Parataxonomy versus taxonomy in biodiversity studies – pitfalls & applicability of 'morphospecies' sorting

FT Krell
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK; f.krell@nhm.ac.uk

In biodiversity studies, sorting of samples to parataxonomic units (RTUs, morphospecies) is generally considered a sufficiently reliable and conservative approach. It is obviously time-saving because it avoids the burdens of taxonomy. However, evaluations of parataxonomic sorting by taxonomic resorting show many overestimations of species numbers and is, therefore, not necessarily conservative. Sorting errors can be more than 100% (median in the present compilation: 22%). Even if the cumulative results for diverse groups like beetles have a low overall error, the error rate within the families is generally much higher, causing misleading results in multivariate analyses. Since the error rate does not depend only on the group to be sorted, but also on the sorter and the sample, the sorting error is not predictable. However, if results of parataxonomic sorting show clear and biologically meaningful patterns, the sorting is likely to be reliable. Weak or no detectable patterns may easily be caused by erroneous sorting. I'll discuss in which type of studies parataxonomic sorting results can be used and in which they are useless.

Evaluation of efficiency & taxonomic bias of the Winkler method for soil macro-invertebrate extraction

FT Krell, P Eggleton, E DeBoise, A Giusti, K Jackson
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, UK; f.krell@nhm.ac.uk

The Winkler method is a cheap and simple method to extract macro-invertebrates from litter and soil, but has never been comprehensively evaluated. We ran the extraction for seven weeks, collected the extracted invertebrates 18 times and completed the experiment by handsorting of the soil/litter (from an English woodland). We identified the minimum extraction times for invertebrate groups, ranging from 2 days for ants, 3 days for adult beetles up to 3 weeks for earthworms and 4 weeks for centipedes. The method is not efficient for woodlice and molluscs. We propose coefficients to estimate the real number of specimens for each invertebrate group from samples obtained after suboptimal extraction periods. To identify taxonomic bias related to extraction time, we checked beetles and centipedes at family and species level. The rank-abundance order of the six most abundant beetle families remains unchanged from three days onwards. The final rank-abundance order of centipede species, however, was reached only after 15 days. Traditional short extraction times of 2 or 3 days might be sufficient for ants and beetles, but not for getting an accurate picture on the relative abundance of most other soil macro-invertebrates.

Evolutionary radiation of stiletto flies in Australia

CL Lambkin, DK Yeates, B Wiegmann, ME Irwin
"CSIRO Entomology, GPO Box 1700, Canberra ACT 2601, Australia; chris.lambkin@csiro.au"

The cosmopolitan lower brachyceran family Therevidae, stiletto flies, have nectar feeding adults and soil-dwelling predatory larvae. Intensive field and systematic research over the last decade now estimates the Australian fauna at 700 species. Phylogenetic studies, including molecular and supertree analyses, show three independent lineages, the *Taenogera* group of genera (150+ spp.), the *Anabarrhynchus* group (200 spp), and the *Agapophytus* group (250+ spp). Large numbers of superficially similar species occur in each lineage and each has a small number of species in Chile or Argentina. Australian therevid alpha diversity is remarkably high, with over 120 species known from sites such as the Warrumbungles where over 8700 specimens have been collected. Field research suggests that faunal turnover (beta diversity) is almost complete over a few huned kilometres in both eastern and western Australia. Why are there so many stiletto flies in Australia? We believe that speciation in these therevid evolutionary radiations has occurred through the Tertiary in response to the increasing aridification of Australian environments, causing changes in the microhabitat requirements of larvae and adults. This gradual aridification has occurred simultaneously with alternating xeric and mesic periods, causing expansion and contractions of species distributions and speciation by allopatry.

Spiders, spinifex, rainfall & fire: factors influencing spider diversity in an Australian desert

PR Langlands, KEC Brennan, DJ Pearson
63 Helena St, Guildford, WA, 6055, Australia; don_quixote@mail.com

Critical to conservation of biodiversity in Australia's arid zone is an understanding of the spatial and temporal patterning of biota. For mammals and reptiles, both rainfall and fire have been found to be forces determining these patterns. Few studies however have considered the influence of these factors on invertebrates. Fewer still are studies where there is a long-term data set available to consider responses over an extended time frame. This talk describes the results from spiders collected using pitfall traps over a period of 14 years (1989- 2003). It was completed as part of an experimental fire study conducted in the Great Victoria Desert, Western Australia. Rainfall was found to be the dominant driving force in this system with fire having a lesser effect. These finding's reinforce the importance of long-term studies when examining complex ecological processes.

Maintaining saproxylic insects in extensively managed boreal forests

D Langor, J Spence, J Hammond, J Jacobs, T. Cobb
Canadian Forest Service, Edmonton, AB, T6H 3S5, Canada; dlangor@nrcan.gc.ca

Recent work on saproxylic insect assemblages in western Canadian boreal forests has demonstrated that diversity and variability are high, and that there are sampling and taxonomic challenges to assessment of these insects. Some major determinants of assemblage structure include tree species, degree of decay, stand age and cause of tree death. Experimental approaches have revealed the differential impacts of the stand-replacing disturbances of wildfire and harvesting on saproxylic insect assemblages. Exploration of saproxylic insect responses to variable retention harvesting and experimental burns is contributing to identification of optimal management prescriptions for boreal forests. Understanding of processes determining saproxylic insect diversity patterns and responses would benefit from increased attention to natural history. Such work would lead to a biologically meaningful classification system for dead wood to help to better identify habitats (and associated species) at risk due to forest management. This tool could also be used to improve strategies to better maintain saproxylic organisms in managed boreal forests.

Conservation of biodiversity in managed boreal forests

S Larsson, M Schroeder, B Ekbom, MA McGeoch
"Department of Entomology, Box 7044, Swedish University of Agricultural Sciences, SE-75007 Uppsala, Sweden; Stig.Larsson@entom.slu.se "

In response to the increasing awareness of the importance of preserving biodiversity, forest management practices have been radically revised over the past few years. A crucial question is whether or not the "New Forestry" will actually achieve the goal of maintaining biodiversity. A major threat to biodiversity in Swedish forests is the decline of Coarse Woody Debris (CWD), which is an essential resource for many organisms and plays an essential role for the structure and function of boreal forests. Removal of CWD in commercial forestry has depleted important resources for many rare wood-living (saproxylic) beetles. Replenishment of CWD has been a prominent goal of the "New Forestry", through practices such as retention of living trees on clearcuts, creation of standing dead wood such as snags, and abstinence from removal of wind-felled trees. In an ongoing project in central Sweden we are studying the dynamics of CWD as well as assessing beetle species richness and composition in a landscape where the "New Forestry" has been applied. Results from the project will be presented.

Solitary bee communities in a vineyard landscape

G LeBuhn, MD Reynolds, RW Brooks, ED Rentz.
Department of Biology, San Francisco State University, 1600 Holloway Avenue, San Francisco, California, USA; lebuhn@sfsu.edu

Because bees do not pollinate grapes, the conversion of oak woodland to vineyard may present an especially difficult problem for solitary bees. These bees may lose both nesting habitat and food resources when oak woodlands are converted to vineyards. The remaining wild habitat fragments in heavily converted landscapes like the Napa Valley of California, are the equivalent of island refuges in an inhospitable sea. To study the effects of these landscape-level changes on the solitary bee communities of the remaining oak woodlands, we developed criteria for matching sampling areas in vineyard-dominated landscapes with similar areas of oak habitat not dominated by vineyards, intensive agriculture, or development to create a randomized block design of 'treatments' (areas with high degree of 'vineyardization') and 'controls' (oak-dominated areas). We compare solitary bee species richness and abundance in these areas and floral host use. We find a significant difference in species richness and floral host use between treatments. In particular, non-native plant species appear to be a significant food resource late in the flowering season.

Speciation in natural test-tubes

R Leijs, SJB Cooper, CHS Watts, WF Humphreys
"Evolutionary Biology Unit, South Australian Museum, Adelaide, SA 5000, Australia; leijs.remko@saugov.sa.gov.au"

Theoretical models for sympatric speciation have become increasingly sophisticated, but empirical evidence remains restricted to a small number of vertebrate taxa. The plethora of subterranean diving beetles (Coleoptera: Dytiscidae) species that recently have been discovered in numerous isolated calcrete (limestone) aquifers in the arid inlands of Australia, might well be the first invertebrate taxa that can be added to this list. Currently, 70+ species have been recognized, each of them restricted to a single calcrete aquifer. Phylogenetic evidence, based on mtDNA, shows that besides numerous cases of allopatric speciation, resulting from isolation of several ancestral species in separate widely distributed calcrete aquifers, approximately 33 % of these aquifers contain pairs of species that are closely related. These sister species pairs also differ considerably in size and morphology. We investigate the mode of speciation for these sympatric sister species pairs by applying a simple model that simulates random occupation of niches by ancestral surface species during colonisation of the subterranean environments. We show that the number of observed sister pairs is better explained by a drive to occupy empty niches by species within the aquifer than by repeated colonisation of the aquifers by the same ancestral surface species.

Islands in the desert: evolution of subterranean diving beetles (Coleoptera: Dytscidae: Bidessini, Hydroporini) in arid Australia

R Leijs, SJB Cooper, CHS Watts, WF Humphreys
Evolutionary Biology Unit, South Australian Museum, Adelaide, SA 5000, Australia; leijs.remko@saugov.sa.gov.au

Isolated calcrete aquifers in arid inland Australia contain a rich invertebrate subterranean water fauna (stygofauna), comprising Amphipoda, Syncarida, Ostracoda, Copepoda and also the world's most diverse assemblage of subterranean diving beetles. Here we test whether the Adaptive Shift Hypothesis (ASH) or the Climatic Relict Hypothesis (CRH) is the most likely mode of evolution for the Australian subterranean diving beetles, by using a mtDNA phylogeny, linearized using a relaxed molecular clock method. We found that, 1) individual calcrete aquifers contain several diving beetle species of distantly related lineages and/or a single pair of sympatric sister species that significantly differ in size and morphology, 2) evolutionary transitions from surface to subterranean life took place in a relatively small time frame, and 3) most of the variation in divergence times of the sympatric sister species is explained by the variation in latitude of the localities, which correlates with the onset of aridity from the North to the South and with an aridity maximum in the Early Pliocene (5 Mya). Several lines of evidence inferred from the molecular clock analyses support the CRH, indicating that the evolutionary transitions took place during the Late Miocene and Early Pliocene as a result of aridification.

Wood, elytra, and antiquity: geologic & phylogenetic history of dead wood Coleoptera

RAB Leschen
New Zealand Arthropod Collection, Private Bag 92170, Auckland, New Zealand; leschenr@landcareresearch.co.nz

Ecologists use beetles as indicators because they are very species-rich, and are easy to collect manage in the laboratory. They are one of the most important groups of dead wood invertebrates, and may have been associated with rotting wood since their origin in the Permian (265 My). While studies in coarse woody debris (CWD) ecosystems are increasing, systematic studies of beetles are lagging: taxonomic revisions are needed for identification while phylogenies are needed to place groups of interest in an evolutionary context. The New Zealand CWD beetle fauna consists of approximately 5,000 species and up to 80% of the species are not described and/or need revision. Phylogenetic study of several Polyphagan groups shows that most CWD beetles are not necessarily basal taxa, and most belong to Gondwanan lineages. New Zealand taxa lineages have relatively long phylogenetic branch lengths suggesting that they are relatively old in comparison to their sister taxa located elsewhere in the world. Among mycophagous beetles, most host associations are primitive and may have predated the split between New Zealand and Gondwana. The CWD fauna could be one of the oldest in the world.

Rearing of *Sarcophaga penicillata* (Diptera: Sarcophagidae), for release as a biological control agent for *Cochlicella acuta* (Mollusca: Hygromiidae) in South Australia

M Leyson, D C Hopkins, N Luke, K Bell
GPO Box 397, Adelaide 5001, South Australia; Australia; leyson.megan@saugov.sa.gov.au

The conical snail *Cochlicella acuta* is a major grain contaminant in South Australia and is concentrated mainly on the lower end of Yorke Peninsula because of the region's limey soil type. Following an introduction from France and a quarantine testing phase over 2-3 years, the parasitic fly *Sarcophaga penicillata* was first released on South Australia's Yorke Peninsula in April 2000 for control of the conical snail *C.acuta*. *S. penicillata* has since established at several release sites. Laboratory rearing for release of *S.penicillata* was conducted at the Waite institute, South Australia. Two methods of rearing were tested and the *S.penicillata* parasitism rate in the laboratory colony ranged from 10-20%. In addition, experiments were conducted to investigate the pollen and nectar feeding habits of adult *S.penicillata* on Queen Anne's Lace (*Ammi majus*, Family: Umbelliferae) and Canola (*Brassica Napus*). This paper presents the recent developments with the laboratory rearing program and results from the 2003/04 fly release season.

Discriminant analysis of the disruptive impacts of a horticultural mineral oil & two synthetic pesticides on citrus ecosystems

WG Liang, GAC Beattie, R Spooner-Hart, A Meats, L Jiang
NSW Agriculture, Locked Bag 26, GOSFORD, NSW 2250, Australia; weiguang.liang@agric.nsw.gov.au

The impacts of an *n*C24 horticultural mineral oil (HMO) and two synthetic insecticides (carbaryl and methidathion) on the abundance and species diversity of soil-dwelling arthropods were evaluated in two citrus orchards on the central coast of New South Wales, Australia. In the first orchard, low (2,000 L/ha) and high (10,000 L/ha) volume sprays of HMO, carbaryl and methidathion were applied in treatments in summer 1996/1997 to mature Valencia orange trees (*Citrus ´ aurantium*). Arthropods present in leaf litter and surface soil samples taken from under trees were extracted with Berlese funnels. Results indicated that while the HMO had no significant impact on the arthropods, the synthetic insecticides, irrespective of spray frequency or spray volume significantly reduced the abundance and species diversity of the arthropods including springtails and the generalist predators, such as spiders, staphylinid beetles and gamasid mites. In the second orchard, HMO and methidathion sprays were applied to blocks of trees twice using an oscillating boom sprayer in February 1998. Results were similar to those observed in the first orchard. No significant disruption of soil-dwelling arthropods caused by HMO was observed. Methidathion was found to be significantly disruptive to most soil arthropods, but not to carabids or ants.

Reconstructing historical species associations among archival natural history specimens to evaluate endangered species status

JK Liebherr
Department of Entomology, Cornell University, Ithaca, NY 14853-0901, USA; jkl5@cornell.edu

Specimens from the *Fauna Hawaiiensis* were associated by cluster analysis, thereby reconstructing historical assemblages of Hawaiian carabid beetles (Coleoptera: Carabidae) observed during the 19th Century. Specimen associations permit concise hypotheses of habitat preferences for many of the 32 carabid species collected during the early period of European scientific exploration (1874-1902) but not observed since. These species associations are diagnosable by ecological situations observable today. Suites of recently rediscovered species collected in sympatry during intensive faunal surveys starting in 1991 are clustered on the phenograms of historical associations, indicating concordance of ecological relationships between historical and present-day faunas. Absence of entire species clusters from recent collections suggests actions of common agents leading to extinction or extreme population reduction. Future consideration of official conservation status for Hawaiian carabid beetle species must account for the status of ecologically associated species, and the limited likelihood that individuals of extant species can be consistently observed in nature due to natural relative rarity or secretive habits within restricted geographic and ecological distributions. Historical specimen associations serve as the best guides for continuing efforts to monitor known faunal members and to rediscover long-missing species. These associations also serve to link information concerning individual species with particular habitats.

Vanuatu platynine Carabidae (Coleoptera) as the impetus for following cladistic tracks across the southwest Pacific

JK Liebherr
Department of Entomology, Comstock Hall, Cornell University, Ithaca, NY 14853-0901 USA; JKL5@cornell

The carabid beetle tribe Platynini includes numerous diverse lineages across a fragmented Laurasia, with associated radiations in South America, Africa and Southeast Asia. The tribes' limited diversification in Australia and the Pacific Islands is constrained by this Laurasian history, though speciose faunas inhabit New Guinea (125 spp.) and Hawaii (131 spp.). This contribution focuses on taxonomic characterization and relationships of the Vanuatu platynine fauna; a modest monophyletic radiation of five species, plus single representatives of five other clades. In order to define generic membership for these taxa, cladistic analysis including numerous taxa from throughout the southwest Pacific and Hawaii was carried out. The cladogram was robustly rooted using a salient character of the male reproductive tract, defining *Lorostema* Motschulsky—6 species ranging from Sri Lanka to the Philippines and Tahiti—as outgroup to the Pacific lineages. Cladistic area relationships define tracks that connect New Zealand and Fiji, and New Guinea and Vanuatu, with these two areas sister to Fiji. Hawaii is placed basal to the extensive radiation of Pacific clades inhabiting Melanesia and Polynesia. This early dating for the Hawaiian diversification is consistent with colonization of the Hawaiian archipelago well before the emergence of the oldest currently occupied island, Kauai.

The extended phenotype of aspen: consequences of variation for ecological interactions

RL Lindroth, JR Donaldson
"Dept. of Entomology, 237 Russell Labs, Univ. of Wisconsin, Madison, WI 53706, USA; linoth@entomology.wisc.edu"

Trembling aspen (*Populus tremuloides*) is a dominant species of early-successional forests over much of North America. It is a primary food plant for over 100 species of herbivores, and can experience massive defoliation over extensive areas during outbreaks by insects such as forest tent caterpillars. It exhibits striking phenotypic variation in secondary chemistry, as a consequence of genetic, environmental, and G x E factors. Genetic variation in chemistry is related to a trade-off between growth and defense, and expresses itself as differential resistance to herbivores (invertebrate and vertebrate) as well as to pathogens. Aspen also exhibits genetic variation in tolerance to defoliation. Aspen chemistry can influence herbivore (e.g., forest tent caterpillar, gypsy moth) performance not only directly (bottom-up effects) but also indirectly, via impacts on insect natural enemies (top-down effects). Moreover, during outbreaks, herbivore-induced changes in foliar chemistry interact with genotypic differences in aspen to alter the quality of both green leaves for late-season folivores and leaf litter for detritus feeders. Differential resistance to, and tolerance of, defoliation, may contribute to a geographic mosaic of community assemblages and ecosystem function in landscapes dominated by aspen clones.

Trunk invertebrate faunas of Western Australian forests & woodlands: relationships with avifauna usage

JD Majer, HF Recher, C Norwood
"Department of Environmental Biology, Curtin University of Technology, PO Box U1987, Perth, WA 6845, Australia; J.Majer@curtin.edu.au"

Trunk–associated invertebrates were sampled on marri, *Eucalyptus* (*Corymbia*) *calophylla*) along a transect from Karragullen, in the hills near Perth, through to yana, 150 km to the southeast. This represents a op in annual rainfall from 1078 mm down to 504 mm. Invertebrates were sampled by intercept traps, which collect animals that attempt to land on the trunks, and bark traps, which collect invertebrates that move, or live, on the trunk. The range and abundance of invertebrates sampled was generally greater in the intercept than the bark traps. Invertebrate abundance, activity and biomass on bark were strongly seasonal, with greater numbers being found during the moister periods. Arthropod levels tended to be greater on marri at the ier, eastern end of the transect, particularly on the three locations within the wandoo woodland. These trends are discussed in terms of soil nutrients, the rainfall gradient and plant community composition. Bark arthropods are an important food source for forest and woodland birds, with 15 to 25% of prey taken by insectivorous birds coming from bark substrates. As many as five species of birds in the southwest forests sampled are bark specialists, taking more than 40% of their prey from bark substrates. The frequency of bark-foraging and the number of bark-foraging specialists increased along the transect as the abundance and richness of bark arthropods increased.

Fire-killed trees provide habitat for arthropods & resources for vertebrates

JD Majer, S Radho Toly
"Environmental Biology, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia; J.Majer@curtin.edu.au"

Dead trees are an unappreciated part of the environment and, in urban parks, are considered a safety hazard that must be removed. In 1989 and 1996, vandal-lit fires in Kings Park, Perth, killed large numbers of jarrah (*Eucalyptus marginata),* tuart (*Eucalyptus gomphocephala*, and sheoak *(Allocasuarina fraseriana)* trees. Trunk-associated arthropods were collected from live and dead trees of these three species in summer 1999 and winter 2000, using intercept and bark traps. Higher numbers of arthropods were sampled in summer than winter. Dead trees had between 0.69-0.84 as many arthropods alighting on them as live trees (intercept trap data), and between 0.36-1.00 as many arthropods living on them as live trees (bark trap data). Levels of many orders on dead and live trees were not significantly different from each other. The variety of beetle species was much lower on dead than live species, although species composition was different. It is concluded that retention of dead trees provides habitat for arthropods, enhances the conservation of biodiversity, and provides additional feeding opportunities for insectivorous vertebrates, that would not be available if they were removed.

Reliability of plants & various groups of animals as indicators of environmental condition: a cross taxon analysis

L Bisevac, JD Majer
"Environmental Biology, Curtin University of Technology, GPO Box U1987, Perth, WA 6845, Australia; J.Majer@curtin.edu.au"

A survey of rehabilitated mineral sand mines and reference heath areas at Eneabba, Western Australia was conducted in order to compare the relative performance of plants, birds, terrestrial vertebrates, and various orders of arthropods as indicators of environmental conditions. Using both PATN, and the 2stage application in the PRIMER5 multivariate package, ants and beetles performed almost as well as plants as indicators of overall environmental conditions. Terrestrial vertebrates and springtails performed acceptably well, but trends in birds and spiders were more closely allied to trends in other taxa than they were to the overall community. A critique of the performance of each taxon is presented.

Conservation status of the mound-building red wood ant *Formica lugubris* in Ireland

H Mäki-Petäys, J Breen
Department of Biology, P.O.Box 3000, FIN-90014 University of Oulu, Finland; hannaleena.maki-petays@oulu.fi.

Formica ants form a substantial component in coniferous forest ecosystems in the northern hemisphere. These locally dominant wood ant species are included in the global red list of IUCN as a result of habitat loss and degradation. In Ireland, the distribution and population size of *Formica lugubris* has declined rapidly in recent decades. Only two small isolated populations remain and the total number of known nests is less than 50 (compared to 200 during the 1970s). For conservation purposes, more information about the species status is needed. We use genetic methods, microsatellites and SSCP, to examine sociality, genetic variability and structure of the populations, and to clarify the origin of *F. lugubris* in Ireland. The genetic variation is extremely low, but there exists only little inbreeding depression measured as the proportion of diploid males. Both populations are monogynous having normally one queen per nest, whereas populations in England have been shown to be polygynous. Thus, Irish *F. lugubris* populations differ from those in England, indicating an even stronger need for conservation. In addition, *F. lugubris* needs urgent conservation as the effective population size is really low and very little genetic variation is left in the remaining populations threatened by forestry.

Why do ants distribute myrmecochorous diaspores? New insights to an old question

V Mayer, R Fischer, MS Ölzant
"Institute of Botany, University of Vienna, Rennweg 14, A-1030 Vienna, Austria; veronika.mayer@univie.ac.at"

Ant-dispersed diaspores usually bear a protein and lipid-rich appendage, the elaiosome. The attractiveness of elaiosomes for ants has been repeatedly demonstrated. The nutritional composition of elaiosomes, however, has received little attention so far. In our study, elaiosomes and the respective seeds of 15 Central European ant-dispersed diaspores were chemically investigated in regard to the possible nutritional requirements of ants. The results suggest that elaiosomes are adapted for the needs of ants. Investigating the distribution of *Corydalis cava* elaiosomes between larvae and working caste of laboratory colonies of *Myrmica rubra* we found them to be mainly consumed by larvae and not by workers. As Oberrath and Böhning-Gaese (2002) could show myrmecochorous plants fruited on average 7.1 weeks earlier than those with other dispersal modes. So both, the highly nutritive elaiosomes and timing the fruiting peak with the seasonal peak of larval abundance are evolutionary adaptations of plants towards myrmecochory. In view of these results the hypothesis, that 1,2 diolein, a diacylglycerol of oleic acid act as trigger for seed dispersal, was examined once more. In a series of bioessays we tried to clarify whether ants prefer single substances over mixtures with nutritionally valuable components. The results give reason for a new discussion of this hypothesis.

The role of hybridization & genetics in landscape dominant sagebrushes (*Artemisia*)

ED McArthur, DC Freeman, JH Graham, SC Sanderson
Shrub Sciences Laboratory, 735 N. 500 E., Provo, UT 84606, USA; dmcarthur@fs.fed.us

The subgenus *Tridentatae* of *Artemisia* (Western North America sagebrush) is composed of a group of about a dozen species. Several species including iconic big sagebrush (*A, tridentata*) encompass subspecific entities. The *Tridentatae* as a whole are closely related. Polyploidy is a reoccurring theme. Studies using hybridization, genome analysis, allozymes, and DNA-molecular genetics on individual populations, species, and higher taxonomic ranks have been useful in clarifying systematics. Classical morphological (alpha) taxonomy has been partially confirmed. Molecular genetics approaches using RAPD, AFLP, ITS, and *trn*L have provided new insights on the limits of *Artemisia* and of *Tridentatae*. The genetic structure of the *Tridentatae* as a whole suggests a group differentiated as a result of strong ectotypic selection over a background of widespread hybridization—chloroplast and ribosomal DNA patterns are not taxon specific. However, some AFLP markers show high subspecific fidelity within *A. tridentata*. Local gene flow and strong evidence for population adaptation has been provided by a series of studies in hybrid zones. Insects have variable responses to parental and hybrid sagebrush populations both in natural hybrid zones and manipulated parental-hybrid sagebrush plantations but the hybrids do not appear to be a sink for herbivorous insects or to have lower herbivore loads.

Status evaluation principles for insects in New Zealand

C McGuinness
Department of Conservation, P.O. Box 10-420, Wellington, New Zealand; cmcguinness@doc.govt.nz

An outline is provided of the principles underlying the system utilised by the New Zealand Department of Conservation (DOC) to assign threat rankings to species. A brief history of previous status evaluation systems used by DOC and background into the development of the current system is covered. Advantages, assumptions and drawbacks of the current system are discussed. A synopsis of how the rankings are integrated into departmental processes and their influence on the management of insect species is provided.

Tracking large rare weta (Orthoptera, Anostostmatidae)

ME McIntyre
School of Biological Sciences, Victoria University Ecology & Health Research Centre, Department of Public Health, Wellington School of Medicine and Health Sciences, Wellington. South, New Zealand; mary.mcintyre@wnmeds.ac.nz

The largest of the giant weta, *Deinacrida heteracantha*, were formerly widespread in northern forests, but now survive only on Little Barrier Island (New Zealand). Rugged topography of the island and arboreal habits of the weta make it difficult to assess their current status, but it is a concern that they are no longer seen in the low coastal shrubs where they were described as 'easy to find' in the 1960s (Richards 73). Surveillance of individual weta using radiotransmitters for up to 25 days of monitoring indicates some aspects of habitat use, with implications for their continued co-existence with kiore *(Rattus exulans)* and for future monitoring.

Accuracy of species richness estimates obtained from incomplete inventories: lessons from a benchmark dataset on tropical ants

M Leponce, O Missa, JHC Delabie
"School of Biological Sciences, University of Aberdeen, Tillyone Avenue, Aberdeen AB24 2TZ, United Kingdom; o.missa@abdn.ac.uk"

Estimating species richness of insect communities is notoriously difficult especially in the tropics where unrecorded species continue to appear in the samples even after years of effort. Methods allowing to extrapolate accurately the species richness (ESR) for larger sampling efforts or the total species richness in the assemblage (TSR) are highly desirable to improve the cost effectiveness of biodiversity inventories. Here, we tested the performance of 1 parametric, 5 non-parametric and 15 curve-fitting extrapolation methods by calculating their bias and precision against a large benchmark dataset, a near complete inventory of a tropical ant assemblage. For low levels of sampling effort (before the species accumulation curve started to level off), beta-P and Soberon & Llorente models allowed extrapolations of species richness for up to 10-fold increases in sampling effort with little bias and reasonable accuracy. There is, however, a minimum sample size below which, little information can be gained, regardless of extrapolation methods. For higher levels of sampling effort the Stout & Vandermeer and the Weibull models, yielded stable estimates of TSR, independent of sample size. Overall, curve-fitting extrapolation methods appeared as a powerful alternative to the popular non-parametric methods.

Discriminatory power of arthropod surveys conducted at family level for monitoring disturbance in tropical forests

O Missa
"School of Biological Sciences, University of Aberdeen, Tillyone Avenue, Aberdeen AB24 2TZ, United Kingdom; o.missa@abdn.ac.uk"

Arthropods were surveyed by local parataxonomists at 12 sites of increasing anthropogenic disturbance (old and young secondary forests, savannah and cultivated gardens) at Gamba, Gabon. Overall 429,541 arthropods were collected in the 38 sampling events (4,712 samples in total) carried out over one year with four sampling techniques: yellow pan, pitfall, flight interception and Malaise traps. Here, I report on the discriminatory power of family level data to monitor disturbance in tropical forests as an alternative to using a single taxon treated at species level. The families most useful to classifying sites along the disturbance gradient were identified on the basis of their indicator value index for each sampling method separately. Discriminant analyses were then performed to select the most effective predictor set of families. The discriminant functions derived from the analyses of the whole dataset were subsequently tested on subsets of the original dataset to determine 1) the minimum sample size recommended for efficient monitoring, 2) the most frequent sources of error and 3) the most accurate sampling method. Overall, this study shows that analysing arthropod surveys at family level can be an effective alternative to a single taxon approach for monitoring disturbance in tropical forests

Current status of the Odonata of Bhutan: a checklist

A Mitra
Lecturer, Department of Zoology, Sherubtse College, Kanglung, Bhutan; mitodonata@yahoo.com.

Lieftinck (1977) has reported only six species of dragonflies from Bhutan. Tsuda (1991) in his distribution list of world odonata has listed 9 species of dragonflies from Bhutan. Mitra (2002) in his recent most work found out 18 new records from Bhutan. In the present study an up-to-date checklist of 34 species and subspecies of dragonflies known from Bhutan has been made of which seven are new records from Bhutan.

Guanophilic arthropod ecology & seasonal spatial distribution in a bat maternity cave

TA Moulds, A Austin, J Jennings
Centre for Evolutionary Biology and Biodiversity, Earth and Environmental Sciences, Darling Building, The University of Adelaide, North Tce, SA 5005, Australia

Australia's most diverse guanophilic arthropod community from Bat Cave, Naracoorte consists of over 30 species of insects, arachnids and crustaceans. Highest species abundances occur during summer when the maternal chamber is occupied by some 30,000 southern bent-wing bats that use the domed chamber for birthing. During summer deposition of fresh guano and urine is greatest in the chamber's centre, under the main bat roost, resulting in dramatic increases in pH, while remaining areas exhibit lower pH. During winter bats vacate the cave to enter torpor in cooler caves in the region, resulting in a cessation of guano deposition and consequently lower, often acidic conditions (pH <5.0). High abundances of guanivorous mites and predatory histerid beetles occur on guano piles during summer corresponding with increased guano deposition rates and high pH (>8). Older more acidic guano in winter enables large population increases of anobiid and other fungal feeding beetles. These species dominate guano piles in the central area. Generalist predatory species including carabid beetles and pseudoscorpions are ubiquitous in the maternal chamber throughout the year and show no preference for position of guano within the chamber. This highly specialised ecosystem provides an invaluable study site for subterranean ecology and cave biogeography in southern Australia.

Body size variation in Australian Coleoptera: comparing canopy assemblages from remnant & plantation forests

W Murray, SA Cunningham
CSIRO Entomology Box 1700, Canberra, ACT, 2601, Australia; craspedia_variabilis@hotmail.com

Body size of insects is related to many ecological traits including diet, reproduction and dispersal. Comparing body size distributions of communities from different habitats informs us of ecological differences over and above that which can be learned from species composition alone. We collected, identified and measured body lengths of 273 beetle species from the canopy of remnant *Eucalyptus marginata* forest and *Eucalyptus globulus* plantation forest from the same region in southwestern Australia. Four survey events were conducted (spring and autumn over 2 yrs) from 8 remnant forest and 15 plantation sites across 4 study areas. We used insecticidal knockdown from canopies of 26 remnant *Eucalyptus marginata* and 53 plantation *Eucalyptus globulus* trees. The mean body size of species (ignoring abundance) was larger in the plantation habitat (t-test, 144 df, P=0.002). The mean size of individuals (ignoring species) was also larger in the plantation habitat (t-test, 5000 df, P<0.001). However, the few most abundant species were not consistently larger than their near-relatives (within-family). Smaller species from both habitats were found to occupy more sites than large species. This relationship between body size and number of sites occupied was over and above the effect of abundance (logistic regressions, 2 independent variables, P<0.001).

The effect of climate change on insect ranges: dynamic profile models

CJ Nagelkerke
Institute Of Biodiversity And Ecosystem Dynamics, Amsterdam, The Netherlands; nagelker@science.uva.nl

The consequences of climate change depend on the species' ability to track it. I model the effect of a moving North-South climate profile on the latitudinal range of an insect metapopulation. It is assumed that climate affects one or more of the metapopulation parameters (amount of habitat that is regionally available, local extinction rate and colonization rate). When the ranges shift in response to the climate, tracking delays may develop on both the advancing and the retreating edge of a range. The difference between these two delays determines the effect on range size. It appeared that a moving climate lowers regional population size. However, ranges may become larger when populations on the retreating edge take a long time to disappear. Remarkably, global population size may increase. Species not able to track the climate fast enough go extinct because their retreating edge moves faster than, and eventually collides with, the advancing edge. Results depend very much on which of the metapopulation parameters climate actually acts on, especially concerning the retreating edge. Tracking ability increases with range size, amount of habitat, dispersal rate and dispersal distance, and climate change greatly increases vulnerability to habitat destruction and dispersal impairment.

Soil & litter arthropod assemblages as indicators of rainforest restoration

A Nakamura, CP Catterall, RL Kitching, APN House
Australian School of Environmental Studies and Rainforest CRC, Griffith University, Nathan, QLD, 4111 Australia; a.nakamura@griffith.edu.au

The devastating impacts of forest clearance are widely recognized, and considerable efforts have been employed to restore cleared areas. However, little is known about the re-assembly of soil and litter fauna in replanted areas, or how assemblages may be affected by different restoration practices. The present study investigates factors that influence the diversity of soil and litter dwelling arthropods in rainforest restoration plantings. Factors include: distance from remnant rainforests; inoculation; litter quality and quantity; and the efficacy of timber plantations versus ecological restoration. A field experiment is in progress to test these factors. The first stage is to select suitable indicator groups by means of a baseline survey. A set of 24 replicate sites was located in pasture and rainforest on the Maleny plateau, in the Sunshine Coast hinterland of eastern Australia. Arthropods were sampled using pitfall traps and Tullgren funnels. Various arthropod taxa are used in the present study, with particular emphasis on ants (Hymenoptera: Formicidae). The usefulness of different taxonomic levels as indicators of rainforest restoration will be compared.

Inter-mutualism conflict: do ant bodyguards deter pollinators?

JH Ness, JL Bronstein
Dept of Ecology and Evolutionary Biology, University of Arizona, Tucson, Arizona 85721, USA; jness@email.arizona.edu

We tested the hypothesis that plant bodyguards (ants) also deter plant pollinators, and explore mechanisms by which a plant bearing extrafloral nectaries (Ferocactus wislizeni, Cactaceae) may limit inter-mutualism conflicts between its pollinators (solitary bees) and a diverse guild of ant bodyguards. No-choice trials demonstrated that floral tissue can deter ants, although that deterrence differed among four ant species. Field inspections of >1000 flowers on plants with different ant associates demonstrated that ant occupation of flowers (the product of % flowers occupied and mean number of ants within an occupied flower) increased in the order predicted by the behavioral trials, and the percentage of flowers occupied by bees decreased in that order. Ant identity also influenced maternal plant reproductive function. Seed mass per fruit was significantly lower on plants tended by Solenopsis xyloni, the ant least deterred by floral tissue, relative to fruits on plants tended by the other three species. That ant exhibited the greatest incidence of flower occupation, the greatest aggressiveness towards other arthropods, and pollinators visited plants tended by that ant least. Inter-mutualism conflicts may be particularly common in facultative, generalized systems, particularly where there is variation in partner quality and in the relative importance of the mutualisms.

Improving conservation focus: refining status evaluation for threatened insect species

TR New, DPA Sands

"Department of Zoology, La Trobe University, Victoria 3086, Australia; zootn@zoo.latrobe.edu.au"

Deciding rational priorities from lists of protected species to receive limited support resources has implicit reference to both absolute need and ranking. Both of these are often somewhat subjective decisions, but purport to reflect imminence or likelihood of extinction. Criteria used to determine conservation need for invertebrates are commonly derived from those designed for vertebrates, and contain reference to quantitative data on extinction thresholds and population sizes of little practical relevance, and which are usually not available. Shortcomings of current schemes for setting such priorities are reviewed, and the distinction between 'rarity' and 'threat' emphasised. A scheme designed to evaluate conservation status of Australian butterflies, based on severity of threat, is outlined and its potential wider applications discussed. Such schemes lead toward more credible and workable priorities for conservation need and may do much to overcome problems of the current listing processes, so leading to better focus and allocation of the limited support available for insect species conservation.

Does a wide host plant range promote speciation?

S Nylin, N Janz, N Wahlberg, E Weingartner
"Dept of Zoology, Stockholm Univ., SE-10691 Stockholm, Sweden; Soren.Nylin@zoologi.su.se"

Phytophagous insects represent a large proportion of global biodiversity, but how and why this diversity has evolved is not clear. The butterflies are an important model group for investigation of this pattern. We make use of recent advances in plant and butterfly systematics to trace the evolution of host plant utilization at several taxonomical levels in the family Nymphalidae. A consistent pattern was found that butterfly taxa with a more diverse utilization of host plants also are more diverse in terms of number of species. We discuss this pattern in terms of Ehrlich & Raven's coevolutionary scenario of "escape and radiate" and West-Eberhard's theory of plasticity as a driver of speciation.

Tracing the great Australian weevil radiations

RG Oberprieler
"CSIRO Entomology, GPO Box 1700, Canberra ACT, Australia; rolf.oberprieler@csiro.au"

The Australian weevil fauna of ca. 4200 described species is characterised by a small number of highly diverse groups that are unique to Australia or not numerous elsewhere. These taxa can be categorised as terricolous (Amycterini, Entimini), phytocolous (Belinae, Gonipterini, Cryptoplini, Storeini) or lignicolous ("Cryptorhynchinae"). All are indicated to have undergone significant radiations; however, understanding the nature and drivers of their radiations is largely impeded by the poorly known taxonomy and phylogeny of the groups. In the phytocolous Belinae, whose taxonomy and phylogeny have recently been studied, the radiation can be traced on a phylogram as being driven by a host shift from conifers to acacias. Radiations in other phytocolous taxa similarly appear to track the diversification of Australian acacias (Storeini) and Myrtaceae (Gonipterini, Cryptoplini). When the phylogeny is unknown, radiations may be estimated from the structure of the diversity. In the terricolous Amycterini and Entimini, diversity profiles suggest the existence of radiations of different ages, origins and drivers. Diversity structure appears largely unaffected by the state of taxonomy of a group: in Amycterini, revisions in 1865-1866, 1909-1923 and 1993 resulted in changed numbers of genera and species but not diversity structure.

Collapse of an island insect fauna due to invasion by an exotic lizard, *Anolis carolinensis*

I Okochi, M Yoshimura, H Makihara, S Makino, H Karube
"Matsunosato 1, Tsukuba city, Ibaraki, 305-8687, Japan; ohkou04@affrc.go.jp"

The Ogasawara (Bonin) islands, located between mainland Japan and the Marianas, have a unique fauna like many other Oceanic islands in the Pacific. The insect fauna is not so rich but is highly endemic – so much so that a species of butterfly, a cicada, four dragonflies and damselflies, a bee, and one jewel beetle are protected as national monuments. Recently, however, their populations have been declining and have become endangered. These declines were thought to have been caused by previous human development of the islands, but this does not explain why some groups are not declining. Butterflies, a cicada, bees, dragonflies, damselflies, and some groups of beetles are declining, while moths, water striders, and other groups of beetles are not. We observed that the species in decline were diurnal and that this decline had begun after the invasion of a diurnal lizard, *Anolis carolinensis*, the green anole, which was originally distributed in southern North America, but has been introduced to a number of Pacific islands. Field and indoor experiments showed that the green anole is an effective insect predator and is the likely cause of the declines

Forest edges: regions of high or low diversity in plantations?

CMP Ozanne, IP Palmer

Centre for Research in Ecology and the Environment, School of Life & Sport Sciences, University of Surrey Roehampton, West Hill, London SW15 3SN, UK; c.ozanne@roehampton.ac.uk

Managing plantations for diversity as well as production can be enhanced by taking into account local and landscape level structural heterogeneity. Forest edges contribute to such heterogeneity and may have positive and/or negative effects on diversity. Although edge-effects have been demonstrated to occur for microclimate, vegetation assemblages and some vertebrates, there are few data for arboreal arthropods communities. This paper presents data on edge-effects for canopy arthropods in UK coniferous plantations. Arthropods were collected using pyrethrum knockdown from a range of patch sizes and tree species. Groups such as the Acarina, Coleoptera and Collembola showed strong responses to edge proximity with some species exhibiting marked changes in density or clear habitat preferences. Responses of canopy communities varied with tree species, for example, in patches of the introduced species Picea sitchensis, there were elevated levels of herbivores and predators at the edge whereas in Pinus sylvestris (native to Caledonia in Scotland) the core habitat supported more diverse arthropod communities with greater numbers of woodland specialists. Recommendations about management strategies for increased biodiversity are discussed.

Impacts of climate change on insect communities

C Parmesan
"Integrative Biology, 1 University Station C0930, University of Texas at Austin, Austin, Texas, 78712 USA; parmesan@mail.utexas.edu"

Observed changes in natural systems, largely over the past century, indicate a clear global climate change signal. Even in the face of apparently dominating forces, such as direct, human-iven habitat destruction and alteration, this climate fingerprint implicates global climate change as a new and important driving force on wild plants and animals. Analyses of climate and of biotic change indicate that on a global scale, climate change has affected about half of the wild species studied (Parmesan & Yohe, 2003). One of the most prominent responses has been poleward and upward shifts in species' ranges, apparently tracking climatic shifts. The implications of shifting species' ranges for maintenance of species' interactions and conservation of local diversity will be discussed.

Ants of Kruger National Park, South Africa: diversity, determinants & conservation implications

CL Parr
"CSIRO Tropical Ecosystems Research Center, PMB 44, Winnellie, Northern Territory 0822, Australia and Spatial, Physiological and Conservation Ecology Group, Department of Zoology, University of Stellenbosch, Matieland 7602, South Africa; clp@sun.ac.za"

Epigaeic ant diversity was surveyed across a range of savanna habitats in Kruger National Park, South Africa, in order to compare diversity between habitats, and investigate the relative importance of local scale processes responsible for maintaining this diversity. A total of 204 ant species were recorded in the park. No invasive or alien species were found in the park. Species richness was greatest in the highest rainfall area (Pretoriuskop), and lowest in lower rainfall areas. Although fire is generally considered an important disturbance in Southern African savannas, burning was not found to significantly affect ant diversity across most of the park. Higher rainfall areas where ant community composition was significantly affected by fire regime, appear to be an exception. While habitat structure did not affect ant body size, ant community composition differed between savanna habitat types. Competition was found to play an important role in determining ant diversity at baits, although how this is reflected at the assemblage level still requires further investigation. The findings have implications for conservation management in Kruger National Park, and will assist with the choice of sites for long-term monitoring.

Caught in the web: assessing spider assemblages as ecological indicators in agroecosystems

S Pearce, MP Zalucki
School of Life Sciences, The University of Queensland, St. Lucia 4072, Australia; s.pearce@uq.edu.au; ph: +61 7 33654822;

Spiders are important ecological indicators that reveal the impacts of environmental change and more importantly management decisions in agroecosystems. Plant and vertebrate species diversity have been frequently used as ecological indicators in natural environments however in agroecosystems these taxa are less useful. Spiders on the other hand satisfy all the requirements of a good ecological indicator in that they are relatively diverse and abundant in most agricultural regions of the world, are easily sampled, and respond rapidly and predictably to their environment in a way that reflects ecological change. Their trophic position means they may have major impact on other invertebrates and are functionally significant as predators of agricultural pests. Previous studies in agroecosystems have shown that spider species richness decreases as farm management intensity increases. The potential use of spider communities to monitor tillage regimes, insecticide usage, and the success of area-wide integrated pest management programs is discussed.

The relative abundance of leaf domatia & extrafloral nectaries in South Florida trees & plant communities: temperate versus tropical comparisons

RW Pemberton
"Invasive Plants Research Laboratory, USDA Agricultural Research Service, 3205 College Ave., Ft Lauderdale, Florida 33314 USA;
bobpem@saa.ars.usda.gov"

Southern Florida is both the southern limit of many temperate trees and the northern limit of many tropical trees. The leaves of most of the trees in the region (122 species) were examined for the presence of leaf domatia and extrafloral nectaries, structures promoting potential plant protection mutualisms with beneficial mites and ants. Leaf domatia were found in 7/21 (33%) trees of temperate origin compared to 15/101 (15%) of the trees of tropical origin. Extrafloral nectaries were found in 2/21 (10%) of the temperate trees compared to 23/101 (23%) of the tropical trees. Plant communities comprised principally of temperate trees (Scrub, Cypress and Everglades Tree Islands) should have relatively high occurrence of leaf domatia based mutualism but low levels of extrafloral nectary based mutualism, with the reverse being true for plant communities comprised primarily of tropical trees (Tropical Hardwood Hammock and Pine Rockland). Tropical Mangrove, however, has similar levels of occurrence of leaf domatia and extrafloral nectary bearing trees. These results agree with past studies showing a greater abundance of extrafloral nectaries in tropical plants, and support findings indicating that leaf domatia are especially common in temperate trees, but suggest clearer tropical vs. temperate delineations in these protective mutualisms.

Evolutionary constraints & adaptation in psyllids

D Percy
"Centre for Plant Research, 302-2357 Main Mall, University of British Columbia, Vancouver BC, V6T 1Z4, Canada; dmpercy@interchange.ubc.ca "

Evolutionary constraints may both promote and restrict adaptation. An obvious way in which specialist phytophagous insects "break" evolutionary constraints is in switching to different host plants. The diversification of plant feeding insects depends on the ability to colonize novel plant groups, but also to specialize on these groups. In many cases, specialization has promoted spectacular radiations in insects, promoting adaptation and diversification. In Australia, there are several examples where the scale of diversification in the host plant appears to have promoted diversification in the insects (e.g. psyllid diversification on Myrtaceae, Fabaceae and Casuarinaceae). The diversification of a plant lineage may influence the development of insect specialization in a number of ways. Joint analysis of associated plant and insect groups is one way to answer some of the questions about the role of evolutionary constraints and adaptation.

Lessons from the mysterious east: the tectonic and biogeographic history of the East Papua composite terrane

DA Polhemus
Dept. of Entomology, MRC 105, Smithsonian Institution, PO Box 37012, Washington, DC, USA 20013-7012; polhemus@si.edu

The tectonics of the eastern Australian Plate margin from the Cretaceous onward were dominated by an initial episode of rifting during which continental slivers moved northeastward into the Pacific, followed by eastward-dipping subduction in the Eocene during which a set of island arcs converged upon the margin in a westward direction. Following subduction reversal to a westward dip in the Oligocene, the predominant direction of arc migration became eastward, the pattern that prevails today. Thus an initial outward rafting of old Australian biota comingled with an inward rafting of more heterogenously derived arc biotas which originated in both Asian and oceanic settings; the results of this biotic interchange are now being rafted eastward into the Pacific at large. In eastern New Guinea, the East Papua Composite Terrane, or EPCT, was caught between these dichotomous tectonic regimes for at least 30 million years, and provides an instructive case history in regard to biotic derivation and fragmentation. The EPCT developed a distinctive endemic biota that still imparts a strong regional signature, and provides useful independent evidence for evaluating models of tectonic evolution in the Solomon Sea region.

Codiversification in an ant–plant mutualism: stem texture & the evolution of host use in *Crematogaster* inhabitants of *Macaranga* in Southeast Asia.

SP Quek, SJ Davies, T Itino, NE Pierce
Harvard University Herbaria, 22 Divinity Avenue, Cambridge MA 02138, USA; quek@fas.harvard.edu

We investigate the evolution of host association in a cryptic complex of mutualistic *Crematogaster* ants inhabiting *Macaranga* trees in Southeast Asia. We use Cytochrome Oxidase I (COI) to reconstruct phylogenetic relationships in a comprehensive sampling of *Crematogaster* from *Macaranga*. Using a published *Macaranga* phylogeny, we test whether the ants and plants have cospeciated. The COI phylogeny reveals ten well-supported lineages, and an absence of cospeciation. Host shifts, however, have been constrained by stem traits that are themselves correlated with *Macaranga* phylogeny. Despite the absence of cospeciation, a correlated succession of stem texture in the ant and plant phylogenies suggests that *Decacrema* and *Pachystemon* have diversified in association, or codiversified. Their confinement to the aseasonal wet climate zone of western Malesia suggests myrmecophytic *Macaranga* are no older than the wet forest community in Southeast Asia, estimated to be ~20 million years (MY) old. Applying a COI divergence rate of 1.5% per MY to a rate-smoothed Bayesian chronogram of the ants, the *Decacrema* from *Macaranga* are inferred to be at least ~12 MY old, suggesting that the evolutionary histories of *Decacrema* and their *Pachystemon* hosts have been contemporaneous since the mid-Miocene. The evolution of myrmecophytism enabled *Macaranga* to radiate into enemy-free space, while the ants' diversification has been shaped by stem traits, host specialization and geographic factors.

Impact of anthropogenic disturbances on litter insect communities in the heavily used forests of Western Ghats (India)

PD Rajan, PA Sinu, S Lele
"Ashoka Trust for Research in Ecology and the Environment (ATREE), # 659, 5th A main, Hebbal, Bangalore- 560 024, India; priyan@atree.org"

"In most parts of the Western Ghats, stand simplification due to human use of forests is the rule rather than exception. In Sringeri Taluk of central Western Ghats, [Karnataka, India] there is a traditional practice of leaving small fragments of forests uncultivated near the farm lands, for the purpose of green manure and fuel wood and are called *Soppinabettas*. Due to over exploitation the diversity of these *Soppinabetts* are depleting very fast and are being converted to less diverse scrub jungles. On the other hand, state forest policy led to the complete replacement of "natural" or "degraded" forests with monocultural *Acacia auricularis* plantations thus further simplifying the vegetational complexity. A study was conducted to compare litter insect diversity in relatively less disturbed natural forest patches with that in well-managed *soppinabettas*, degraded *soppinabettas*, and acacia plantations. Using satellite imagery and GIS techniques, five sites containing each of these four land-use types were identified.. Insects sampling was carried out across three seasons using pitfall traps and Berlese-Tullgren funnels. Data on environmental variables, vegetation structure and litter density were also collected. The results show that species richness is maximized in the well-managed *soppinabettas* while acacia plantations are the least diverse. Insect abundance is maximised at 'intermediate levels of disturbance' and increased frequency of disturbance limit diversity to those species can tolerate stress due to disturbances.
"

Here today, gone tomorrow: selecting appropriate bioindicators for temporary habitats

EC Regan, AO Connor, M Gormally, J Moran, MS Skeffington, M Visser
Applied Ecology Unit, Environmental Change Institute, National University of Ireland, Galway, Ireland; eugenie.regan@nuigalway.ie

Temporary habitats, such as floodplains and ephemeral ponds, are important on a worldwide scale for many rare and threatened invertebrates. The conservation status of these systems is difficult to assess and monitor because of their temporal instability. Turloughs are temporary water bodies that occur in the west of Ireland. As unique habitats, turloughs are designated for nature conservation under the European Union Habitats Directive. Ireland is therefore obliged to designate sites for conservation and monitor their habitat quality. There are a number of questions that this paper addresses. Firstly, are the conservation agencies taking appropriate account of all aspects of turlough biodiversity? Should both phases of the habitat be monitored? Or can terrestrial invertebrates be used as bioindicators for the aquatic invertebrates and vice-versa? This paper considers invertebrate communities of both the dry and the wet phases of turloughs. There were a number of similarities between the terrestrial and aquatic assemblages. However, the major environmental factors influencing the groups differed, with some sites being noteworthy for their terrestrial fauna, but not their aquatic fauna, and vice versa. This work sheds new light on the conservation and management of temporary habitats.

The adventure of few and gain of many: adaptive radiation of spiders & planthoppers on remote islands of the Pacific

RG Gillespie, GK Roderick
Division of Insect Biology, University of California, Berkeley CA 94720-3112, USA; gillespi@berkeley.edu

Remote islands have been heralded as "natural laboratories", with spectacular cases of adaptive radiation. How is the diversification achieved? To elucidate commonalities underlying patterns of adaptive radiation we have studied (1) spiders in the genus *Tetragnatha* which are generalist predators; and (2) planthoppers in the genus *Nesosydne* which are specialist herbivores. Comparing three archipelagoes of differing isolation across the Pacific we have shown that both genera have undergone adaptive radiation within each archipelago, although the lineages within each group are only distantly related. Focusing on the Hawaiian Islands, where diversification is most prolific, we show that lineages have generally progressed down the island chain from older to younger islands, a common pattern for arthropod radiations. For the spiders, species on any one island are generally closely related to others on the same island, and the same set of ecological forms has evolved repeatedly on different islands. The planthoppers show a similar pattern of within-island proliferation, though diversification is associated with plant diversity, some lineages tending to diversify in concert with their host (host tracking), while others diversify through host switching. Comparison of diversification in the spiders and planthoppers allows us to infer general mechanisms underlying adaptive radiation.

Alien invasive species in Galapagos: challenges for the conservation of insect diversity

H Rogg, C Causton, L Roque
Charles Darwin Foundation, Puerto Ayora, Isla Santa Cruz, Galápagos, Ecuador; hrogg@fcdarwin.org.ec

The conservation of the approx. 2000 indigenous Galapagos insect species is being threatened by the presence of introduced species including almost 500 insect, 600 plant and 15 vertebrate species. Population decline and even extirpation of endemic Galapagos insects are directly related to predation by invasive species such as *Polistes* wasps and fire ants, and indirectly affected by herbivores such as goats and the cottony cushion scale, and invasive plants. To reduce the risk of new incursions, an inspection and quarantine system for the Galapagos Islands was set up by a multi-institutional task force. At the same time, the Charles Darwin Foundation has developed an integral strategy to conserve the unique Galapagos insect fauna. An ecological monitoring system has been developed that acts as an "early warning system" for new species arrivals and provides important data for the analysis of ongoing mitigation and restoration actions. A model is being developed to predict the invasiveness of potential quarantine insect pests and insect species that have already been introduced in order to prioritize management actions. Several successful eradication and control programs have been executed to deal with invasive species such as the little fire ant, the cottony cushion scale, goats and invasive plants.

Specialist seed insects can affect the conservation of endangered conifer species

A Roques, MA Auger-Rozenberg
"INRA, Unité de Zoologie Forestière, BP 20619 Ardon 45166 Olivet cedex, France; Alain.Roques@orleans.inra.fr"

Most insects exploiting conifer seed cones are highly host- specific. Several ecological adaptations, especially prolonged diapause, allow these insects to cope partially with the annual variations usually observed in host abundance. Long-term, standardized surveys were carried out in Europe and China in order to assess subsequent insect impact on the potential of natural regeneration of conifers. In widespread species (e.g., larches, *Larix* spp.), insect impact dramatically decreased the potential seed yield but a sufficient natural regeneration occured when unforeseeable climatic events (e.g. late frosts) perturbed the natural synchrony between insect populations and cone abundance. Contrasted results were obtained for endangered conifers. In incense- juniper (*Juniperus thurifera*), a relict species with a very scattered range, low numbers of initial seeds per cone in Morocco and France resulted in a quasi- absence of viable seeds following insect attack whereas higher seed numbers allowed an important natural regeneration in Spain. In China, intensive forest exploitation limited the range of *Keteleeria xerophylla* and *Pseudotsuga sinensis* to very small, isolated plots where up to 100% of the seeds were annually destroyed by insects. Insect control seems the only way to prevent species disappearance.

Invasive alien plants & insect diversity conservation

MJ Samways
"Department of Entomology and Nematology, Faculty of Agricultural and Forestry Sciences, University of Stellenbosch, Private Bag X1, Matieland, 7602, South Africa; Samways@sun.ac.za"

Invasive alien plants (IAPs) are among the most threatening of processes to insect diversity. The magnitude of the impact is uncertain, but is large and increasing. The impacts of IAPs at the local scale on various indigenous insect taxa can be negative, neutral and, in some cases, positive. Similarly, the planting of alien trees for timber can be variable depending on the types of alien tree and indigenous insect. Using examples from Africa and the Western Indian Ocean islands, a range of situations and outcomes will be given in the search for general patterns. These findings are then used as a baseline for developing a strategy for ameliorating the threats and searching for opportunities to optimally manage to secure the future of insect diversity.

Habitat fragmentation and connectivity changes hymenopteran parasitoid community composition but not overall diversity

FR Schnitzler, PJ Lester
PO Box 600, School of Biological Sciences, Victoria University of Wellington, Wellington, New Zealand; bug_me@globe.net.nz

Higher trophic levels (parasitoids and predators) might be more sensitive to habitat fragment area and isolation than species at the lower trophic levels. We investigated the hymenopteran parasitoid communities in native-forest fragments (small-isolated, small-connected, large-isolated, large-connected) ranging from 473 ha to 10685 ha over a period of two years from Wellington in New Zealand. MDS and analysis of similarities (ANOSIM) showed a significant difference in species composition between fragments (R 0.413, p=.001). However, there was no effect of fragment size or connectivity on the overall diversity (Shannon's H') of parasitoids. Species composition changed between different sized fragments and ratios of exotic: endemic taxa changed between various fragments, though not necessarily according to size or connectivity. In a case study, we examined the abundance of the kawakawa moth (*Cleora scriptaria*) and its parasitoid fauna, primarily consisting of an endemic and exotic braconid wasp species between fragments. Fragment size and connectivity did not influence the abundance of the moth larvae, but resulted in lower parasitism rates by the exotic braconid wasp. These results demonstrate how community composition can significantly change while overall levels of biodiversity remain similar. Thus, attempting to make decisions on the conservation value of individual habitat fragments becomes complicated.

Effects of reduced prey choice caused by GM plants on a predatory insect

TH Schuler, A Clark, GM Poppy, I Denholm
Division of Plant and Invertebrate Ecology, Rothamsted Research, Harpenden, Hertfordshire, AL5 2JQ, UK; tanja.schuler@bbsrc.ac.uk

Bt plants are highly toxic to certain pest species. Predatory insects may be affected by the reduced abundance of target pests if sufficient alternative prey is not available. This paper will present experiments investigating such indirect effects under laboratory conditions. Lacewing (*Chrysoperla carnea*) larvae were released into large cages containing Bt and wildtype plants previously infested with a constant number of diamondback moth (*Plutella xylostella*) eggs but different numbers of aphids (*Myzus persicae*). No *P. xylostella* larvae survived on Bt plants but aphid populations reached high densities on both plant types. Lacewings recovered from Bt plants at the end of the experiment did not differ in weight from ones recovered from wildtype plants. At the highest initial aphid densities there was also no difference in the proportion of lacewings surviving on the two plant types. Significantly fewer lacewings were recovered from Bt plants than from wildtype plants as initial aphid numbers were reduced. Interestingly, however, numbers of *C. carnea* recovered from wildtype plants were only significantly correlated with numbers of surviving *P. xylostella* at the highest aphid densities. Possible roles of escape behaviour of *P. xylostella* as well as cannibalism between *C. carnea* larvae in these interactions will be discussed.

Community conservation of threatened flagship species: with reference to recovery of the Richmond birdwing butterfly

S Scott, D Sands
"SciComEd, 2 Emily Street, Marsden QLD 4132 Australia; Susanne.Scott@bigpond.com "

Community participation has been effective for recovering threatened butterfly species and is a valuable tool for invertebrate education in Australia. Flagship species of conservation concern have been actively managed in South Australia, Victoria, New South Wales and Queensland. Community groups have focussed on protecting habitats and by protecting specific food plants at the breeding sites. In Queensland and New South Wales, a Project on the Richmond birdwing butterfly, *Ornithoptera richmondia* (Gray), started by a CSIRO entomologist and a national parks ranger, linked with educational and environmental personnel, to conserve the butterfly. The Project commenced in 1989, when the lowland butterfly food plant, the vine *Pararistolochia praevenosa*, was cultivated by a plant nursery for distribution to schools and community groups. An Officer from CSIROs Double Helix Science Club later coordinated activities, and by 1998, more than 32,000 vines had been distributed from the nursery. Support from CSIRO, Brisbane's Southbank Corporation, Bayer Australia and a Threatened Species Network Community grant, enabled wider community (8 groups) and participation in workshops. Progress has been achieved after more than 10 years, by providing ecological guidance to the community (>2000 members) and schools (>200 involved) towards conserving the butterfly, and management and restoration of its habitats.

Evolutionary origins of cave cockroaches in the genus *Paratemnopteryx* Saussure (Blattodea: Blattellidae), Australia

DP Slaney, D Blair, P Weinstein
"Ecology and Health Research Centre, Dept. of Public Health, Wellington School of Medicine & Health Sciences, University of Otago, PO Box 7343, Wellington South, New Zealand; slaney@wnmeds.ac.nz"

For over 150 years scientists have debated the origins of cave dwelling organisms. To investigate the origin of cavernicolous fauna in North Queensland, we selected the cockroach genus *Paratemnopteryx* Saussure (Blattaria, Blattellidae) to test alternative hypotheses for the evolution of cave dwelling species within the genus. Our initial hypothesis was that some surface dwelling species within this genus gave rise to cavernicolous species as a result of increasing aridity in Australia during the late Cenozoic, based on Vandel's 1965 Pleistocene-effect model for the origin of cave organisms in temperate regions. To test this, we used a combined morphological (30 characters) and molecular (ITS2 and COII) approach. Results indicated that cave colonisation events occurred independently on at least three occasions, once in Western Australia and twice in North Queensland. Evidence from species distributions, the structure of the phylogenetic trees, and the possible timings of cave colonisation events (calculated from the maximum likelihood analysis), support the Pleistocene-effect model for the evolutionary origin of cave cockroaches in the genus *Paratemnopteryx*. Increasing and spreading aridity over much of Australia in the late Cenozoic may have provided strong selective pressures for surface dwelling species to colonise caves in search of moisture refugia.

Are invertebrate focal taxa fulfilling their promise?

S Spector
Invertebrate Conservation Program, Center For Biodiversity and Conservation, American Museum of Natural History, Central Park West @ 79th St., New York, NY 10024, USA; spector@amnh.org

Pervasive scarcities of data on the distribution, taxonomy, and population status of invertebrates have seriously impeded the inclusion of invertebrate diversity in the conservation process. For nearly two decades, the development of invertebrate focal taxa has been suggested as a means to pry conservation-relevant information out of this hyper-diverse, poorly known invertebrate realm.. A review of our progress toward establishing such focal taxa reveals decidedly mixed success. While there have been huneds of studies debating the criteria for selecting focal taxa and detailing the effects of anthropogenic disturbances and ecological changes on dozens of different invertebrate taxa, they have resulted in a fragmented and often incomparable dataset. As a result, virtually none of the many proposed invertebrate focal taxa have been universally embraced, though a slate of promising candidates has been identified. However, we have developed a clearer understanding of the informational, methodological, and taxonomic infrastructure needed to support fully functioning focal taxa, and the coordinated effort necessary to produce it. Rapidly improving information technologies and more focused efforts by collaborative networks of taxonomists, ecologists, and conservation biologists have the potential to rapidly develop a suite of invertebrate focal taxa with utility in a variety of conservation contexts.

Does biomonitoring guard against loss of rare, threatened or endemic species?

J Spence, D Langor, J Volney, T Work
Dept. of Renewable Resources, University of Alberta, Edmonton, AB, T6G 2E3, Canada; john.spence@ualberta.ca

Extensive biomonitoring programs are being recommended and established worldwide with the intention of protecting various jurisdictions from loss of biodiversity. Despite the fact that arthropods account for a huge share of biodiversity and are demonstrably at risk from large-scale anthropogenic impacts on landscapes, proposed biomonitoring schemes frequently ignore well understood aspects of arthropod assemblages. For example, detection of many arthropod species can be highly seasonal, and thus, short pre-planned visits do not give reliable data about the presence of a species at a particular site. Most importantly, as will be illustrated with data sets from many taxa, our most 'threatened' species are also our rarest and their loss will be undetected by any but the most thorough studies. Simplisitc monitoring studies, planned without reference sites, forgo strong cause and effect inferences about the causes and, hence, proper response to species declines. Rather than the 'half-baked' apple pie and motherhood of senseless monitoring, we recommend careful consideration of objectives and development of more rigorous efforts to ascertain effects of anthropogenic disturbance on vulnerable elements of invertebrate biodiversity.

Do invertebrates use willows? The influence of landscape matrix on the impact of an invasive weed

MC Stanley, DF Ward
Landcare Research, Private Bag 92170, Auckland, New Zealand; stanleym@landcareresearch.co.nz

Native animals, particularly invertebrates, often respond negatively to invasive weeds because they are often associated with resources that are plant specific. However, the surrounding landscape is also likely to have a strong influence on native fauna and their use of resources. Crack willow (*Salix fragilis*) has been used extensively for erosion and flood control in New Zealand and is now an invasive weed, particularly in riparian zones. This study aimed to quantify the use of willow trees by invertebrates and to determine whether willow use by invertebrates is dependent on landscape matrix. We examined invertebrate communities associated with willow or native kanuka (*Kunzea ericoides*) trees in riparian zones surrounded by either native forest or pasture. Invertebrates responded strongly at the level of tree species; the larger landscape matrix appeared to have little influence on invertebrate abundance, richness and composition. Lower invertebrate abundance and richness were associated with willow trees. However, there were beetle species-level responses to both tree species and landscape type. Kanuka trees surrounded by pasture had similar invertebrate compositions as kanuka trees within intact forest, indicating that small remnant patches of kanuka are valuable invertebrate habitat.

Moth beta-diversity patterns in Papua New Guinean rainforest

AJA Stewart, V Novotny, SE Miller
School of Life Sciences, University of Sussex, Falmer, Brighton, BN1 9QG, UK; a.j.a.stewart@sussex.ac.uk

Local and large-scale patterns of beta-diversity in moth assemblages have been examined in forest habitats in Papua New Guinea, in a project funded by the UK Darwin Initiative. Moths were surveyed quantitatively by light-trapping and identified to morpho-species. Undisturbed primary forest sites and areas that have been re-vegetated as environmental remediation after open-pit gold/silver mining were compared on Misima Island, Milne Bay Province. Standard community analyses indicated that natural forest and re-vegetated areas were remarkably similar in moth species composition, richness, alpha diversity and dominance structure. Similarity measures showed that heterogeneity between natural forest and re-vegetated areas was not consistently greater than that within these habitat types, indicating considerable species exchange between sites. Indicator species, defined as those that occurred solely or predominantly in one of the habitat types, comprised approximately 2% of the total assemblage. The ratio of numbers of Pyralidae to the combined total of Geometridae and Noctuidae (the three most prominent families) proved to be a useful index of progression towards a community typical of natural forest. The Misima data will be compared to data from surveys in lowland forest in Madang Province (approximately 1,000 km away), to place these local beta-diversity patterns into a larger-scale context.

Blattodea in the genus *Nocticola* from Australian cave & surface habitats.

FD Stone
"Hawai`i CC, 200 W. Kawili St., Hilo, Hawai`i, USA 96760; fred@hawaii.edu"

A rich fauna of cave-adapted arthropods, including cockroaches in the genus *Nocticola*, (Blattodea: Nocticolidae) was discovered in the early 1980's in limestone caves of the Chillagoe area and lava tubes of the McBride Formation, North Queensland. This was remarkable because prevailing theories for troglobite evolution predicted that they would not occur in tropical areas. Further discoveries of cave species in Cape Range of Western Australia and across tropical Australia have shown that cave adapted *Nocticola* species are widespread in the Austalian tropics. Search of epigean habitats in the rainforest of east Queensland and in suitable environments inland has revealed surface-dwelling relatives of the cave *Nocticola*. However, the original question remains: are these species the result of allopatric, vicariant evolution or could they have evolved by adaptive shifts in parapatric populations? Major dessication of tropical Australia in the Pliestocene has been substituted for glaciation to explain occurrence of the cave species. Morphological data needs to be used with DNA comparisons to resolve the question of adaptive shift versus allopatric evolution.

The Oniscidea (Crustacea, Isopoda) from groundwater calcretes of Australian arid zones

S Taiti, WF Humphreys, SJB Cooper, K Saint, R Leijs
Istituto Per Lo Studio Degli Ecosistemi, Cnr, Via Madonna Del Piano, Sesto Fiorentino, Florence, Italy; stefano.taiti@ise.cnr.itstefano.taiti@ise.cnr.it

Groundwater calcrete aquifers of the Australian arid zone are inhabited by a highly diverse stygofauna, including several species of terrestrial isopods (Oniscidea). Twelve species are presently known: *Anicophiloscia pedisetosa* Taiti & Humphreys, 2001, tentatively included in the family Philosciidae, and 11 blind species in the genus *Haloniscus* (seven from the Yilgarn craton in Western Australia, and four from the Ngalia Basin, Northern Territory). The genus *Haloniscus* includes also *H. searlei* Chilton, 1920, an aquatic species widely distributed in the salt lakes of Western Australia, South Australia, Victoria and Tasmania, and *H. anophthalmus* Taiti, Ferrara and Iliffe, 1995 from anchialine waters in a cave of the Isle of Pines, New Caledonia. All stygobitic species of *Haloniscus* are very similar in external morphology and species separation is mainly possible by examination of the male sexual characters (pleopods and pereopods). A molecular analysis of mitochondrial DNA (CO1) of several populations of the stygobitic species of *Haloniscus* and of *H. searlei* showed that the Australian species form a monophyletic group, while the New Caledonian species is distantly related. The systematic position of the genus *Haloniscus* within the Oniscidea is discussed and the time of divergence of the Australian species of the genus tentatively estimated.

Interaction effects of patch size, edge & stratum on arthropod community on a Japanese oak, *Quercus serrata*, in a fragmented temperate forest

S. Tanabe, K. Kimura, A. Ohwaki, H. Tokumoto, K. Nakamura
PO Box 920-1192, Institute of Nature and Environmental Technology, Kanazawa University, Kakuma, Kanazawa, Japan, tshin@kenroku.kanazawa-u.ac.jp

Arthropods were sampled by branch clipping from two foliage strata (canopy and understory) of Japanese oak trees (*Quercus serrata*) at two forest zones (edge and interior) in two fragments (small and large) of a *Quercus*-dominated secondary forest in Central Japan. In this paper, we focused on interaction effects of fragment size, edge and stratum on four arthropod guilds (chewers, miners, predators and others). The specific aims were to examine 1) whether the impact of edge on guild abundance differs between two foliage strata, exploring a two-factor interaction effect of edge and stratum, and if so, 2) whether fragment size affects the two-factor interaction effect, exploring a three-factor interaction effect of fragment size, edge and stratum. For miners, we distinguished between two groups of weevils (Coleoptera, Curculinidae) and other insects and analysed them separately. Among arthropod guilds and groups, significant two-factor interaction effects on abundance were found in both groups of miners, resulting in less impacts of edge on canopy-dwelling miners than on understory-dwelling miners. A significant three-factor interaction effect on abundance was detected in miners of insects other than weevils, showing the significant less impact of edge on canopy-dwelling miners than understory-dwelling miners only in the large fragment. These results emphasize the importance 1) for the effect of stratum to be taken into account in studies on forest fragmentation and 2) for the edge effect to be evaluated from the viewpoint of interactions with effects of stratum and/or fragment area.

Gall-flies, nematodes & the Myrtaceae: phylogenetic congruence in a tritrophic system

GS Taylor, SJ Scheffer, W Ye, KA Davies, RM Giblin-Davis
Centre for Evolutionary Biology and Biodiversity, Waite Campus, The University of Adelaide, PMB 1, Glen Osmond, South Australia 5064, Australia; Gary.Taylor@adelaide.edu.au

Flies of the Australasian family Fergusoninidae form galls in a mutualistic association with *Fergusobia* nematodes (Tylenchida: Sphaerulariidae) on various myrtaceous hosts, namely *Angophora*, *Corymbia*, *Eucalyptus, Melaleuca*, and *Syzygium*. Galls are initiated by the feeding of juvenile nematodes deposited by the female fly into meristematic plant tissue during oviposition. Fly eggs hatch and larvae form cavities within the gall into which the nematodes migrate and cohabit with the fly larva. Female nematodes then invade female fly larvae and feed within the haemolymph. Nematode eggs deposited in the fly haemolymph hatch, juvenile nematodes migrate to the fly ovaries, and are inserted into new plant tissue once the female fly emerges from the gall and disperses. It is postulated that speciation in the Fergusoninidae has been driven by radiation of the Myrtaceae and possible incidents of host switching to closely related taxa within it, and that cospeciation between flies and nematodes has been driven by aspects of the fly/nematode life cycle that includes a maternal lineage of fly parasitism, and successive generations of parthenogenetic reproduction and sibling mating in the nematode. In this unique tritrophic system, phylogenetic congruence between flies and nematodes and their myrtaceaeous hosts is investigated.

A review of European temperate forest arthropod canopy studies, using an example from Norway to postulate similarities in host associations & diversity

KH Thunes, I Gjerde
Norwegian Forest Research Institute, Fanaflaten 4, N-5244 Fana, Norway; karl.thunes@skogforsk.no

We review canopy arthropod studies from four European countries; Denmark, England, Poland and Norway, using available data from published studies in the countries comparatively to assess degrees of host associations and species diversity. A recent study from Norway forms the baseline in the review. Despite geographical differences, differences in sampling methodology and species composition, some similarities were found with respect to host association, faunal structure (e.g. guild composition) and diversity on higher taxonomic levels. We also draw comparisons with studies from North American temperate forests as well as relatively comparable works from the tropics.

Insect diversity in the Great Himalayan National Park Conservation Area, Western Himalaya

VP Uniyal, PK Mathur
Wildlife Institute of India, Post Box # 18, Chanabani, Dehra Dun, 248 001 Uttaranchal, India; uniyalvp@wii.gov.in

Study on insect diversity along altitudinal gradient was undertaken in one of the globally significant protected sites i.e. Great Himalayan National Park Conservation Area (GHNPCA), Himachal Pradesh, Western Himalaya. The GHNPCA due to its strategic location, and large altitudinal variation (>1,500 to 6,000m) provide a diversity of habitats and associated flora and fauna. Thirty two surveys of average 10 days each covering three different sub-watersheds and 18 intensive study sites in three different seasons were carried out. Only six insect orders *viz.* Coleoptera, Hymenoptera, Diptera, Hemiptera, Odonata, and Lepidoptera were selected for the present study. Assessed insect diversity represented 37 families, 108 genera and 125 species belonging to six orders. The order Lepidoptera represented higher diversity in terms of 55 genera and 61 species followed by order Coleoptera which had 41 genera and 47 species. Out of 37 families, seven (7) families were found in wide altitudinal range (1,500 to >3,500m) while seven (7) families had a narrow distribution (1,500 - 2,000m). Attempt was also made to establish ecological relationships between flowering plants of sub-alpine and alpine areas and corresponding insect visitors. Insect distribution was documented in four broad altitudinal range categories corresponding to major vegetation types *viz.* sub-tropical broad leaved forests (1,500 - 2,000m); temperate mixed conifers (>2,000 - 2,500m); temperate conifers (>2,500 - 3,000m) and alpine pasture (>3,000m).

Rubecula **(Braconidae), introduced biological control agents of** *Pieris rapae*

RG Van Driesche
"Department of Entomology, University of Massachusetts, Amherst, MA, 01003, USA ph 513-545-1061; vandries@nre.umass.edu"

In New England (northeastern USA), *Pieris rapae* is an invasive butterfly (ca 1860), against which two braconid parasitoids were introduced: *Cotesia glomerata* (1884) and *Cotesia rubecula* (1988). Neither introduction was preceded by formal host range estimation. Two butterfly species are at potential risk in the region: *Pieris virginiensis* and *Pieris napi*. Recent studies have shown that both are physiologically acceptable hosts for both parasitoids. Field studies showed that the univoltine woodland nature of *P. virginiensis* protects it from attack by either parasitoid. In contrast, a range reduction of *P. napi* appeared to occur shortly after the *P. rapae* invasion. Currently, critical host plants are abundant in both areas retaining *P. napi* (northern New England) and areas now lacking the species (southern New England), and host plants do not explain this range change. Parasitism by *C. glomerata* is high (66-100%) in the summer generation of *P. napi* in both areas retaining and areas lacking the butterfly. The critical difference appears to be a higher rate of commitment to first generation pupal diapause by caterpillars in wooded habitats in northern New England and absence of these parasitoids in wooded areas has protected northern *P. napi* populations, which has avoided parasitism by effectively becoming univoltine in a parasitoid-free habitat.

Effect on native *Pieris* butterflies in New England, USA, by *Cotesia glomerata* and *C. rubecula* (Braconidae), introduced biological control agents of *Pieris rapae*

R Van Driesche
"Dept Entomology, Fernald Hall, UMASS, Amherst, MA, 01003 USA; vandries@nre.umass.edu "

In New England (northeastern USA), *Pieris rapae* is an invasive butterfly (ca 1860), against which two braconid parasitoids were introduced: *Cotesia glomerata* (1884) and *Cotesia rubecula* (1988). Recent studies have shown that both are physiologically acceptable hosts for both parasitoids. Field studies showed that the univoltine woodland nature of *P. virginiensis* protects it from attack by either parasitoid. In contrast, a range reduction of *P. napi* appeared to occur shortly after the *P. rapae* invasion. Currently, critical host plants are abundant in both areas retaining *P. napi* (northern New England) and areas now lacking the species (southern New England), and host plants do not explain this range change. Parasitism by *C. glomerata* is high (66-100%) in the summer generation of *P. napi* in both areas retaining and areas lacking the butterfly. The critical difference appears to be a higher rate of commitment to first generation pupal diapause by caterpillars in wooded habitats in northern New England and absence of these parasitoids in wooded areas has protected northern *P. napi* populations, which has avoided parasitism by effectively becoming univoltine in a parasitoid-free habitat.

Life-history traits of invasive phytophagous forest insects

TO Veteli, P Niemelä, WJ Mattson
Faculty of Forestry, University of Joensuu, POB 111, FI-80101 Joensuu, Finland; Timo.Veteli@joensuu.fi

Exotic phytophagous insects are transforming forest ecosystems worldwide. So far, 36 North American phytophagous insect species have established populations in Europe. 50% of these species belong to the order Homoptera; 17% to Lepidoptera; 14% to Hymenoptera and 11% to Coleoptera. Many of these immigrating species have haplo-diploid or parthenogenetic breeding systems. 75% of the 400 immigrant tree- and shrub-dwelling insects in North America originate from Europe. The same taxonomic order also dominates those European species that have invaded to North America. However, the proportion of European coleopterans that have invaded to North America is two times higher than that from North America to Europe. No North American hemipteran species has been able to colonize the European continent, but 13 European hemipteran species have successfully invaded to North America. The majority (56%) of North American phytophagous insects in Europe live on deciduous trees. 20% of those host plants are of North American origin. 44% of the invaded species live on conifers and 63% of the coniferous host plants are of North American origin. Of the European emigrants in North America, only a few have been able to colonize native North American plant genera. This is especially true among homopterans feeding on conifers.

The composition of mangrove ant communities as indicator for human impacts of a wildlife refuge in Taiwan

YS Wei
No. 188 Sec. 5 An-Chung Rd., Tainan City, Taiwan; yswei@mail.leader.edu.tw

The Wildlife Refuge is one of five categories of protected area system in Taiwan. Since central and local governments share the responsible authorities of Wildlife Refuges, the effectiveness of the protection and maintenance of biodiversity is limited. The Wildlife Refuge which the study was carried out, located in southwestern coast of Taiwan and famous for its diverse mangrove plants and migratory birds, is confronted by human interferences, such as traditional fishery uses of local people and intensive domestic tourism activities. To understand the impacts of human activities on the territorial areas of the mangrove system, the survey was conducted during October 2002 to September 2003 by using food baits and pitfall traps to collect ants monthly. Based on sampling in two different management areas which were also divided into four levels of human disturbances, the community structure and species richness of ants were determined. There were a total of 58 ant species collected in the Wildlife Refuge, and there were differences of ant abundance and species richness between study sites and between months. Species richness and ant abundance were highest in October and lowest in January. The more the management involved and the less human disturbance level the site, the more was the species numbers and more species supported.

Pattern and process in subterranean speciation: comparative analysis of Australian and Hawaiian cave planthopper radiations (Hemiptera: Fulgoromorpha: Cixiidae)

A Wessel, P Erbe, H Hoch
"Institut für Systematische Zoologie, Museum für Naturkunde, Humboldt-Universität zu Berlin Invalidenstrasse 43, D-10115 Berlin, Germany; aneas.wessel@museum.hu-berlin.de."

Ongoing studies have revealed numerous cases of parallel evolution of cavernicolous planthoppers all over the world in tropical and subtropical caves. Given that concepts of genetic change and speciation dynamics are subject to review by natural model systems, the comparative study of these independent evolutionary lineages and radiations can provide critical information. We survey species complexes from Australian and Hawai'ian caves exhibiting different degrees of troglomorphy. In Australia (Qld), *Solonaima* and *Undarana* species have colonized old karst caves as well as young lava tubes. On the Hawai'ian Islands, the cave-dwelling *Oliarus* species represent at least seven independent cave colonizations on three islands of different age, including the *Oliarus polyphemus* species complex from various, partly still active volcanic systems on Hawai'i Island . The diversity of external factors (e.g., ressource availability and stability, migration possibilities, macro- and microclimatic changes, predators) as well as internal factors (e.g., genetic variability, population structure and density) allows us to incorporate these into concepts of evolutionary change. On this basis we explore verbal models of cave adaptation (Relict hypothesis sensu BARR, Adaptive shift hypothesis sensu HOWARTH) and analyze the influence of sexual selection and founder effects sensu MAYR and CARSON.

Paradise lost? A long-term term perspective on species endemicity, rarity & extirpation using the fossil Coleoptera record

NJ Whitehouse
School of Archaeology and Palaeoecology, Queens University Belfast, Belfast BT7 1NN, Northern Ireland, UK; n.whitehouse@qub.ac.uk

This paper examines the dimension provided by the study of fossil insects (mostly beetles) preserved in waterlogged deposits in bogs and archaeological sites to study long-term changes to our insect fauna. It examines the contribution of the fossil insect record to our understanding of species evolution and what it can tell us about endemic species, rarity and extirpation. The paper draws upon examples from northern Europe and in particular upon the author's research from lowland raised bogs in the Humberhead Levels, eastern England, where the particular faunal characteristics, including its endemics, of these lowland raised mires were already in place 4000 years ago. Additionally, research indicates that over 38 species of Coleoptera (mostly saproxylics) have become extirpated from the British Isles within the last few thousand years, probably due to a combination of forest clearance and human activities, ainage of wetlands, edaphic and competition factors affecting distribution of host trees, climate change, forest fire decline and a decline in grazing. The fossil insect work provides a long-term perspective on the effects of such factors upon the beetle fauna and most of all, highlights the important part played by time and history in shaping the nature of our fauna today.

What can forest managers learn from research on subfossil insects?

NJ Whitehouse
School of Archaeology and Palaeoecology, Queens University Belfast, Belfast BT7 1NN, Northern Ireland, UK; n.whitehouse@qub.ac.uk

This paper outlines the usefulness of using fossil insects, particularly Coleoptera, preserved in waterlogged deposits to understand the changing nature of forest ecosystems and their associated insects over the last 10,000 years. Research in Europe has highlighted the complex nature of early woodland ecosystems. In particular, the role of dead wood as well as grazing animals will be discussed, suggesting that the north European primary forest has similarities to pasture woodlands, rather than the forester manager's perception of closed canopy. Later on, human activity had a major impact on these ecosystems, with the concurrent expansion of plants and animals associated with cleared landscapes and pasture and resulting in the local extinction of a sizeable proportion of taxa from the forests of northern Europe. The decline in these species has been seen as resulting from habitat loss due to human forest clearance, which intensified from about 2500 years ago onwards, coupled with subtle climate change effects. These extirpations will be discussed, with particular reference to the management of forest ecosystems for the benefit of their invertebrate species.

The effects of the exotic weed Bitou Bush (*Chrysanthemoides monilifera* ssp. *rotundata* L.) on terrestrial arthropod communities in a littoral habitat

L Wilkie, G Cassis, M Gray
Centre For Biodiversity And Conservation Research. The Australian Museum, 6 College St., Sydney, NSW, 2010, Australia; lancew@austmus.gov.au

This study investigates the impacts upon selected arthropod assemblages of habitat invasion by bitou bush (*Chrysanthemoides monilifera* ssp. *rotundata*). Sixteen sites were placed at four geographic localities on the coast of New South Wales. The sampling design had two spatial scales (between and within localities) and eight repeat temporal measures. Arthropods were collected from a variety of microhabitats using several sampling techniques, and specimens of ants, beetles, true bugs and spiders were identified to species level. Differences in α diversity and population abundance structures between the taxonomic assemblages are described, along with comparisons of data contrasts between bitou-free ("control") and bitou-invaded ("impact") habitats and between geographic localities. A subsidiary impact associated with herbicide application for control of the weed is also examined. Univariate diversity descriptors detected some differences between control and impact treatments within a locality, however they are not as apparent as between geographic localities. Constrained ordination analyses detected evidence for associations between arthropod assemblages and particular vegetation types. They also demonstrated arthropod community composition change that appeared to be related to herbicide application for some taxonomic groups.

Rot type, log size and forest type; characteristics that influence saproxylic beetle assemblages

M Yee, S Grove, C Mohammed
"Ms Marie Yee, CRC-Sustainable Production Forestry, University of Tasmania, Private Bag 12, Hobart, Tasmania 7001, Australia; Marie.Yee@ffp.csiro.au"

In Tasmania, as seen in Northern Europe, saproxylic communities are at risk of being negatively affected by intensified forest management that results in the removal of oldgrowth elements, such as late successional forests and large diameter logs. As there is a shorter history of forest management in Tasmania, there is still time to reduce any ecological impacts through understanding characteristics that influence beetle assemblages. We intensively sampled saproxylic beetles and rot types within decomposing *Eucalyptus obliqua* logs in Tasmania's wet eucalypt forests. We compared the beetle assemblages between large (>100 cm) and small (30-60 cm) diameter logs, in multi-aged unlogged and logging regenerated forests. Logged forests support a diverse but significantly different beetle assemblage to multi-aged unlogged forest, possibly representative of early successional forest. Large logs host a distinct suite of beetles not found within small logs. As indicated by their rot types large and small logs appear to undergo different decomposition processes, explaining, in part, the distinct faunas associated with different log sizes. Results are discussed in relation to addressing conservation issues within a production forestry landscape.

Can tree planting be a threatening process for invertebrates?

AL Yen
Primary Industries Research Victoria, Private Bag 15, Ferntree Gully DC, Victoria 3156, Australia; alan.yen@dpi.vic.gov.au.

Since European settlement in Australia, large scale tree clearing for agriculture and urban development has resulted in significant losses in the biodiversity of native plants and animals, although some native species have benefited from this. Major initiatives to replant lost trees have presumed that tree planting will enhance native biodiversity. This approach is necessary and appropriate, and in the main, will enhance invertebrate biodiversity primarily through provision of food and habitat. There could, however, be environmental harmful effects with biosecurity implications. Some of these, such as the introduction of exotic species of invertebrates, are readily apparent, but some are more subtle. Tree planting may change the host plant relationships of endemic invertebrates by altering the composition of insect assemblages on these plants, and this has potential evolutionary implications. The insect assemblages on *Eucalyptus* and *Acacia* have a unique coevolutionary history in Australia, and this could be severely disrupted or altered by inappropriate selection of plant species. Even the well-meaning intension of planting native flora, requires care in the choice of plant chosen in revegetation projects.

Genetic structure and gene flow in island populations of pollinating fig wasps

M Zavodna, P Arens, B Vosman, PJ van Dijk, JMM van Damme
"Netherlands Institute of Ecology (NIOO-KNAW), Centre for Terrestrial Ecology, Postbus 40, 6666 ZG Heteren, The Netherlands;
m.zavodna@nioo.knaw.nl"

Pollinating fig wasps (*Hymenoptera, Agaonidae*) are associated with fig trees (*Ficus, Moraceae*), a keystone plant species for the functioning of many tropical ecosystems. The Krakatau islands in Indonesia are an ideal natural experiment site to study colonization and gene flow processes in disturbed and fragmented habitat, as they were completely sterilized by volcanic eruption in 1883. Since then, vegetation has been returning to the islands in a successional manner, with several *Ficus* species being pioneer species. However, pollinator limitation has been observed in some populations of dioecious *Ficus* on the Krakatau islands. We used recently developed microsatellite markers for pollinating fig wasp *Liporrhopalum tentacularis* (pollinator of dioecious *F. montana*) to estimate genetic differentiation between islands and surrounded Indonesian mainland of Java and Sumatra. Our results indicate that genetic diversity in the investigated pollinating fig wasp on the island is similar to that on the mainland and gene flow is not restricted between island and coastal sites of the mainland. However, gene flow between Krakatau islands and distant Java inland sites was found to be more restricted. Consequently, we discussed wasp dispersal and the implications of our findings on the maintenance of the fig – fig wasp mutualism.

Biodiversity of tropical rainforest bark beetles & timber borers: results from an intensive inventory

L Kirkendall

Paper not available at time of production

&The phylogenetic position of Sericini examined by morphology based cladistics (Coleoptera: Scarabaeidae).

D Ahrens
"Deutsches Entomologisches Institut (DEI) im ZALF, Eberswalder Str. 84, D-15374 Müncheberg, Germany, ahrens.dirk_col@gmx.de, dahrens@zalf.de"

In contrast to the coprophagous Scarabaeidae, the phylogeny of the of phytophagous Scarabaeidae is far from being resolved. I produced a cladistic analysis to investigate the basic phylogenetic relationships of Sericine chafers and the systematic position within the family Scarabaeidae employing 107 morphological characters of 49 extant scarabaeid genera. These taxa represent most of the 'traditional' subfamilies of coprophagous (only two subfamilies included) and phytophagous Scarabaeidae. The cladogram obtained from the parsimony analysis confirms a monophyly of phytophagous Scarabaeidae (including e.g. Orphninae, Cetoniinae, Dynastinae, Euchirinae, Rutelinae, Melolonthinae). While the respective monophyly of Cetoniinae and Rutelinae is well supported, the Melolonthinae result paraphyletic, since both former groups are nested within melolonthine lineages. The Ablaberini were shown to be the sister group of the Sericini at the top of a clade, with mainly pectinate branching including tribes of southern continents (e.g. Diphucephalini, Scitalini, Heteronycini). Preliminary results obtained from the phylogeny and knowledge of recent distribution of the clades favour one hypothesis for the evolution of the Sericini: the evolution of main lineages have taken place on African continent supposingly after the splitting of the Gondwanian continent and the ancestor of Neotropical Sericini dispersed during Tertiary over the atlantic ocean.

Polypedilum (Diptera: Chironomidae) from Egypt with description of a new species

M Ghonaim, A Ali,
University of Florida, IFAS, MREC 2725 Binion Road, Apopka, FL 32703-8504, USA, aali@mail.ifas.ufl.edu

A survey of chironomid midges (Diptera: Chironomidae) conducted from September 1997 to October 1999, covering all major geographical zones in Egypt, resulted in the capture of 5 species of the genus *Polypedilum* Kieffer. Three of these species are new records, while one new species, *Polypedilum (Uresipedilum) marsafae*, is described from male and female imagines. The Egyptian list of *Polypedilum* Kieffer is updated to include 11 species. A key to the male imagines is presented. New distributional data for the species encountered are also given.

Abdominal morphology of the Protura (Hexapoda) and phylogenetic implications

N Arnhold, *M Koch*
Free University of Berlin, Institute of Biology, Königin-Luise-Str. 1-3, 14195 Berlin, Germany, narnhold@zoosyst-berlin.de

Cladistic analyses of arthropod phylogeny presently support the view that insects are closer related to crustaceans than to myriapods. Available data, however, neither permit to specify the insect sister group, nor do they significantly support the monophyly of the Hexapoda (= Insecta *s. lat.*). Instead, the relationships of the basal subgroups remain unclear that are traditionally united as "Entognatha" (Collembola, Protura, Diplura). In order to contribute to a clarification, we started a comparative study on the morphology of the abdomen in primarily wingless insects with emphasis on the skeleto-muscular as well as nervous system. Main focus is targeted at the Protura as these seem to be less derived relative to all other insects in maintaining anamorphic development and articulated appendages at the first three abdominal segments. Details on the morphology of the proturan pregenital abdomen are presented based on a combined approach by transmission electron microscopy and confocal laser scanning techniques. This approach permits to establish hypotheses on the primary homology of the abdominal muscles by the criteria of topography and innervation. Preliminary insights derived from the results obtained are discussed in the light of the assumption favoured by some molecular data that the Hexapoda form a paraphyletic assemblage.

The evolutionary history of insect storage hexamerins and phylogeny of the insects

T Burmester
Institute of Zoology, University of Mainz, Germany, burmeste@uni-mainz.de

Insect hexamerins are large hemolymph proteins (~500 kDa) that are related to arthropod hemocyanins, but have lost the ability to bind oxygen. They are composed of six similar or identical subunits. Hexamerins may accumulate to extraordinarily high concentrations, usually in larval or nymphal stages. Some hexamerins are rich in methionine ("methionine-rich storage proteins") or aromatic amino acids ("arylphorins"). Most hexamerins are considered mainly as storage proteins that provide amino acids and energy for non-feeding periods, e.g. pupal stages. However, in recent years, other specific functions like cuticle formation, transport of hormones or humoral immune defense have been proposed. Hexamerins emerged from hemocyanins early in insect evolution. The phylogeny of the hexamerins has been reconstructed based on a multiple sequence alignment, employing distance methods, maximum parsimony and Bayesian inference. The data show that the hexamerins evolved in line with the phylogeny of the insect orders. Within the orders, there is a notable diversification of these proteins into various subtypes, which probably reflects specific functions.

On the non-homology of several phallic "spiculae" of Plant Bugs (Heteroptera, Miridae).

F Chérot
Laboratoire de Systématique et d'Ecologie animale, cp 160/13, Université Libre de Bruxelles, av. F.D. Roosevelt, 50, B-1050 Bruxelles, Belgique.
fcherot@ulb.ac.be

Male genital structure has been used in the taxonomy of the Miridae for nearly 100 years. The importance of male genitalia to the diagnoses of plant bug taxa is obvious. However, the terminology used to describe these structures remains plethoric and ambiguous. This situation is the result of a combination of structural complexity and absence of agreement by specialists on homology assumptions for these diverse structures. This terminological ambiguity is well illustrated by the term phallic "spiculum." Currently reference to this term in the taxonomic literature applies to three different non-homologous structures. These structures are illustrated and briefly described.

A new species of *Prosopistoma* (Ephemeroptera: Prosopistomatidae) from Myanmar

DJ Chun, TH Ro, MC Kim, SS Han,
djchun@Korea.Ac.Kr

A new species, *Prosopistoma konanwina* (Ephemeroptera: Prosopistoma) is described and illustrated, based on larval material from Mon state, Myanmar

Morphological and mitochondrial DNA marker analysis of burrowing mayflies, *Ephemera (Ephemeroptera: Ephemeridae) in Korea*

DJ Chun, JH Kim, MC Kim, TH Ro, SS Han djchun@korea.ac.kr

Morphological characters of the burrowing mayflies, *Ephemera* spp. (Ephemeroptera: Ephemeridae) in Korea were studied using scanning electron microscopy. Random amplified polymorphic DNA polymerase chain reaction markers proved complementary to the morphological identification of the burrowing mayflies. From each species of the burrowing mayflies, a region of the mitochondrial DNA COI gene was amplified, cloned and the sequence determined. Parsimony and distance analyses were performed and the results were similar to those based on morphology. The combination of morphological and molecular traits is useful in understanding the diversity and evolution of these burrowing mayflies.

Systematic revision of the Cossulinae (Lepidoptera: Cossidae) of Costa Rica

S Davis, C Mitter, P Gentili-Poole
University of Maryland, College Park, MD, USA, 20742, steved@wam.umd.edu

The Cossidae is an economically important family consisting of six subfamilies and more than 700 species globally. Their larvae are often of serious concern to forestry and horticulture in that they are known to bore in the branches and trunks of a wide range of trees and shrubs. In the course of my examination of the extensive collections of the Smithsonian Institution and the Instituto Nacional de Biodiversidad of Costa Rica, I have found the Costa Rican Cossulinae to consist of 17 species, including 8 new to science. The phylogenetic relationships of all cossuline genera, including 4 new genera, will be analyzed using the computer programs PAUP, WINCLADA and NONA. Data for the study has been derived from extensive microscopic slide preparations and examinations of both external (body, leg, and wing morphology) and internal (primarily genitalic morphology) anatomical structures. Diagnostic characters of all taxa have been photographed using digital equipment involving automontage, supplemented with camera lucida drink drawings for additional detail where necessary. Diagnostic descriptions and identification keys accompanied by detailed illustrations of every species are being generated, and the recorded distribution of each species will be clearly displayed using topographic maps of Costa Rica.

Phylogenetic relationships among species of the genus *Stelis* in North America (Hymenoptera: Megachilidae)

DR Frohlich, V Phouc, FD Parker, TL Griswold
Department of Biology, University of St. Thomas, Houston TX, 77006, USA, frohlich@stthom.edu

The genus *Stelis* comprises a colorful group of parasitic Anthidiine bees that are seldom encountered or collected at floral resources. Adults spend most of their time searching for hosts or waiting near host nests until they are available for parasitism. Like their parasites, all hosts are in the family Megachilidae. Herein, we describe 65 North American species in this Holarctic genus, including twenty new species, and analyze the group with respect to morphological characters, host, and host nest characteristics by parsimony analysis and successive approximation character weighting.

The genus *Acrosternum* Fieber, subgenus *Chinavia* Orian (Hemiptera, Pentatomidae, Pentatominae) in Brazil: systematics, distribution, host plants, immatures and bionomics.

J Grazia, CF Schwertner
Department of Zoology, Federal University of Rio Grande do Sul, Av. Bento Gonçalves 9500, 91501-970 Porto Alegre RS, Brazil, jocelia@ufrgs.br

The genus *Acrosternum* includes a significant number of the so-called "green stink bugs" which are widespread in the world, except in the Australian region. Many species of *Acrosternum* are associated with agroecosystems. Two sub-genera are recognized: *Acrosternum*, with 15 spp., and *Chinavia* with 77 spp. More than sixty species, belonging to *Chinavia*, are found exclusively in the neotropics, testifying the great species diversity in this region. The monophyly of the group has been discussed, and this subject is under investigation at our laboratory, including the revision and biogeography of *Acrosternum*. About 30 species are known from Brazil, near fifty percent described in the last two decades; five of them were recognized as knew by the authors. At least ten species are associated with important agricultural crops as cotton, green-beans, soybeans and tomatoes, but information on biology and natural history of those species are relatively unknown. In the present study the systematics, geographical range, host plants, morphology of immature stages and bionomics of the species recorded to Brazil are discussed, based mostly on unpublished data, as in literature.

Two new species of Heliozelidae (Lepidoptera) associated with myrtaceaous plants from southern China

T Hirowatari, BW Lee, M Wang
Entomological Laboratory, Graduate School of Agriculture and Biological Sciences, Osaka Prefecture University, Sakai 599-8531, Japan, hirowata@plant.osakafu-u.ac.jp

The family Heliozelidae includes very small-sized moths with forewing length of 3-9mm, comprising 12 genera and about 100 species in the world. It has a worldwide distribution mainly in the Nearctic and Australian regions, but it has not been known from South East Asia. In March and December 2003, participating in a research project "Network construction for the establishment of insect inventory in Tropic Asia (TAIIV: organized by O. Yata of Kyushu Univ.)", we collected larvae of 2 unknown heliozelid species mining on plants of Myrtaceae in southern China (Guangzhou and Hainan Is.). Larvae of these species have different types of mines. One (Heliozelidae sp. 1) mines into the miib of *Syzygium jambos*, and the other (Heliozelidae sp. 2) into the blade of *Rhodomyrtus tomentosa*. Examination on morphological characters of emerged adults showed that Heliozelidae sp. 1 was assignable to *Heliozela* but Heliozelidae sp. 2 could not be placed in any described genera. As regards the host plant family, Nielsen (1985) suggested presence of a heliozelid species of unnamed genus associated with myrtaceaous shrubs and trees in South America, but the species has not been described. Discovery of heliozelid species associated with myrtaceaous plants in southern China may indicate their Gondowanian origin.

Structure and function of bristle-like sensilla on the maxillary palp of *Priacma serrata* (Coleoptera: Archostemata)

O Eikel, T Hörnschemeyer
Institute for Zoology and Anthropology, Dept. Morphology and Systematics, Berliner Str.28 D-37073 Göttingen, Germany, thoerns@gwdg.de

Priacma serrata LeConte, 1861 is a member of Cupedidae, the most ancient taxon of Coleoptera. Scanning electron micrographs show that there is a clearly defined sensilla area on the apical segment of the maxillary palp of *P. serrata* and all other archostematan beetles. In *P. serrata* this area contains 10 to 17 erect bristle-like sensilla. In other Coleoptera, Adephaga as well as Polyphaga, there usually is a field of characteristic digitiform sensilla in the same area of the apical palpomere. Each of these sensilla is counter-sunk into an elongate depression of the cuticula of the palp. The function of these sensilla is still unknown. One aim of our investigation of the ultra-structure of the bristle-like sensilla of *P. serrata* was to answer the question, whether these and the digitiform sensilla of other Coleoptera are homologous structures. The second aim was to identify the function of these sensilla. So far the study shows that the bristle-like sensilla have numerous, deep, longitudinal grooves and no apical porus. Each sensillum is moveably inserted into the cuticula and innervated with a single sensory cell. This combination of characters is indicative of a chemo-sensitive olfactory receptor.

The wing base of Ephemeroptera and the ground-pattern of insect flight

J Willkommen, T Hörnschemeyer
Institute for Zoology and Anthropology, Dept. Morphology and Systematics, Berliner Str.28 D-37073 Göttingen, Germany, thoerns@gwdg.de

The ability to fly is the decisive factor for the evolutionary success of winged insects (Pterygota). Despite this, very little is known about the ground-pattern and evolution of the functionally very important wing base. This research project endeavours to contribute to the knowledge of the evolution of the flight system of the insects. The skeletal elements of the wing base, as well as the associated muscles are examined. For this purpose, in addition to classical methods, micro-x-ray-computer-tomography is used. This method enables an investigation into the muscular and skeletal systems and a straightforward reconstruction of virtual 3D models without any artefacts. The results so far include new findings regarding the flight musculature of the Ephemeroptera and the homologisation of individual sclerites of the wing bases of Ephemeroptera and Neoptera. The final goal of this research project is to establish the ground-pattern of the axillary areas of the wings of the Pterygota. Furthermore, the investigation of the wing apparatus will provide important information for the analysis of the phylogenetic relations between individual taxa of the Ephemeroptera.

Molecular phylogeny among the subfamilies of Ichneumonidae (Hymenoptera) inferred from the COI gene sequences

FMH Bennar, MA Adura, AB Iis
School of Environmental and Natural Resource Sciences , Faculty of Science and Technology, Universiti Kebangsaan Malaysia, 43600 Bangi, Selangor

A phylogenetic study among four subfamilies of the Malaysian Ichneumonids (Hymenoptera) were examined using the complete mitochondrial cytochrome oxidase I (COI) gene sequence data. A total of 1688 base pairs of the COI gene were sequenced from 23 individuals comprising the subfamilies of Anomaloninae, Campopleginae, Cryptinae and Metopiinae. Members of the subfamily Braconidae were selected as an outgroup. Phylogenetic analysis was conducted using both the Maximum Parsimony and Neighbor-Joining methods. The Maximum Parsimony analysis showed the Ichneumonidae group to be monophyletic with two major clades; I) a clade containing members of Campopleginae and Anomaloninae and II) a clade containing members of Cryptinae and Metopiinae. The close relationship of Campopleginae and Anomaloninae is supported by previous morphological classifications which classified them into the Ophionoid group. However, the relationships of Cryptinae and Metopiinae is not supported by the previous studies as they belong to a different subfamily group. A broader sampling effort throughout Malaysia should be made to provide a clearer picture of the genetic differentiation within this family.

A world revision of the genera of the family Scelionidae (Hymenoptera: Platygastroidea).

NF Johnson, L Musetti, L Masner
Department of Entomology, The Ohio State University, 1315 Kinnear Road, Columbus, OH 43212 USA, Johnson.2@osu.edu

The family Scelionidae encompasses 165 genera and 3308 species, and is found worldwide. All species are egg parasitoids of other arthropods, attacking hosts in the Araneae, Odonata, Orthoptera, Mantodea, Embiidina, Hemiptera, Coleoptera, Neuroptera, Lepidoptera, and Diptera. A revision of the genera of the world is underway, redefining known genera based on extensive new collections and the examination of type species; describing new genera; and documenting the results via an on-line accessible database. Recent results: The genus Thoron Haliday was known from only a single Holarctic species, parasitic in the eggs of Nepidae (Hemiptera). The limits of the genus have been redefined and the name Neothoron Masner is considered a junior synonym. The genus Plaumannion is described as new, with two species in South America. This taxon lacks one of the fundamental characters of the family and may merit recognition at a higher taxonomic levelResolution of the question is part of the ongoing phylogenetic analysis of the group. The species and monophyly of the putatively basal genera Nixonia, Sceliomorpha and Archaeoscelio are being revised.

A new tribe and two new genera of Eulophidae (Hymenoptera) from West Australia

NF Johnson, L Musetti, L Masner
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia, john.lasalle@csiro.au

A new tribe of gall associated wasps is described from West Australia to contain two new genera. One genus is associated with plant galls on *Melaleuca* (Myrtaceae), and may be phytophagous; the biology of the second genus is unkown. The tribe is considered to be most closely related to a group of tribes with includes Ophelimini, Anselmellini (both phytophagous) and Platytetracampini (parasitoids of whiteflies). Morphological characters to support the monophyly of this tribe are provided, and include: antenna placed very low on the face, submarginal vein with only a single dorsal seta, and antenna with 4-5 small segments between the pedicel and club which are not clearly differentiated into anelli and funicle. Both new genera display morphological adaptations associated with extremely long ovipositors.

Phylogenetic reconstruction of black flies (Diptera: Simuliidae) from Thailand, using ITS2 rDNA

A Thanwisai, C Kuvangkadilok, V Baimai
Department of Biology, Faculty of Science, Mahidol University, Rama VI Road, Bangkok 10400, Thailand, scckv@mahidol.ac.th

The sequence of internal transcribed spacer (ITS2) of ribosomal DNA (rDNA) was used to estimate the phylogenetic relationships of 40 black fly species belonging to at least 4 subgenera of the genus Simulium: Gomphostilbia (12 species), Nevermannia (5 species), Montisimulium (1 species) Simulium sensu stricto (21 species), and an unknown subgenus (Simulium baimaii). Maximum parsimony (PAUP version 4.0b10) analysis revealed two major monophyletic groups. The first monophyletic group consists of Gomphostilbia and Nevermannia + Montisimulium. The second monophyletic group consists of the subgenus Simulium and one species of an unknown subgenus. (Simulium baimaii). The molecular phylogeny in the present study generally agrees with existing morphology-based phylogenies.

Phylogenetic relationships of *Megoura* species (Hemiptera: Aphididae) in the world

S Lee, HJ Choe, HJ Kim
200-6102 Lab. of Insect Biosystematics, School of Agricultural Biotechnology, Seoul National University, Seoul 151-742, Korea (ROK), seung@snu.ac.kr;

The genus *Megoura* Buckton, 1876 consists of 7 species in the world, which are related with Leguminosae. A total of 42 morphological characters are selected and two DNA markers, mt COII (mitochondrial cytochrome oxidase subunit II) and EF1α (elongation factor 1 alpha) are sequenced for the phylogenetic analysis. All of the 7 species are used in the morphological analyses, but 2 species (*M. litoralis* F. P. Müller, 1952 and *M. dooasis* (A.K. Ghosh & D.M. Raychaudhuri, 1969)) are not available for the molecular phylogenetic analyses. When analysed with maximum parsimony and maximum likelihood methods and rooted with *Acyrthosiphon* species on Leguminosae species, both independent and combined phylogenetic trees are coincident with and support the previous discussion based on morphology (Lee et al., 2002). This results also elucidate the taxonomic status of the three similar species (*M. viciae* Buckton, 1876, *M. crassicauda* Mordvilko, 1919, and *M. nigra* Lee, 2002) on the herbaceous Leguminosae, *Vicia* Tourn. Ex Linn. and *Lathyrus* Linn. Both morphological and molecular results support that *M. crassicauda* in the Eastern Palaearctic, the former subspecies of *M. viciae* Buckton, 1876, is very close, almost identical to *M. viciae* in the Western Palaearctic, while *M. nigra* Lee, 2002 in Korea is distinctively separated from the other two species. The 7 world *Megoura* species are divided into two clades, one group consisting of *M. crassicauda*, *M. viciae*, *M. nigra*, and *M. litoralis*, on the herbaceous legume plants and the other group of *M. dooasis*, *M. lespedeza* (Essig & Kuwana, 1918), and *M. brevipilosa* Miyazaki, 1971, on the woody legume plants (*Hedysarum* Linn., *Indigofera* Linn., *Cajanus* DC., *Desmodium* Desv., *Lespedeza* Michx.). This implies that the speciations of *Megoura* species have occurred in the close relationship with the host plant radiations, although the evolutionary relationships of the host plant genera in Leguminosae have not been solved clearly yet.

A taxonomic study of Chinese phorid flies(Diptera: Phoridae)

G Liu
College of Biological and Environmental Engineering, Shenyang University, Shenyang 110044, China, liugc18@mail.sy.ln.cn

China, meeting both the Palearctic and the Oriental region, is rich in phorid fly resources. At present study 87 species of phorid flies in 22 genera are recorded, of which 22 species are new to science , 7 genera and 4 species are reported for the first time in China. The following genera are covered: *Hypocera* Lioy, *Borophaga* Enderlein, *Latiborophaga* Brown, *Godavaria* Brown, *Chaetogodavaria* Liu, *Ctenopleuriphora* Liu, *Stichillus* Enderlin, *Phora* Latreille, ,*Spiniphora* Malloch, *Psyllomyia* Loew, *Diplonevra* Lioy, *Dohrniphora* Dahl, *Conicera* Meigen, *Chouomyia* Liu, *Triphleba* Rondani, *Rhopica* Schmitz, *Metopina* Macquart, *Trophithauma* Schmitz, *Puliciphora* Dahl, *Gymnophora* Macquart, *Woodiphora* Schmitz, *Phalacrotophora* Enderlein. Keys to genera and species are presented to facilitate identification. All the genera and species are described or rediscribed.

The Neotropical genus *Rotundicerus* Maldonado-Capriles, 1977 (Hemiptera: Cicadellidae: Idiocerinae)

PW Lozada
Departamento de Entomologia, Museo de Historia Natural, UNMSM, Apartado 14-0434, Lima 14, Peru, and Servicio Nacional de Sanidad Agraria (SENASA), Psje. Francisco de Zela s/n, Jesus Maria, Lima, Peru, plozada@senasa.gob.pe

The genus *Rotundicerus* was described by Maldonado-Capriles (1977, Proc. Entomol. Soc. Wash. 79(3): 317-325), with its type species *R. luteus* Maldonado-Capriles from Guyana. This genus is characterized by the vertex finely shagreen and its anterior and posterior margins strongly curved and parallel, forewings with the inner anteapical vein without a cross vein, aedeagus without socle and caudal side on apical half with scaly appearance, pygopher triangular in lateral profile, and anterior dorsum mostly yellow. Dietrich (in Dietrich & McKamey, 1990, Proc. Entomol. Soc. Wash. 92(2): 214-223) described two more species, *R. minutus* Dietrich and *R. rubripictus* Dietrich, from Guyana. In this paper, four more species of this genus are added, two from Peru (Jenaro Herrera, Loreto) and two from Brazil (Jacareacanga and Santo Antonio de Taua, Para). Based in the study of this additional material, the two species described by Dietrich are excluded from *Rotundicerus*, representing species of two undescribed genera.

Diperocarp seed predation by weevils: succession and specificity (Coleoptera: Curculionidae)

CHC Lyal, L Curran, J Bupabanpot
The Natural History Museum, Department of Entomology, London SW7 5BD, UK, c.lyal@nhm.ac.uk

Dipterocarp trees dominate much of South-East Asian forests. There are more than 400 species of the family, and species grow in mixed stands. The fruit is attacked by a number of beetles and moths, and mortality of up to 100% has been recorded. Although traditionally seed predators have been grouped into 'pre-dispersal' and 'post-dispersal' this categorisation does not capture the successional aspect of weevil attack on dipterocarp seeds, where time of oviposition is allied to physical condition of the developing fruit and whether the fruit is on the tree or not on emergence of the adult beetle. *Alcidodes* weevils show specificity at the level of host genus or species group, although quantitative studies show a host preference within the range, while Nanophyinae show specificity at the generic or species level. Host tree individuals can have several congeneric beetles attacking the fruit.

LOWD: Leafhoppers of the World Database

SH McKamey
USDA Agricultural Research Service, Systematic Entomology Laboratory, National Museum of Natural History, MRC-168, Smithsonian Institution, Washington, D.C. 20560 USA, smckamey@sel.barc.usda.gov

An electronic, relational species database of world leafhoppers (Cicadellidae) is nearing completion using the software program *Biota* 2 (Colwell 2004). Presently there are 18,972 valid species and subspecies among 2,609 valid genera and subgenera. The database includes the current taxonomy, synonymy, and taxonomic history since 1955 for 21,769 available species names, including type depositories for 13,447 and country-level distribution for 20,302. Data is derived from Metcalf's Catalogue of the Homoptera (10,952 species, coverage 1758-1955), Oman, Knight & Nielson's 1990 generic checklist and bibliography, the Zoological Record, and original descriptions (10,035 species, 1,397 papers). Only 782 databased species names remain to be checked against their original descriptions and perhaps 1,500 species have been described but not yet databased. LOWD is also exceptionally well suited for specimen data and collection management. Within this year, specialists will be invited to import specimen records directly from remote stations to establish an unparalleled directory of specimens available for research. Within five years, the periodically updated database will be posted for free access on the WWW. Receipt of publication lists and reprints of taxonomic papers on Cicadellidae (and other Auchenorrhyncha) will be appreciated most gratefully and will ensure their incorporation into the database.

Liposcelis bostrychophila **Badonell: RAPD fingerprinting pinpoints its geographic origin**

KM Mikac, G Clarke, N FitzSimmons, DP Rees
CSIRO Division of Entomology, GPO Box 1700, Acton, ACT 2601 Australia, katarina.mikac@csiro.au

Liposcelis bostrychophila (Psocoptera: Liposcelididae) is a cosmopolitan pest of stored grain in Australia and internationally. It has become a pest due to its parthenogenetic life history and tolerance to adverse environmental conditions. As there is currently limited information on the invasion biology of *Liposcelis* species, a greater understanding of the general population biology of *Liposcelis* species, including population structure and dynamics, gene flow among populations, geographic origin of source populations and dispersal mechanisms is required. Elucidation of genetic structure in geographic populations is an important aspect of pest studies providing insight into the geographic origin of colonised populations. *L. bostrychophila* is thought to have dispersed globally via commerce. It is suspected that *L. bostrychophila* has been introduced to Australia, but from unknown sources. To define the origin of pest populations, genetic markers can be used to test for levels of genetic similarity. This poster details the use of Randomly Amplified Polymorphic DNA (RAPDs) to elucidate the geographic origin of *L. bostrychophila* populations in Australian grain storage systems.

The higher classification of cicadas: a tentative cladogram

MS Moulds
Australian Museum, 6 College St, Sydney, NSW 2000, Australia, maxm@austmus.gov.au

Opinions on family and subfamily groupings within the Cicadoidea remain varied. A broad consensus has emerged for the recognition of just two families, the Tettigarctidae comprising mostly fossil genera and two extant species, and the Cicadidae which encompasses all other living cicadas as well as fossil taxa. Traditionally the large majority of Cicadidae have been divided into subfamilies, the Cicadinae and Tibicininae. The status of other groupings, particularly those based on *Plautilla* and *Tettigades,* as either subfamilies or families remains in contention. I have tested the validity of all family and subfamily groupings using cladistic parsimony. Support for just two family groupings, the Tettigarctidae and Cicadidae was very strong. The subfamily Cicadinae, those cicadas of which the males possess timbal covers was also supported, as were the Tibicininae. A notable transgression from current thinking was the monophyly of *Platypedia, Tettigades* and *Tibicina.* This group falls as the sister group of all other Cicadidae and is proposed as the new subfamily Tettigadinae. One further subfamily grouping is identified, proposed as the Zammarinae. The monophyly of the large tribe Cicadettini, based upon the partial fusion of fore wing veins M and CuA, is challenged. The Cicadettini are here considered to include some genera lacking fusion of these veins.

Proteininae (Coleoptera: Staphylinidae) in Gondwana: ancient distribution patterns?

AF Newton
Field Mus. Nat. Hist., 1400 S Lake Shoredrive, Chicago IL 60605, USA anewton@fieldmuseum.org

Prior work and ongoing studies indicate that the subfamily Proteininae is a monophyletic, basal lineage within the huge beetle family Staphylinidae, and consists of five evidently monophyletic tribes of two or three genera each. Four tribes are restricted to austral or Gondwanan regions, while the fifth and largest (Proteinini) is most diverse in the northern hemisphere but includes species in tropical regions and a few on the fringes of southern temperate areas. Among the four austral tribes, earlier taxonomic work based on a few dozen known specimens identified a total of 8 genera and 11 species, but systematic review of abundant material from recent and continuing field surveys indicates the presence of at least one new genus and dozens of new species, and significant range extensions for each group including new trans-austral connections. All four austral tribes now show southern connections between three areas (Silphotelini and Austrorhysini, each found in Australia, New Zealand and southern South America) or two areas (Anepiini in Australia and New Zealand, and Nesoneini in New Zealand and New Caledonia). Continuing generic and species-level systematic revisions of the austral tribes attempt to elucidate phylogenetic relationships among all taxa and analyze global and local distribution patterns.

Higher phylogeny of Zygaenidae (Lepidoptera) and evolution of chemical defence

O. Niehuis, SH Yen, B Misof, CM Naumann
Alexander Koenig Research Institute and Museum of Zoology, Molecular Laboratory, Adenauerallee 160, D-53113 Bonn, Germany, o.niehuis.zfmk@uni-bonn.de;

The higher phylogeny and evolution of chemical defence mechanisms of Zygaenidae are investigated using morphological characters and 4 molecular markers (18S rRNA, 28S rRNA, ND1, 12S rRNA). Both morphological and molecular evidence show that the Phaudinae does not belong to the Zygaenidae because it forms a clade with Lacturidae, which in turn is shown to be the sister-group of the limacodid-family group. Anomoeotinae and Himantopteridae also do not belong to Zygaenidae because the clade comprising these two families is the sister-group of Somabrachyidae. Within the Zygaenidae, the morphological and molecular trees show significant topological incongruence. The morphological phylogeny shows that Procridinae is the most basal zygaenid group and the Zygaeninae is the sister-group of (Callizygaeninae + (*Heteropan* + Chalcosiinae)). However, the molecular phylogenies suggest that the Zygaeninae forms the most basal group, with the remaining subfamilies forming an unresolved polytomy. According to the morphological phylogeny, absence of the cuticular cyanic fluid storage system in the larvae is supposed to be a plesiomorphic state, but the molecular phylogeny indicates that absence of this mechanism may be due to a secondary loss. We also compare the parasitoid faunas associated with the larvae of different zygaenid groups to see if there is significant difference in host use under different chemical defence systems of the host caterpillars.

Life stages and biology of *Filinota brunniceps* (Felder & Rogenhofer) (Lepidoptera: Elachistidae: Depressariinae) from Costa Rica

K Nishida, D Adamski
Sistema de Estudios de Posgrado en Biología, Escuela de Biología, Universidad de Costa Rica, 2060 San, José, Costa Rica; knishida@cariari.ucr.ac.cr

For over 100 years, *Filinota brunniceps* (Felder & Rogenhofer) was known only from a single adult specimen from Colombia SA, until it was rediscovered in Mexico and later by K. Nishida in Costa Rica. All life stages for this species, its biology, and some larval and adult behaviors are described here. Larvae feed on leaves of *Rivina humilis* (L.) [Phytolaccaceae]. Eggs are ovoid with a transverse medial ridge slightly beyond each end margin. Eggs are usually laid in grooves of the host plant stem. Larvae live as leaf scraper then rollers. Pupation occurs within rolled leaf away from the host plant. The pupa is deeply excavated laterally between the labrum and the proximal margins of the maxillae and possesses a ridgelike "cocoon cutter" on the dorso-lateral area of the head. Adults are diurnal to crepuscular and exhibit an unusual survival behavior for Microlepidoptera. When at rest, conspicuous adults rolls their wings around their abdomen, exposing an "eye spot" on each side of the posterior end of the forewing while the terminal portion of the antennae extend well beyond the posterior wing margins, giving a "false head" search image to would be predators.

Moving toward Thysanopteran phylogeny: DNA extraction methods that preserve voucher specimens

CA O'Donnell, DE Ullman, MP Parrella
University of Californina, Davis, One Shields Avenue, Davis, CA., USA caodonnell@ucdavis.edu

Our ultimate goal is to estimate thrips phylogeny using morphological and molecular characteristics. Reliable thrips identification using morphological methods requires use of a compound microscope to view cleared specimens mounted on slides. For molecular phylogenetic research, it is essential that specimens from which DNA is extracted are identified accurately. However, preparation for molecular analysis is usually destructive, and identification based on other thrips from the same collection may be confounded by the presence of more than one species in a sample. To avoid such misidentifications, we developed a technique that preserves the thrips exoskeleton for mounting as a morphological voucher, while extracting strong DNA product for our molecular analysis. We make a small incision along the abdomen, and place the whole thrips into a Qiagen^{TM} DNeasy tissue kit, proteinase K lysis buffer (ATL) for processing. We do not grind up the specimen. The thrips exoskeleton is then retrieved from extraction kit, dehydrated and mounted in Canada balsam on a microscope slide. We also extracted thrips DNA using the methods of Sunnucks and Hales (1996) and D.C. Morris (*pers.com.*), but obtained lower DNA yields than with our method.

Phylogeny of the Hippoboscoidea (Diptera), based on molecular characters.

JFT Petersen, BM Wiegmann, R Meier
"Zoological Museum. Universitetsparken 15. DK-2100 Copenhagen O. jftpetersen@zmuc.ku.dk"

The Hippoboscoidea is a superfamily of Diptera that include Glossinidae (tsetse flies), Hippoboscidae (keds and louse flies), Streblidae and Nycteribiidae (bat flies). All members are blood feeders of mammals or birds. While the Glossinidae are free-living, the remaining members of the group are all obligate ectoparasites, spending most or all of their life-cycle in the plumage or the fur of their host. We present the results of a phylogenetic analysis of the Hippoboscoidea based on molecular markers. DNA was sequenced from portions of the nuclear ribosomal gene 28S as well as the nuclear protein coding gene CAD. More than 30 taxa were included representing over 15 genera. Results are presented from both separate and combined analyses using parsimony and Bayesian methods. We discuss the implications for the family-level classification of the Hippoboscoidea as well as the placement of the superfamily within the Calyptratae.

Cladistic analysis of the subtribe Catopina (Coleoptera: Leiodidae) from continental Asia

J Ruzicka
Department Of Ecology, Faculty Of Forestry And Environment, Czech Agricultural University, Cz-165 21 Praha 6, Czech Republic, ruzicka@lf.czu.cz

The cladistic analysis of the genera of the subtribe Catopina (Insecta: Coleoptera: Leiodidae: Cholevinae) is presented. The analysis is focused on external morphology of adults, including detailed study of characters on male and female terminal abdominal segments and genitalia. The following genera are covered in the study: *Catopodes* Portevin, *Catops* Paykull (with several species groups), *Cholevinus* Reitter, *Dzungarites* Jeannel, *Himalops* Perreau, *Mesocatops* Szymczakowski, *Rybinskiella* Reitter and *Scioepoides* Hatch, with representants of the sister subtribe Cholevina selected as outgroup.

Monophyly of the Papilionoidea (Lepidoptera) families based on the male genitalia

ET Saigusa
2-7-1, Clover Height Ropponmatsu 402, Baikôen, Chuô-ku, Fukuoka-shi, Fukuoka Pref., 810-0035, Japan, Toyohei. Saigusa@ma2.seikyou.ne.jp

Recently monophyly of families of the Papilionoidea are established based on morphological and molecular data. However, autapomorphic features of the male genitalia supporting monophyly of butterfly families are rather poorly investigated. In this paper, I worked on this problem. The results are as follows, and all the features stated below are considered apomorphic in the Papilionoidea. The Papilionidae are supported by the presence of the epicosta, which is a detached basal part of the costa of valva. The Pieridae are supported by the presence of the Valvenansatz, which is a prolongation from the laterodistal portion of tegumen, and is articulated with basal portion of costa. The Nymphalidae including Satyrinae and Morphinae are supported by the presence of the appendix angularis, which is the appendicular process for the costa of valva, and is projected from the tegumen close to the vinculum. The Danaidae are supported by the transformation of the scaphium (10th abdominal dorsum) into a pair of setiferous lobes. The Libytheidae are supported by the peculiar prolongation of a pair of sclerotic bands from the tegumen connecting the juxta. The Lycaenidae including Riodininae are supported by the presence of a pair of falces, which are main organ connecting the female genitalia.

Parthenogenetic species in the aphid genus *Colopha* (Aphididae: Eriosomatinae) as a relic

M Sano, S Akimoto
Department of Ecology and Systematics, Graduate School of Agriculture, Hokkaido University, Sapporo 060-8589, Japan, msano@res.agr.hokudai.ac.jp

It is widely conceived that parthenogenetic species are exceptional and difficult to last for a long time in animals. This study tested the possibility of long-term persistence of an aphid species by means of parthenogenesis (relic hypothesis). Aphids of the Eriosomatinae are typically associated with primary and secondary host plants and alternate host plants seasonally. Sexual reproduction takes place on the primary host plant. However, some species are not host-alternating and wholly parthenogenetic on the secondary host plant. The genus *Colopha* is a small aphid group represented by three sexual and three asexual species. The sexual species are associated with two *Ulmus* species that are most closely related and are distributed disjunctively in Europe and eastern North America. In East Asia, an asexual species, *Colopha kansugei*, is distributed widely on the secondary host. We tested whether the relic hypothesis is applicable to *C. kansugei* by constructing molecular phylogeny. A high rate of substitution (3.4% at the maximum) was found in the mitochondrial COI sequence between local populations. Evidence available suggests that *Colopha kansugei* has persisted on the secondary host plant through parthenogenesis as a relic, probably since the local extinction of the primary host.

Computerized checklist and database on Peruvian Chrysomelidae (Coleoptera): Alticinae and Galerucinae

J Santisteban
Departamento de Entomología, Universidad Nacional Agraria La Molina, Av. La Universidad, s/n, Apdo. 456, La Molina, Lima – Peru, Santisteban@lamolina.edu.pe

The family Chrysomelidae *s.l.* (Coleoptera) is one of the most diverse in the Neotropics and throughout the World Tropical Regions. Comprising close to 1000 nominal genera, the traditional subfamilies Alticinae and Galerucinae (now both included in Galerucinae) constitute one of the so-called "Hiperdiverse" groups of living organisms. Circa 200 genera of traditional Alticinae are regarded as endemic for the Neotropical realm. Chrysomelidae importance stems not only from their high diversity and ecosystem services, but also from a number of important pest species in the country and elsewhere. Currently, no checklist of Chrysomelidae is available for Peru or neighbour countries. Latest published listing for Peru dates back to Blackwelder outdated compilation. Here, I present the preliminary results of a computerized taxonomic checklist of traditional Galerucinae and Alticinae from Peru, based on literature and species records of autoritatively identified material housed in research entomological collections in Peru. Data from both literature and individual specimens have been incorporated into a custom-made computer database, which includes taxonomic and geo-referenced distribution data. Database design was based on ASC information model and followed TSWG recommended standards. Data contained in the database will be made accesible through the web, following GBIF data access and interoperability proposal.

New findings on Agyrtodini, with adult and larval descriptions (Coleoptera: Leiodidae)

A Seago
201 Wellman Hall, ESPM- Insect Biology, University of California, Berkeley CA 94720-3112 USA; seago@nature.berkeley.edu

The basal leiodid subfamily Camiarinae comprises the tribes Agyrtodini, Neopelatopini, and Camiarini, united by plesiomorphic characters alone. This weakly-supported subfamily contains the most primitive leiodids, and includes many taxa of use for polarizing evolutionary trends within Staphylinoidea. Sadly, Camiarinae is a miasma of unresolved tribal relationships and poorly-known genera with many undescribed species. Although agyrtodines such as *Agyrtodes* and *Zearagytodes* are collected with considerable ease and frequency in Australia and New Zealand, their scientific utility is severely constrained by taxonomic obscurity and a paucity of reliable keys. As a first step towards a better understanding of relationships within Leiodidae, a revision of the genus *Agyrtodes* (the most speciose genus within Camiarinae) is proposed. Keys are provided to adults of *Agyrtodes* and to genera of Agyrtodini. Larval forms are newly described for several agyrtodine species and surveyed for phylogenetically significant morphological characters .

New Zealand Carabidae – a revision of the *Mecodema curvidens* species complex

DS Seldon.
School of Biological Sciences, University of Auckland, Private Bag 92019, Auckland, New Zealand, d.seldon@auckland.ac.nz

Worldwide the Carabidae (ground beetles) family is comprised of 25,000-50,000 species, within 6 subfamilies and 85 tribes. In New Zealand the carabid fauna is small compared to warmer regions. However, several ancient tribes have reached their greatest diversity and endemism is high at both genera (58%) and species (92%) levels. One tribe, the Broscini is represented by 5 genera, of which *Mecodema* is the most species-rich with 74 taxa divided into 8 species groups. My research will focus on a revision of the *Mecodema curvidens* species group, which has five species listed as endangered. This complex has a unique distribution in coastal forests of the North Island's northeast coast, from Cape Reinga to the East Cape and on four offshore island groups. Both morphological characters (external and genitalia) and molecular analysis will be used to resolve taxonomic confusion of the 5 currently described species and identify a possible 7-9 new species. Population distributions will be looked at through pitfall trapping within suitable habitats along the recognized distribution. This research will increase the overall knowledge of *Mecodema* beetles in New Zealand and give more insight into the distribution and species diversity of the *curvidens* group, allowing conservation groups to concentrate management on rare or endangered species.

Phylogenetic relationships in the Swallowtail Butterflies of the tribe Troidini (Papilionidae) based on COI, COII, and Ef1a Genes

KL Silva, AVL Freitas, VN Solferini
Pós-graduação em Ecologia; [2] Dept. de Genética e Evolução – Instituto de Biologia, Universidade Estadual de Campinas - Unicamp. Campinas, SP, Brazil. Cep 13083-970; klucas@unicamp.br

Butterflies of the tribe Troidini (Papilionidae, Papilionini) are predominantly tropical, with three genera present in the New World: *Battus*, *Euryades*, and *Parides*. They are often regarded as classic examples of coevolution with their larval host plants (Aristolochiaceae). There are three different hypotheses of Troidini phylogeny, all based primarily on morphology. The central aim of this work is to obtain a phylogenetic hypothesis for this group based on molecular characters. We have sequenced three genes, COI and COII (mitochondrial), and EF-1α (nuclear), in 20 species of Troidini. Phylogenetic analyses were performed with PAUP, using Maximum Parsimony and Maximum Likelihood on the full data set (3285 nucleotides; 890 informative sites). Parsimony searches gave two most parsimonious trees, with 3400 steps (CI=0.456, RI=0.683). The monophyly of the Troidini clade was supported by bootstrapping with 92% confidence, still more likely was the *Parides* clade (98%). The genus *Battus* appeared as basal, followed by *Euryades, Parides, Pachliopta* and *Troides+Atrophaneura*. The maximum likelihood analysis for the combined data set under the GTR+I+G model, revealed a single tree with a score of –ln *L*=21564.053, very similar to those obtained by MP. Separate analyses showed that there is significant congruence among mitochondrial and nuclear genes (ILD test, p=0.746).

Molecular phylogeny of Larentiinae and Ennominae (Lepidoptera: Geometridae)

N Snäll, N Wahlberg, T Tammaru, K Ruohomäki, K Huoponen, M-L Savontaus
Laboratory of Genetics, University of Turku, FIN-20014, Finland, niina.snall@utu.fi

Geometridae is a family with more than 20 000 described species. In this study, we focus on the subfamilies of Larentiinae and Ennominae, and use nuclear DNA markers in order to resolve some of the ambiguities of the proposed phylogenetic relationships. Further, we are interested in how many independent changes from winged to wingless females there have occurred. Portions of nuclear DNA genes, 28S rRNA and EF-1α, were sequenced from 36 species. Sixteen Geometridae and six outgroup sequences published elsewhere were combined with our data. Direct optimisation was used to infer a phylogenetic hypothesis from the combined sequence data set. Our preliminary results show that Larentiinae form monophyletic group, but Ennominae is paraphyletic. In both subfamilies traditional tribes are not fully supported. Furthermore, the current data suggests that in both subfamilies female winglessness has evolved independently more than once. Future plans of this work include sequencing one more gene fragment and increasing the number of taxa studied.

A new genus and the larvae of Tanygnathinina (Coleoptera: Staphylinidae: Staphylinini)

AYu Solodovnikov
Field Mus. of Nat. History, 1400 S Lake Shore Drive, Chicago IL 60605, USA, asolodovnikov@fieldmuseum.org

Until recently, the subtribe Tanygnathinina (Staphylinidae: Staphylininae: Staphylinini) contained only the single genus *Atanygnathus* (about 50 described species; mostly tropical; predominantly hygrophilous). Morphologically, *Atanygnathus* is a rather peculiar taxon of Staphylinidae with substantial controversies about its taxonomic placement within the family. Recently a less specialized new genus (including its larvae) closely related to *Atanygnathus*, and larvae of *Atanygnathus* have been found. Detailed morphological examination of the adults and larvae of both genera revealed new synapomorphies of Tanygnathinina with the rest of Staphylinini. Several very interesting autapomorphies of Tanygnathinina and *Atanygnathus* have now been found, too, especially in larvae, and some earlier interpretations of particular adult character states are put in doubt. The new findings support the recently published idea about the isolated position of Tanygnathinina within the tribe Staphylinini. Probably, Tanygnathinina is a highly derived lineage of Quediina. At the moment, however, meaningful testing of this hypothesis is impossible because the composition of Quediina is not properly understood on a world basis, and larvae of Staphylinini are still inadequately known.

The Agathidinae (Hymenoptera: Braconidae) of Australia; parasitoids of lepidopteran larvae.

NB Stevens, AD Austin, JT Jennings
Centre For Evolutionary Biology & Biodiversity, School Of Earth & Environmental Science, The University Of Adelaide, SA, 5005, Australia.
nick.stevens@adelaide.edu.au

One of the largest parasitoid wasp families is the Braconidae (Hymenoptera) with nearly 15,000 valid species world-wide, and possibly three to four times this many species waiting description. The Braconidae are well represented in Australia with 29 of the 34 subfamilies recognised occurring here. However, the Australian fauna has received little attention. This project focuses on the systematics of the Agathidinae in Australia. This subfamily is a relatively speciose group with over 1200 described species in over 50 genera worldwide. Little is known of the Australian fauna with only 36 species in eight genera described to date. Agathidine taxa are solitary endoparasitoids that parasitise lepidopteran larvae, most commonly concealed larvae. The distributions of described agathidines show they are diverse in a wide range of climatic zones from tropical/subtropical regions, to more temperate and arid environments. The Australian continent encompasses a wide range of climatic regions, providing a myriad of habitats into which agathidines have diversified. Preliminary investigation has discovered many new species. The most dramatic example is for the cosmopolitan genus *Bassus* Fabricius which is presently represented in Australia by only one introduced species. However, over 25 new taxa have already been discovered.

Systematic study of the *Diplodoma* genus group (Lepidoptera, Psychidae)

M Sugimoto, ET Saigusa
6-10-1, Hakozaki, Higashi-ku, Fukuoka, 812-8581, Japan, osugi@agr.kyushu-u.ac.jp

In the family Psychidae, body structures of adult females are reduced in various degrees, and morphology of adult males and biology of both sexes associated with the female body reduction show various specializations. Therefore this family is suited to evolutionary study. However, as the adult morphology is so diversified that no stable taxonomic system has been established, and intrageneric phylogenetic relationships in the family are poorly known. In this paper we studied on morphology and ethology of the monophyletic *Diplodoma* group that includes two types of genera, one with winged and legged females, the other with wingless and legged females, and analyzed phylogenetic relationships among the genera. As the result, this group is divided into five clades. One clade is supported by the presence of apomorphic fultura inferior in the male genitalia, and includes *Diplodoma*, *Narycia* and *Paranarychia* with winged females and *Dahlica* and its allies with wingless females. The reduction of female wings appeared also in other three clades. Therefore, the wing reduction occurred many times in different clades in the group, and it suggests that reductions of female body structures appeared independently in various groups in this family. A preliminary work on molecular systematics of the group is also mentioned.

Geographical variation of the male genitalia of *Sciara humeralis* Zetterstedt, 1851 (Diptera, Sciaridae)

M Sutou, MT Ito
Soil Ecology Research Group, Environment and Information Sciences, Yokohama National University, Hodogaya-ku, Yokohama, 240-8501 Japan, d01ta006@ynu.ac.jp

We have collected 8 species of *Sciara* from Japan: *S. thoracica*, *S. hemerobioides*, *S. helvola*, *S. multispinulosa*, *S. humeralis*, *S. melanostyla*, *Sciara* sp.1 (undescribed sp.), *Sciara* sp. 2 (undescribed sp.) (Sutou, unpublished).
One of them, *S. humeralis* is known to be widely distributed in the Holoarctic region, and also from the Oriental region. Menzel and Mohrig (1991, 2000) pointed out the morphological variation of the male genitalia of this species, and categorized it into 3 types based on the materials from Europe, Taiwan, and USA. We call them Palaearctic type, Oriental type, and Nearctic type, respectively. So far, Oriental type has been recorded from Taiwan, southern China (Guizhou Province), and northern Vietnam. We recorded many specimens of Palaearctic type from mainland of Japan (Akita, Iwate, Tokyo, Kagoshima), and Oriental type from southernmost islands in Japan (Ishigaki Is. and Iriomote Is.). Based on these materials, we estimated that the distributional borderline between Palaearctic type and Oriental type lies within southern islands of Japan.

Phylogeny of the bee flies (Diptera: Bombyliidae)

MD Trautwein, BM Wiegmann, DK Yeates
Department of Entomology, North Carolina State University, Raleigh, North Carolina 27695, USA, mdtrautw@ncsu.edu

Bombyliidae, or bee flies, rank among the largest and most diverse families of Diptera. This striking diversity contributes to the complexity of determining their evolutionary relationships using comparative morphology alone. Only a small number of studies, however, have relied on molecular data to reconstruct phylogenetic relationships within the Bombyliidae. The most recent comprehensive phylogenetic analysis of bombyliid subfamilial relationships was based on morphological characters. Our current molecular study provides additional data to confirm, test, and further resolve higher-level classification within the Bombyliidae. To do this we sequenced large fragments of CAD, a protein encoding gene, and the 28S ribosomal DNA for more than 35 taxa, representing 12 of the 15 currently recognized subfamilies, along with several outgroups. Based on phylogenetic analyses of these data using parsimony and Bayesian methods, we assess support for the monophyly of currently recognized subfamilies and the position of various genera within the family. An analysis of congruence between the DNA sequence data sets and previously compiled morphological data is also presented. Evidence in support of alternative sister groups for the Bombyliidae is discussed within the broader context of relationships among asiloid Diptera.

The redefinition of the ejaculatory reservoir *s. str.* in Pentatomomorpha (Hemiptera: Heteroptera)

JF Tsai, MM Yang, CT Yang
Department of Entomology, National Chung Hsing University, 250 Kuo Kuang Road, Taichung 40227, Taiwan, afu0630@yahoo.com.tw

Singh-Pruthi (1925) defined the ejaculatory reservoir as "an expansion of the ejaculatory duct at the base of the vesica [= aedeagus] present in Heteroptera." After carefully examining the external male genitalia of Dinidoridae, Scutelleridae, Tessaratomidae, and Cydnidae, we found that Singh-Pruthi's definition could not be satisfactorily applied to the above families. Therefore, it is necessary to redefine the ejaculatory reservoir in the Pentatomomorpha. We found that the structure protrudes from the dorsobasal portion of the expansion of the ejaculatory duct within the apical half of the aedeagus. We redefine that part of the structure outside the base of the aedeagus as the "ejaculatory reservoir" and the other part within the aedeagus, including the expanded ejaculatory duct, as the "reservoir lumen." There are three differences between our and Singh-Pruthi's definition of the ejaculatory reservoir. (1) The position (an evolutionary event) within the middle of the aedeagus vs. at the base of the aedeagus, (2) The nature of the structure protruding from the expanded ejaculatory duct vs. an expansion of the ejaculatory duct, and (3) The presence in only Pentatomomorpha vs. in Heteroptera.

Phylogeny and classification of the Iceryine Margarodids (Hemiptera: Coccoidea)

CM Unruh, PJ Gullan
University of California, Dept. of Entomology, One Shields Ave., Davis, CA 95616 cmunruh@ucdavis.edu

This study examines the taxonomy and evolutionary relationships of selected members of the tribe Iceryini within the scale insect family Margarodidae. This tribe is monophyletic and belongs to the subfamily Monophlebinae. Relationships among iceryine genera and species are largely unknown. The only phylogenetic studies of margarodids are a cladistic analysis of morphology including three genera of Iceryiniand an unpublished preliminary molecular phylogeny. The subfamily Monophlebinae consists of five tribes, of which the Iceryini is the largest and best known because many species are important pests of commercial agriculture across the world. The six genera in this tribe are *Auloicerya* Morrison (2 species), *Crypticerya* Cockerell (15 species), *Echinicerya* Morrison (1 species), *Gueriniella* Fernald (2 species), *Icerya* Signoret (40 species) and *Steatococcus* Ferris (14 species). This poster presents a preliminary molecular analysis of the iceryine tribe and its outgroups with species from the Americas, Australia, New Caledonia, Hong Kong and Thailand. These molecular data are from the mitochondrial gene cytochrome oxidase subunit I (COI) and a nuclear gene from the D2 expansion region of the large subunit ribosomal DNA gene (28S).

Phylogeny of fossil and extant Sciaroidea (Diptera: Bibionomorpha)

P Vilkamaa
Finnish Museum of Natural History, PO Box 17, FI-00014 University of Helsinki, Finland pekka.vilkamaa@helsinki.fi

The phylogeny of the main groups of Sciaroidea, including the fossil Antefungivoridae†, Archizelmiridae†, Mesosciophilidae†, Pleciofungivoridae, Pleciomimidae†, Protopleciidae† and Bolitophilidae: Mangasinae†, and an extant new taxon, was studied by parsimony analysis. Two cladistic analyses of 78 morphological characters from adults were made. One analysis, with forty-one extant taxa in the ingroup and the other, with twelve fossil taxa in addition, produced both two most parsimonious cladograms. The phylogenetic hypotheses obtained differed from each other, and partly largely from previous ones although the most traditionally recognized groups appeared monophyletic, including the speciose Cecidomyiidae and Sciaridae. Cecidomyiidae (fossil analysis) or Keroplatidae-Ditomyiidae (extant analysis) appeared as the sister group of the rest of the Sciaroidea. According to the present solution, we propose to emend the current Sciaridae to include five subfamilies: Archizelmirinae† stat. n., Rangomaraminae stat. n., Sciarinae, Subfam. n.1 and Subfam. n.2. A new genus from Namibia is described, and, according to the phylogenetic analysis, placed into Sciaridae, as the type-genus of one of the new subfamilies. As the sister group of Sciaridae in its new concept appeared the Mycetophilidae group, in the extant analysis including Mycetophilidae, Manotidae, Lygistorrhinidae, *Pterogymnus* and *Sciaropota*, in the fossil analysis also Mesosciophilidae† and the *Ohakunea* group (*Ohakunea* + *Colonomyia*).

Systematics, biogeography and conservation in the *sari* group of Old World *Eurema*

O Yata, K Odagiri
PO Box 810-8560, Faculty of Social and Cultural Studies, Kyushu University, Ropponmatsu, Fukuoka, Japan, yatarcb@mbox.nc.kyushu-u.ac.jp

The *sari* group, the largest group of the genus *Eurema* occurring in the Old World, has its distributional center in the Oriental Region and is a distinct monophyletic group consisting of 18 species and 4 subgenera (Yata, 1989). Since the group consists of many rare and local species inhabiting forests and shows remarkable allopatric speciation on Southeast Asian Islands, it is suitable to discuss the phylogeny and biogeography of the butterfly. The phylogenetic relationships within the subgenus *Terias* including the *sari* group were inferred in a revision of the genus *Eurema* (Yata, 1989). This revision, however, was mainly based on morphological characters and DNA information not used. In the present study, the phylogenetic relationships among 12 *Eurema* species including this group were inferred using the base sequence of COI region of mitochondrial DNA (mtDNA). The monophyly within three groups, *hecabe - alitha*, *nicevillei – tilaha - lombokiana* and *novapallida - lacteola*, was distinct and well coincident with that from morphology, respectively, but not for *hiurai* from the Philippines including the subgroup *lacteola* with *novapallida - lacteola*. Based on these results were discussed the systematics / biogeography of these groups and the meaning of their habitat for conservation biology.

Preliminary phylogenetic analysis of Musotiminae (Lepidoptera, Crambidae) and the implications on biological control of weedy ferns

SH Yen, T Wright, JA Goolsby, MA Solis
Department Of Biological Sciences, National Sun Yat-Sen University, Kaohsiung, Taiwan, shenhornyen@hotmail.com

The crambid Musotiminae has 24 genera recognized from around the world, most of which are obviously not monophyletic, and many species are undescribed. We seek to address the following aspects of musotimine systematics: (1) what are the relationships of this subfamily to other crambid subfamilies; (2) what are the synapomorphies of this subfamily; (3) what can new adult morphological characters tell us about the relationships within the group. We show that several 'clades' within the subfamily can be defined based on some putative synapomorphies, but their internal relationships are blurred because information of immature stages is still scarce. Fern-feeding behaviour of the musotimines from different parts of the world has been discovered in the past two years, and thus these moths may have potential for controlling the weedy ferns. We mapped the known host fern families on to a preliminary genus-level phylogeny of Musotiminae and found no evidence of co-phylogenesis between the fern families and moth genera though there is a tendency for closely related species and genera to utilize the same fern family. However, some fern families such as Schizaeaceae have been colonized by unrelated lineages of musotimines. We expect that more exploration for biological control agents will result in an improved picture of the fern-musotimine relationships.

Evolution of the Australian endemic Geometridae

CJ Young
Department of Primary Industries, Water and Environment, 13 St Johns Ave, New Town, Tasmania, 7008, Australia, Cathy.Young@dpiwe.tas.gov.au.

The Australian endemic Geometridae form a large part of the Australian indigenous macromoth fauna. Most of these species belong to the tribe Nacophorini. New molecular and morphological evidence from all stages of the life cycle enabled the characterisation of this group in a phylogenetic framework. The Tasmanian Archiearinae was well separated from the Holarctic fauna on both molecular and morphological evidence. The alpine taxa of this group are most likely an endemic clade closely related to the Nacophorini, but may have affinities with the Neotropical Archiearinae. The proposed phylogeny from this work provides a context for the interpretation of the evolution of key characters such as the presence or absence of extra prolegs, host-plant relationships and the biogeography of the Nacophorini. It is apparent from this phylogenetic evidence that the development of extra prolegs in geometrids may be a labile character, subject to independent reversals in several geometrid lineages. The relationship of the Tasmanian Archiearinae with the Nacophorini is very well-resolved and provides an interesting case-study in insect-host plant relationships. The phylogeny of the global Nacophorini is explained by Gondwanan fragmentation. Furthermore apparent close relationships between the American Nacophorini and another Nearctic ennomine tribe can be explained by recent dispersal of Neotropical taxa to North America.

Phylogeny of the Australian Geometridae

CJ Young
Department of Primary Industries, Water and Environment, 13 St Johns Ave, New Town, Tasmania, 7008, Australia, Cathy.Young@dpiwe.tas.gov.au.

The Australian endemic Ennominae, frequently postulated as a possible primitive group within the Geometridae, was described and characterised using material from all stages of the life cycle. These descriptions were used as a basis for the construction of a morphological phylogeny for the Australian Ennominae in the context of the world fauna. Sequences from two nuclear gene fragments were also used to construct a molecular phylogeny in order to more confidently propose a robust evolutionary pathway for the Australian Geometridae. Phylogenetic trees obtained from all data sets recovered almost identical, supported relationships. The major findings from these analyses were as follows (a) The Epanidae as sister group to the Geometridae; (b) The Larentiinae as basal within the Geometridae; the Sterrhinae as the penultimate basal group, except that in the morphological analysis this relationship is reversed so that the Sterrhinae are basal; (c) The Oenochrominae s. str. as sister group to the Geometrinae; (d) The Ennominae as not monophyletic; (e) The Tasmanian Archiearinae as misplaced in the Archiearinae and with close affinities to the Australian Nacophorini; (f) The Australian Nacophorini as not monophyletic. These results were at odds with traditionally held beliefs on the origins of the Geometridae.

Phylogeny of the Gelechioidea: Evolution of larval food substrate use

L. Kaila
Zoological Museum, Finnish Museum of Natural History, P.O.Box 17, FI-00014 University of Helsinki, FINLAND, lauri.kaila@helsinki.fi

The phylogeny of the lepidopteran superfamily Gelechioidea was estimated using 193 characters derived from larval, pupal and adult morphology and larval ecology. 143 species represented the diversity of the putative Gelechioidea in the analysis, and further 13 species representing three monotrysian and eight other ditrysian families were included to test the monophyly of the Gelechioidea. The Gelechioidea was nested within Apoditrysia instead of being its sister group as previously suggested. The well-resolved cladogram suggested a largely different concept of interrelationships of constituent gelechioid families as compared to other studies. The Gelechioidea was basally divided into two main lineages, herbivory as the ancestral larval feeding strategy of one, and, depending on character optimization, either saprophagy or herbivory of the other. Therefore it is not possible to unambiguously determine which of these traits is the ancestral one in the Gelechioidea. It is also sometimes questionable whether such a classification of the food substrate can be applied, .e.g. if the larva uses dry seeds and other dry vegetable matter. Detritivory/fungivory may have evolved only twice within Gelechioidea, though the evolution of larval food substrate use has been quite dynamic with frequent reversals.

Systematics of parasitoids (Hymenoptera: Chalcidoidea) of the Emerald Ash Borer ,*Agrilus plannipennis* (Buprestidae).

M Gates and M Schauff
"Systematic Entomology Lab., USDA, Bldg. 005, Rm. 133, BARC-W, Beltsville, MD 20705. Mschauff@sel.barc.usda.gov"

In May 2002, an unknown species of beetle was reported by researchers to be attacking and killing at least 3 of the 4 native species of ash trees (*Fraxinus spp.*) in southeastern Michigan. The species was subsequently identified as the Emerald Ash Borer (EAB), *Agrilus planipennis* (also known as *Agrilus marcopoli*) on July 08, 2002. Extensive mortality of ash trees attributed to EAB has been reported in the Detroit area of Michigan and it appears to be a damaging pest to trees growing in both urban and forested sites. Researchers at the U.S. Forest Service and Michigan State University have reared two parasitoids (Hymenoptera: Chalcidoidea) of EAB from a study plot in Livonia, Michigan, USA. We received representative specimens of these parasitoids for identification and determined them to be *Balcha* sp. (Eupelmidae) and *Pediobius* sp. (Eulophidae). Both species are believed to be undescribed. The *Pediobius* species is a parasitoid of ash borer eggs while the *Balcha* attacks *Agrilus* larvae. Foreign exploration is continuing to try to find additional parasitoids. Details of the systematics and biology are given.

An interactive key to *Liriomyza* parasitoids in South East Asia

N Fisher, R Ubaidillah, P Reina, J La Salle
CSIRO Entomology, GPO Box 1700, Canberra, ACT 2601, Australia; john.lasalle@csiro.au

Invasive *Liriomyza* species are a severe pest in South East Asia, affecting a variety of vegetable and ornamental crops. An interactive, multiple entry key, using Lucid software, has been developed for identification of indigenous parasitoids of SE Asian vegetable leafminers. This key will support activities aimed at sustainable management of these pests. The key includes 20 species from 4 families (Braconidae, Eucoilidae, Eulophidae, Pteromalidae). Species pages are provided for all species, which give information on: classification, diagnostic characters, distribution, hosts, biology, comments and references. Additional information pages are presented for each family, subfamily, and genus. A tutorial section is included to facilitate the use of the key.

Non-destructive investigation of the internal anatomy of insects utilising high-resolution X-ray computed tomography

T Hoernschemeyer, J Goebbels
Institute for Zoology and Anthropology, Dept. Morphology and Systematics, Berliner Str.28 D-37073 Göttingen, Germany; thoerns@gwdg.de.

The investigation of the internal anatomy of insects involves very time consuming processes of preparation and usually results in the destruction of the specimen. Nevertheless, detailed knowledge of insect anatomy is indispensable for many research areas like phylogenetic investigations, parasitology, etc. During recent years the authors optimised the application of high-resolution X-ray computed tomography (µCT) for the study of the anatomy of small insects. This method has a number of advantages over methods like serial-sectioning and free-hand preparation: Due to the very simple preparation and the fast and artefact-free data sampling it is possible to investigate a large number of specimens in very short time. This, e.g., allows for studies of intra- and inter-specific variation of internal structures. Further more, the specimen remains intact, which is very important for valuable specimens like holotypes. The data sets are easy to handle and it is possible to produce virtual sections in any desired cutting plane from one data set. Also the preparation of virtual (and real) 3D models is straightforward, since there are no deformed or missing sections. The 3D models are excellent tools for teaching insect anatomy. Here the preparation of specimens, the data-acquisition, and some examples of data handling, interpretation and presentation are demonstrated.

Tracking specimens, taxonomic nomenclature, & literature in Mandala

GE Kampmeier, ME Irwin
Illinois Natural History Survey and University of Illinois, 1101 W. Peabody Drive, Urbana, IL 61801, USA; gkamp@uiuc.edu

Mandala is a Windows and Macintosh-compatible data management system designed in FileMaker Pro to support four major realms of data acquisition and management for systematics and biodiversity studies: specimens, literature, taxonomic names, and illustrations. Development began in 1995 as part of a US National Science Foundation PEET project on the fly family, Therevidae, and has progressed into the current feature-rich system that is freely available upon request. Mandala details the complex history of taxonomic names; exports data for phenological plots, specimens examined lists, and distribution maps; links to GenBank records; tracks museum loans and batches of organisms; catalogues images and illustrations; stores and links literature to appropriate taxonomic names, specimens, illustrations, and collecting localities; and records numerous details about individual specimens including a literal transcription of the label(s), enhanced locality and collecting event data as interpreted from the label(s), taxonomic determination history, physical condition of the specimen and how it has been preserved, ecological/biological associations with other collected specimens or other taxa associated but not collected, and type designation. Mandala also features context sensitive help, electronic problem management, and tracks structural changes made to Mandala's architecture. Mandala is a powerful tool packed with features waiting to be exploited.

Pipilika: an identification and information system for the ant fauna of India

M Zacharias, P Dharma Rajan
ATREE, No. 659, 5th A main, Hebbal, Bangalore –560 024, India; priyan@atree.org

Pipilika is a digital key for identification of ants of India featuring a minimum technical language is provided to assist the identification of all subfamilies and genera. The sources of information for the development of this key are diverse, ranging from C.T. Bingham's work on the Indian ant fauna, to works and collections of various myrmecologists and individual researchers from India and overseas. This is the first attempt to provide a digital checklist for the fascinating and diverse Indian ant fauna. The user-friendly software is an innovative and comprehensive program that enables one to make accurate identification of ants. The most important diagnostic attributes (characters) are used to describe a taxon. Hence, each taxon has a unique combination of characters assigned to it. It prompts the user to answer a series of questions about the specimen that needs to be identified. These questions have choices, which are made on screen from text. Then, through a process of selection, the key interprets the user's answers to reach an identification of the specimen. Each subfamily and genus includes information on its biology, identification and distribution, illustrations and a summary of publications dealing with the subfamily and genus.

An interactive key to sharpshooter genera of the tribe Proconiini (Hemiptera: Cicadellidae)

DM Takiya, DA Dmitriev
Center for Biodiversity, Illinois Natural History Survey, 607 East Peabody Drive, Champaign 61820, IL, USA; takiya@acd.ufrj.br

The New World Proconiini comprises approximately 350 species in 56 genera, all potential vectors of the bacterium *Xyllela fastidiosa* causing diseases of over 20 economically important plant species. The last taxonomic revision of the tribe (Young 1968: *Bull. U.S. Nat. Mus.* 261) contained a dichotomous key to genera. Since this revision, one additional genus has been described, two are in manuscript format, and at least three should be transferred to this tribe. Several steps in Young's key emphasize characters that are subjective (e.g., claval veins fused almost throughout their length), variable (e.g., *Pseudophera* species smaller than 16 mm will key to *Homalodisca*), or from the male genitalia of difficult study by non-specialists. An Internet-based interactive generic key will update and facilitate the identification of this economically important leafhopper group by enabling users to choose characters in any order and providing illustrations explaining each character states. A list of all species, photographs of over 100 species, and bibliography are also included. The key was developed using the software package 3I (Internet-accessible Interactive Identification) composed of a MS Access database and ASP pages for Internet publishing developed by the junior author. The key is still under construction and hosted at http://ctap.inhs.uiuc.edu/takiya.

Acridoidea fauna of Brazillian Amazonia

CV Assis-Pujol, CMA Santos
Museu Nacional - Universidade Federal do Rio de Janeiro. Quinta da Boa Vista, São Cristóvão, 20949-040, Rio de Janeiro, RJ, Brazil; cpujol@acd.ufrj.br

The superfamilly Acridoidea (Orthoptera) is considered of economical importance because its species may cause enormous damages to the cultivations and sometimes destruct entire crops. The knowledge of this species, its taxonomy and geographical distribution are of great importance to the science. With the purpose to increase the knowledge of this superfamilly, a list of the species from the Brazilian Amazonia was elaborated. To complement this work, the taxonomy and geographical distribution of the species are bring up to date, as well as the location of the types and principal bibliographical records. Until now the list comprises six families, twelve subfamilies, one hundred and sixty-four genera and five hundreds and forty-nine species. The numbers show the great diversity of Acridoidea in this area, one of the most riches in grasshoppers. A major part of the species listed are deposited in the collection of Museu Nacional – UFRJ and are originated from collects realized by staff of this museum, others were donated from others collections or were included based on information from bibliographical records.

A review of the Southern African Acroceridae (Diptera) with particular reference to the endemic genus *Psilodera* Gray

DA Barraclough, CM Conway
School of Life and Environmental Sciences, University of KwaZulu-Natal, Durban, 4041, South Africa; barracloughd@nu.ac.za

The recognized Southern African fauna of Acroceridae is reviewed (10 genera – *Astomella*, *Corononcodes*, *Pterodontia*, *Stenopialea*, *Africaterphis*, *Thyllis*, *Acrocera*, *Ogcodes*, *Psilodera*, *Sabroskya*); their life history discussed and gaps in the literature highlighted for future investigation. One of the two endemic genera, *Psilodera* Gray, is assessed in more depth. The nine named species of *Psilodera* are large, conspicuous flies that appear to be the only long-proboscid acrocerids in Africa. Two strongly defined species-groups (*fasciata* group with five species and *bipunctata* group with four species) are suggested from this ecologically interesting genus, using characters such as the genitalia, not fully explored previously. The *fasciata* group includes species with a dark thorax and abdomen, and minutely branched pile, while the *bipunctata* species have a patterned thorax and abdomen and simple pile. The more clearly understood pollination activities of adults are given. They pollinate three endemic *Plectranthus* species (*P. ciliatus, P. hilliardiae* and *P. zuluensis*) as well as species of *Impatiens*, *Gladiolus* and *Aeolbnthus*. The known distribution of the *fasciata* group includes all of South Africa (the arid Northern Cape excepted) and the esatern highlands of Zimbabwe. The *bipunctata* group is found in the southern and eastern coastal provinces of South Africa.

Atlas of the butterflies of the Iberian peninsular and Balearic Islands

J Martin Cano, E García-Barros, ML Munguira, P Garcia-Pereira, H Romo, E Maravalhas
Departamento de Biología, UAM, 28049 Madrid, Spain; jose.martin.cano@uam.es

The Atlas is the first referred to the distribution of the butterfly species of the Iberian Peninsula and Balearic Islands. The maps use the UTM system with a 10 x 10 km grid. The Atlas has been produced by research teams from Spain and Portugal have taken part of it. In the making of the Atlas we started compiling a database (ATLAMAR1) with the distribution data on Iberian butterflies. Each record in the database contained at least four fields: 1) name of the species, 2) name of the locality in which it had been recorded 3) reference to the UTM grid system using 10 km squares and 4) identification of the source from which the information came (publication, collection, etc.). For ATLAMAR 1 we have gathered a total of 292000 records. Data come from three different sources: 1) bibliographic information, 2) data from collections and 3) unpublished data from the authors and collaborators. Bibliographic information represents approximately 73% of the records, and is based on the revisión of more than 1500 references in journals and books. These data gather information on at least 421500 butterfly specimens. We estimate that a 98% of the relevant bibliographic information has been compiled for the project. Collections represent around 37000 records, and another 45000 records come from unpublished data.

A complete beetle fauna on the web: Mauritius as a model case

S Motala, FT Krell, S Ganeshan, A Raman, V Florens, Y Mungroo, L Winder
Soil Biodiversity Programme, Department of Entomology, The Natural History Museum, Cromwell Road, London SW7 5BD, U.K.; f.krell@nhm.ac.uk

Mauritius is a tropical, mountainous island in the Indian Ocean of 1865 km^2. Its beetle fauna comprises around 1020 species and has been covered by a comprehensive catalogue of Vinson (1956-1962) and recently by a synoptic list by Yves Gomy (2000). Keys and illustrations are available for only a few small groups. Jean Vinson deposited 1480 specimens of his beetle collection in The Natural History Museum, London, in 1972. On the basis of these specimens and additional material to be collected within the Darwin Initiative Programme 'Rediscovering neglected insects of Mauritius: building in-country capacity', we compile a web-based catalogue of the complete Mauritian beetle fauna, illustrated by colour photographs of each available species, and accompanied by references on economic importance and ecology of the species. This will be the first web catalogue of a complete beetle fauna on an up-to-date taxonomic basis and might serve as a model case for similar, larger-scale projects.

Taxonomic survey of the South-East Asian Ethmiidae (Lepidoptera)

A Kun
Hungarian Natural History Museum, Department of Zoology, H-1088 Budapest, Baross u. 13, Hungary; kuni@zoo.zoo.nhmus.hu

The genus *Ethmia* is cosmopolitan, more than 40 species were shown from the south-eastern Palaearctic. The Ethmiid fauna of China is known as the richest within this region with 33 formerly recorded taxa; by comparison 11 have been recorded from India, 6 from Nepal, 9 from Japan, only three from Korea, 7 from the Philippines and 14 from Australia. In the last few years several Hungarian lepidopterists worked intensively in different regions of South East Asia, including Taiwan, Vietnam, Pakistan, South Korea, and Thailand. Due to the effective methods used in these expeditions, a large material of Ethmiinae containing more than 300 individuals has been collected during the last five years. As a result of the treatment of this material and of the collections of the British Museum (Natural History), London; Zoologische Staatssammlung München; Staatliches Museum für Tierkunde, Dresden; Landesmuseum für Naturkunde, Karlsruhe; Witt Museum, München; Taiwan Forestry Research Institute, Taipei; Center for Insects Systematics, Kangwon University, Chuncheon, Korea; National Institute of Agricultural Science and Technology, Suwon, Korea; the Hungarian Natural History Museum, Budapest, as well as the survey of the literature data, further 11 *Ethmia* species were described as new to science, with taxonomic comments and corrections. The Ethmiid fauna of the region is, however, still not well-explored and several taxonomic novelties are expected from the continuation of the research.

A faunistic analysis of Chinese phorid flies (Diptera: Phoridae)

G Liu, H Fang
"College of Biological and Environmental Engineering, Shenyang University, Shenyang 110044, China; liugc18@mail.sy.ln.cn "

The Phoridae fauna in China is zoogeographically heterogeneous due to the geological diversity of this region. On basis of our collection, the Chinese phorid flies are grouped into three principal complexes: Palearctic, Oriental and Boundary complexes. Species in Northeastern, Northern China and Xinjiang-Mongolia region are included in Palearctic complex, which mainly belong to Palearctic elements. The species composition in Xinjiang-Mongolia region is more similar to central Europe type than that in Northeastern- and Northern China. Species in Centro-China, South-China and West-southern China area belong to Oriental complex. This complex is rich in species. More than 50% of record species of China belong to the complex. Some of species spread to Palearctic region, for example, Diplonevra peregrina (Wiedemann). The Qing-Zhang plateau is the boundary of Oriental and Palearctic region. More than 3000m-altitude constitutes a special ecological environment. Species in the region are morphologically distinguished from others and comprise a special complex.

An overview of the phylogeny of the Brentoid Complex (Col.: Curculionoidea)

MA Alonso-Zarazaga, A Sforzi, M Wanat
Depto. de Biodiversidad y Biología Evolutiva, Museo Nacional de Ciencias Naturales-CSIC, José Gutiérrez Abascal, 2, E-28006 Madrid, Spain; zarazaga@mncn.csic.es

The so-called Brentoid Complex includes a group of taxa which are thought to be evolutionarily intermediate between the "lower" weevils (Nemonychidae to Attelabidae) and the "higher" weevils (Brachyceridae to Curculionidae). The complex seems to have originated in Gondwana. The status of the included groups is much disputed: Ithyceridae, Brentidae (+ Cyladinae), Eurhynchidae, Apionidae (+ Antliarhininae) and Nanophyidae. Carina has also been related to this group. While most of these groups seem to be clearly monophyletic on morphological grounds, their relationships inside this complex or even whether this complex is monophyletic are not clear. Current analyses of morphology and DNA sequences are contradictory. Wanat (2001), after a thorough cladistic analysis of morphological data, concluded that the families Brentidae (including Cyladinae), Caridae, Nanophyidae, Eurhynchidae and Apionidae (incl. Antliarhininae) are well supported. Ithyceridae have been placed (Marvaldi & Morrone 2000) as a subfamily of Curculionidae. Oberprieler (2000) and Marvaldi (2002) exclude the Carinae from the Brentidae. Nanophyidae were related by Zimmerman (1993) to the most primitive of the "higher" Curculionoidea (his Heteromorphi). However, promising preliminary molecular data by the senior author relate Caridae to Nanophyidae as part of this complex. The internal phylogeny of the diverse family Apionidae is also matter of debate.

Unity of Psychodomorpha? The position of Trichoceridae & Anisopodidae in the system of the Diptera based on thorax morphology

DS Amorim, GC Ribeiro
Depto. de Biologia, FFCLRP/USP, Av. Bandeirantes 3900, 14.040-901 Ribeirão Preto SP Brazil; dsamorim@usp.br

The Trichoceridae have been traditionally placed in the Tipulomorpha, together with Tipulidae, Limoniidae, and Cylinotomidae. Most authors included the Anisopodidae in the Bibionomorpha. The position of both families was challenged by studies using immature morphology. From the immature features perspective, Trichoceridae and Anisopodidae fit with Psychodidae, Perisommatidae, Canthyloscelidae, and Scatopsidae into the Psychodomorpha. A detailed study of thorax morphology corroborates that Trichoceridae stands apart from the Tipulomorpha, nested into the Psychodomorpha. Synapomorphies for all Diptera except Tipulomorpha are shared by Trichoceridae, while apomorphic features shared by the Psychodomorpha families are clearly present in Trichoceridae. The Anisopodidae, however, are obviously plesiomorphic for the thorax features seen in the Psychodomorpha, it additionally shares modified characters with the Bibionomorpha families. Thorax morphology, hence, corroborates that immature information is powerful to develop a phylogenetic system for the Diptera, but at least some of the immature features are clearly subject to homoplasy. Plates of thorax morphology of basal families of Diptera are presented.

Mitochondrial gene rearrangements & the evolution of eusociality in bees

MC Arias, D Silvestre
Departamento de Biologia-IB-USP, rua do Matão 277, 05508-900, São Paulo, Brazil; mcarias@ib.usp.br

Mitochondrial DNA sequences data and, more recently, gene order have been widely used as characters to infer phylogenetic relationships. For the subfamily Apinae, phylogenetic relationships have been inferred from morphological and sequence characters, although considerable ambiguity remains. We recently sequenced the mitochondrial genome of *Melipona bicolor* and compared the gene order to *Apis mellifera*. Nine tRNA gene translocations were observed. These translocations identified between two highly eusocial species led us to investigate the mtDNA gene order among Apinae tribes. So far 10 species, representing 8 tribes, have been analyzed for all the tRNA gene positions. Several rearrangements were reported. The very conserved order D-K was present in all species excepted in *Melipona*, which had only the gene D. We expanded our analyses to 5 Meliponini genera and data showed that the presence of D and the absence of K was a very conserved character in this tribe. To better address questions concerning the origin and evolution of social behavior in Apinae, we need to obtain more data about tRNA rearrangements. In addition to investigating mtDNA gene order, we sequenced three mitochondrial genes (16S, COI and CytB). Sequence data support Meliponini and Bombini as sister taxa and a dual origin of eusociality in the Apinae.

Molecular markers in identification: lessons from the Tephritidae

KF Armstrong, GK Roderick
PO Box 84, Lincoln University, Canterbury, New Zealand; armstron@lincoln.ac.nz

Exploitation of molecular markers for the identification of tephritid species and populations has been adopted by the quarantine authorities of New Zealand, Australia and North America. The lack of morphological markers for immature life stages associated with the export of fruit and the inappropriateness of morphology for distinguishing populations within a species left managers ill equipped to monitor and control the exotic and cryptic invasion pathways of key high impact horticultural pest species, in particular the medfly and oriental fruit fly. Development of DNA markers, such as polymorphic restriction profiles and microsatellite loci, has overcome this. Now, across laboratories, the identification of around 90 species is supported by DNA markers, several of which can also be traced at the population level. This reflects a growing collaborative effort between molecular and taxonomic researchers and the regulatory authorities. Advances recently have been in a convergence of approaches, preferring to apply novel bioinformatic and statistical analyses of whole sequence data for a few common gene regions. This methodology provides a much more flexible platform on which to continue building identification profiles for additional species and populations and is aimed at superseding the previous disparity in molecular methods.

Phylogeny & homologization of genital sclerites of Neuropterida - arguments between Skylla & Charybdis

U Aspöck, H Aspöck
Naturhistorisches Museum Wien, Burgring 7, A-1014 Wien, Austria; ulrike.aspoeck@nhm-wien.ac.at

Most recent molecular and previous holomorphological cladistic analyses of Neuropterida coincide in revealing 1) Raphidioptera + (Megaloptera + Neuroptera), and 2) the suborder Nevrorthiformia as adelphotaxon of all other Neuroptera. Conflicts arise with the disruption of the suborder Hemerobiiformia into Sisyridae, Osmylidae, and a clade comprising the remaining Hemerobiiformia, and including the Myrmeleontiformia. Segment nine of male Raphidioptera with tergite, sternite, gonocoxites, styli, and gonapophyses, serves as a model of reference for homologization of male and female terminalia of all three orders. Phylogenetic relevance is obvious, conflicts derive from 1) independent/joint obliterations or modifications of sclerites, 2) parallel apomorphies in derived representatives of diverse taxa (e.g. threadlike penisfilum in certain Coniopterygidae, Berothidae, Rhachiberothidae, Mantispidae), 3) reappearance of serial homologous structures (female gonocoxites and gonapophyses as digitiform processus and flat appendices in segment eight of certain Myrmeleontidae, as wart-like processus and flat circular sclerites in segment seven (!) of certain Berothidae, gonocoxites eight as pseudosternites in certain Nemopteridae, but digitiform processus of tergite 9 as pseudogonocoxites in Rhachiberothidae).

Neighbour-joining goes the distance: a comparison of methods for analyzing DNA barcoding data

SL Ball, RH Cruickshank, KF Armstrong, PDN Hebert. Molecular Diagnostics Laboratory,
National Centre for Advanced Bio-protection Technologies, Box 84, Lincoln University, Canterbury; New Zealand.

Short DNA sequences, called DNA barcodes, have been shown to provide a highly reliable means of species identification for a diversity of animal taxa. However, there has been disagreement over the appropriateness of currently used methods for analyzing DNA barcoding data. DNA barcoding has relied upon Neighbour-joining (NJ) of Kimura-2-Parameter distances to group sequences based on sequence similarity. This distance-based approach has been highly criticized despite its extremely high success rate in species identification. Here, we compare four methods to test their suitability in barcoding data analysis. We assessed two distance-based methods (Neighbour-joining, Neighbour-net) and two character-state based methods (Maximum likelihood and Bayesian analysis) using three independent datasets. Each method was assessed for: 1) percentage of correct species identifications; 2) speed of analysis. Results showed that NJ was as or more successful (success rate = 95-100%) in correctly identifying species compared to non-distance based methods and also provided the most rapid means of analysis. Given the reliability and speed of analysis, we conclude that this approach provides a highly effective means of species identification through DNA barcoding.

A combined morphological & molecular approach to reconstruct the phylogeny of delphacid planthoppers (Hemiptera: Fulgoromorpha)

CR Bartlett, JR Cryan, C Beal
University of Delaware, Department of Entomology and Wildlife Ecology, 250 Townsend Hall, 531 S. College Ave., Newark, DE, 19717

Although the Delphacidae are the largest family of planthoppers (Fulgoromorpha), and include species of major agricultural importance; surprisingly little is known about their phylogeny. The two current competing hypotheses are morphologically based and consider delphacid phylogeny only among the higher taxa (subfamilies, tribes). Here we combine morphology and molecular techniques to reconstruct the phylogeny of delphacids with particular emphasis on the genera of Delphacini, an advanced tribe which comprises 80% of delphacid genera and 60% of species. At present, these analyses are preliminary and based primarily on taxa from Eastern North America. For these analyses, a morphological dataset and four molecular datasets (EF-1a, wingless, 18S rDNA, and 28S rDNA) were generated. Individual datasets did not provide sufficient resolution to address the phylogeny of the Delphacini. As expected from comparable analyses, non protein-encoding ribosomal DNA datasets provide most informational support for the deeper nodes of the phylogeny, while the nuclear protein-encoding genes provide greater resolution for the more recent nodes. Both kinds of molecular data show support for the morphological tree. The resultant combined consensus topology shows a series of intuitive clades, some of which imply ecological or host-based causative evolutionary mechanisms.

Structure of ovaries in apterygotous hexapods & its implications for the phylogeny of arthropods

SM Biliński, J Kubrakiewicz
Department of Systematic Zoology, Institute of Zoology, Jagiellonian University, R. Ingardena 6, 30-060 Kraków, Poland; sbili@zuk.iz.uj.edu.pl

Evolutionary relationships among extant arthropods (insects, crustaceans, myriapods, and chelicerates) are not consistently resolved and remain controversial. Traditionally, it was believed that the largest arthropod subtaxon, Hexapoda (insects and their apterygotous allies, *e.g.* springtails and diplurans) is related to myriapods. Recent molecular data have challenged this alliance in favor of a close relationship between insects and crustaceans. In this context, we have decided to reinvestigate the structure of ovaries and process of oogenesis in representatives of wingless hexapods (springtails, diplurans and proturans), lower crustaceans (branchiopods) and myriapods (symphylans). Special attention has been focused on the following characters: organization of germ-cell clusters, presence (or absence) of mesodermal follicular cells, mode of yolk formation, synthetic activity of the oocyte, presence (or absence) of a mitochondrial cloud (*i.e.* Balbiani body) and origin of egg envelopes. Obtained results support close affinity between Hexapoda and Crustacea. Moreover, we found that myriapods and chelicerates (spiders and pantopods) share important "ovarian" synapomorphies.

Evolution of extreme prey specialization in bolas spiders

TA Blackledge, CY Hayashi
Department of Biology, University of California, Riverside, CA 92521, USA; todd.blackledge@ucr.edu

Moth hunting bolas spiders construct some of the most specialized webs found within the Araneidae. These highly reduced webs are hypothesized to have evolved through a gradual reduction of the orb web within the Cyrtarachninae, which accompanied an increased specialization upon male moths as prey. However, this classic evolutionary story has never been empirically tested. We used both mitochondrial and nuclear DNA sequence data to construct a phylogeny of the Araneidae to test the monophyly of these moth specialists and to examine the pattern of evolution of bolas webs. We also compare our results with the current phylogenetic hypothesis of araneid relationships based upon morphology and behavior.

On the chemoecology of Danainae

M Boppré
Forstzoologisches Institut, Albert-Ludwigs-Universität, D-79085 Freiburg, Germany; boppre@fzi.uni-freiburg.de

Danaine butterflies have multiple relationships to plants and utilize different secondary chemicals: larval hostplants which may contain cardiac glycosides (CGs), adult nectar plants, and plants providing pyrrolizidine alkaloids (PAs) which are taken up pharmacophagously by males. Some danaines make up neat biological stories, opening one's eyes for several phenomena and giving general lessons, e.g. on individual variation of traits. However, overviewing the entire subfamily in some detail unmasks our knowledge to be quite fragmentary and shows the common view of danaines to be full of incorrect paradigms and of speculations. CGs and PAs are both protective – but likely against different types of predators. Are CGs or PAs the basis for Batesian and Mullerian mimicry associations? Where lies the origin of the relationships to PA-plants? What drives elaborate sexual communication, what speciation? Open questions are many and multifold. Comparing the chemoecology of danaines (and combining morphological, ecological and chemical data) with those of arctiine moths reveals interesting parallels and similarities and challenges evolutionary hypotheses.

Molecular phylogeny of the Pieridae (Lepidoptera: Papilionoidea): systematics, higher classification & host plant associations

MF Braby, NE Pierce
Museum of Comparative Zoology, The Australian National University, Canberra, ACT 0200, Australia; michael.braby@anu.edu.au,

Characters from the nuclear gene *Elongation Factor*-1 *alpha* were used to reconstruct the phylogeny of the butterfly family Pieridae. The sample included 86 species representing all but five currently recognised genera. 364 of the 1066 sequenced bp (34%) were parsimony informative, with most variable sites in the third codon position. The strict consensus of nine equally MP trees recovered four clades, plus two smaller, less well supported groups, and these show concordance with a higher-level classification based primarily on morphological characters. We use these data and others from the literature to present a revised classification of the Pieridae in which the Pierinae is divided into three tribes (Anthocharini sens. strict., Pierini sens. strict., Aporiini) and two informal groups (*Eronia* group, *incertae sedis*). The topology of our cladogram suggests the following evolutionary relationships among the higher taxa: Coliadinae + (*Eronia* group + ((Pseudopontiinae + Dismorphiinae) + (Anthocharini + (Pierini + Aporiini)))). Our data show that host plant use is correlated with phylogenetic relationship, with Brassicales feeding evolving once, Fabales feeding evolving at least twice, and Santalales feeding evolving independently three times as a derived state. The ancestral food plant was most likely Fabales, and host shifts appear to facilitate adaptive radiation within the family.

Phylogeny & the Evolution of Wings in extant Phasmatodea (Insecta: Polyneoptera)

S Bradler, MF Whiting, JA Robertson
Institut für Zoologie und Anthropologie, Berliner Strasse 28, D-37073 Göttingen, Germany; sbradle@gwdg.de

The Phasmatodea (stick and leaf insects) have recently been subject to several phylogenetic analyses, based on both morphological and molecular data. While a sister group relationship of the Nearctic genus *Timema* to all remaining Phasmatodea, the Euphasmatodea, has appeared uncontroversial, the primary internal splits of the Euphasmatodea remain debatable (Bradler et al. 2003 Ent. Abh. 61: 132-133). The first molecular analysis based on 18S rDNA, 28S rDNA and histone 3 sequence data proposes that several wingless taxa form the basal lineages of extant phasmids (Whiting et al. 2003 Nature 421: 264-267). This well supported finding implies that the ancestral phasmid lacked wings, followed by a long diversification of wingless taxa and multiple derivations of wings during phasmid evolution. Consequently, wings must have been recovered in those clades that contain fully winged or brachypterous species. The controversial assumptions regarding the phylogenetic relationships among basal phasmids highlight the need for future research. New phylogenetic trees inferred from morpho-anatomical characters of the adult form and egg capsule, additional molecular markers, and a larger taxonomic sampling (~100 species) are presented.

A New Family of Chrysidoid Hymenoptera from New Jersey Cretaceous Amber

DJ Brothers
School Of Botany And Zoology, University Of Kwazulu-Natal, Private Bag X01, Scottsville Pietermaritzburg, 3209 South Africa; brothers@ukzn.ac.za

Two conspecific specimens of aculeate wasps found in Late Cretaceous amber from New Jersey (USA) cannot unambiguously be assigned to any known family. Features of the wing venation, mesosoma and mandibles indicate that they clearly belong in the Chrysidoidea. The wing venation is more complete than in any other member of the superfamily, but does not show the development of RS2 (as found in Plumariidae) sometimes considered to be primitive. The antennae have sparse long erect setae similar to those found elsewhere only in Plumariidae, and the pronotum is similar to that in Plumariidae and Scolebythidae. Cladistic analyses of the fossil in various combinations with the genera of Plumariidae, with groundplans for the families of Chrysidoidea and with the families of Aculeata, and using different character sets as appropriate, produced trees of similar length, with the fossil as the basalmost taxon in Chrysidoidea, the basal taxon within Plumariidae or as a taxon originating immediately after Plumariidae (and so sister to all other chrysidoids). The last topology (Plumariidae + (fossil + (Scolebythidae + (Bethylidae + Chrysididae) + (Sclerogibbidae + (Embolemidae + yinidae)))) was most often the most parsimonious and therefore preferred. It is thus proposed that the fossil taxon be recognised as a new family.

Molecular systematics of mimetic butterflies

A Brower
Dept. of Zoology, Oregon State University, Corvallis, OR USA; browera@science.oregonstate.edu

Since the time of Bates and Müller, the study of mimicry has advanced both theoretically and experimentally. Study of the taxonomy of butterflies was what led Bates to his discoveries in 1862, and as our work advances in this area, so do patterns of mimetic convergence become ever more complex. The molecular systematics of Heliconiina and Ithomiini will be reviewed. To a large extent, DNA evidence corroborates prior hypotheses based on morphology, but there are still controversies to be resolved and surprises yet to be revealed.

Moss bugs (Hemiptera: Peloridiidae): Systematics & biogeography

D Burckhardt
Naturhistorisches Museum, Augustinergasse 2, CH-4001 BASEL, Switzerland; daniel.burckhardt@unibas.ch

Moss bugs or peloridiids constitute the only extant family of Coleorrhyncha, the sister group of Heteroptera or true bugs. The family has attracted a lot of attention due to its phylogenetic position within the Hemiptera, its Gondwana distribution as well as the scarcity of available specimens. Based on important collections the internal taxonomy and phylogeny was investigated. Seventeen genera are recognised containing almost 30 species. A cladistic analysis with using 28 adult morphological characters yielded 3 most parsimonious trees. The biogeographic analyses suggest that Peloridiidae diversified together with the break-up of Gondwana (New Zealand/New Caledonia, (South America+Australia). The position of New Caledonia is within and not sister to the New Zealand clade as is suggested by geology. Of particular interest is a taxon from Lord Howe Island which is closest related to a Northern Queensland genus.

Molecular evidence on phylogenetic relationships among major lineages of Pterygota

MF Whiting, M Terry, TH Ogden, GJ Svenson, K Jarvis, SL Cameron
Dept. of Integrative Biology, Brigham Young University, Provo, UT, 84502, USA

Molecular data combined with morphology are leading to robust hypotheses for cladogenetic events among the basal pterygote lineages, and providing new insights into the diversification of insects. Multiple genetic markers from an extensive sampling of taxa were used to evaluate the monophyly of Paleoptera and to propose a phylogenetic hypothesis for the basal neopterous insect orders (="Paleoptera"), including the phylogenetic placement of Mantophasmatodea. Results from extensive phylogenetic analyses of the orders Ephemeroptera, Odonata, Plecoptera, Mantodea, Dermaptera, and Grylloblattodea will be presented.

Phylogenetic utility of mitochondrial genomes in resolving insect interordinal relationships

SL Cameron, SC Barker, MF Whiting
Dept. of Integrative Biology, Brigham Young University, Provo, UT, 84602, USA

The phylogenetic utility of the mitochondrial genome includes two main approaches – use of shared gene rearrangements as molecular synapomorphies and the use of sequence data in "traditional" phylogenetic analysis. In resolving the interordinal relationships of insects, gene rearrangements are virtually worthless; rearrangements whilst not uncommon do not unite any orders and are commonly variable within orders. The use of gene rearrangement data in resolving lower level relationships will be discussed. In contrast use of the mt genome sequence data in phylogenetic analysis shows considerable promise as a phylogenetic marker at the interordinal level. A phylogeny of insect orders using mitochondrial genome data will be presented.

Biodiversity, host plant associations & biogeography of the Heteroptera of continental Australia

G Cassis
Centre for Biodiversity and Conservation Research, Australian Museum, 6 College St, Sydney, 2010, Australia; gerryc@austmus.gov.au

The true bugs of Australia are both diverse taxonomically and highly endemic. The true bug fauna is currently represented by 2000 species, within 64 families and almost 800 genera. In terms of percentage of true bug species richness globally, the Australian fauna is only 5% of the global estimate of 40,000 species. However, the Australian fauna is likely to be less than 50% described, with families such as the Miridae represented by at least another 1000 new species. In addition, the endemicity of the Australian fauna is extremely high, with 50% of the genera and 80% of the species found only in Australia. The diversity of true bugs is information exists regarding their host plant associations. These bugs have particularly close relationships with rosid and asterid angiosperms, suggesting a temporal correlation with the diversification of the angiosperms in the Cretaceous. The pentatomomorphans are often found in association with the "big two" of the Australian flora – *Eucalyptus* sensu lato and *Acacia* – and there is significant overlap in their distribution, both in terms of species richness and endemism. In addition, to these landscape patterns, the origins of the Australian true bug will be discussed in terms of historical biogeography.discussed in terms of host plant associations and biogeography. For the Pentatomomorpha, considerable

Phylogenetic position of the Hymenoptera within the Holometabola using entire mitochondrial genomes

LR Castro, M Dowton
Department of Biology, University of Wollongong, NSW 2522, Australia; lrc89@uow.edu.au

We sequenced the mitochondrial genome of the sawfly *Perga condei* (Insecta: Hymenoptera: Symphyta: Pergidae) and tested different models of phylogenetic reconstruction in order to resolve the position of the Hymenoptera within the Holometabola, using entire mitochondrial genomes. The mitochondrial genome of *Perga condei* had less compositional bias and slower rates of molecular evolution than the honeybee, as well as a less rearranged genome organization. Phylogenetic analyses showed that, when using mitochondrial genomes, both adequate taxon sampling and more realistic models of analysis are necessary to resolve relationships among insect orders. Both parsimony and Bayesian analyses performed better when nucleotide instead of amino acid sequences were used. In particular, this study supports the placement of the Hymenoptera as sister group to the Mecopterida.

Towards an evolutionary history of tortoise and leaf-mining beetles: systematics, major events & diversity (Coleoptera: Chrysomelidae: Cassidinae *sensu lato*)

CS Chaboo

Division of Invertebrate Zoology, American Museum of Natural History, Central Park West @ 79th St., New York, NY, 10024-5192; tortoisebeetles@excite.com

Systematics research in Cassidinae *s. l.* has been focused on three fundamental questions: their monophyly, position within Chrysomelidae, and internal relations. Borowiec (1995), Hsiao and Windsor (1999) and Chaboo (in press) addressed these issues. Their results are briefly compared. These studies help narrow the range of phylogenetic hypotheses and provide a historical context for evaluating evolutionary patterns in Cassidinae *s. l.* Evolutionary models using character mapping are developed to explain general trends and major innovations in cassidine diversification. Alteration of the adult head from prognathous to hypognathous appears in the early stages of their evolution. Compaction of the body, legs and elytral locking mechanisms are recurrent themes in adult morphology. Cassidine ecological guilds represent changes in life cycles, mouth morphology, and specialization on particular groups of host plants and specific parts of hosts (stem, leaf, or flowers). Fecal shields represent a crucial landmark in cassidine history. They are correlated with morphological innovations in larvae (urogomphi and anus) and pupae (urogomphi) and their appearance coincides with the transition from leaf-mining to open exophagy. A major radiation of ~3000 species followed the origin of shields.

Revision of the genus *Bambusiphaga* (Homoptera: Delphacidae) from Oriental Region, with descriptions of two new species

XS Chen, AP Liang
Institute of Entomology, Guizhou University, Guiyang, Guizhou Province, 550025, P.R. China; xschen@tmail.gzu.edu.cn

The oriental planthopper genus *Bambusiphaga* Huang and Ding, 1979, feeding exclusively on Bambusoideae, is revised. Eighteen species were recorded formerly in the world, distributed mainly in China (16 species), Singapore (2 species), Malaysia (2 species), Philippines (1 species) and Northeastern Himalaya (1 species). In the present paper, 2 new species are described and illustrated in detail: *B. maolanaensis* Chen *et* Liang, sp. nov. and *B. pianmaensis* Chen *et* Liang, sp. nov.. Based on the characters of male genitalia, 20 species are divided into 7 groups of species. Two new synonymies are reported: *Malaxa herioca* Yang, 1989 is a junior synonym of *Bambusiphaga facia* Huang *et* Tian, 1980 and *Bambusiphaga latispina* Qin *et* Yuan, 1999 is junior synonym of *B. bakeri* (Muir), 1919. One new combination is proposed: *bakeri* Muir, 1919 is transferred from *Malaxa* Melichar to *Bambusiphaga* Huang *et* Ding. A key to the 20 species of *Bambusiphaga* is provided.

Biodiversity & ecology of marine water-striders (Gerromorpha)

L Cheng
"Scripps Institution Of Oceanography, University Of California, La Jolla, CA 92093-0202, USA;
lcheng@ucsd.edu"

At least five families of Gerromorpha are found in various marine environments: -

1. Gerridae, with ca.700 described species, comprise more than 80 species (number in brackets) in 9 genera and 3 sub-families: Halobatinae – *Asclepios* (3), *Halobates* (46); Trepobatinae – *Pseudohalobates* (1), *Rheumatometroides* (8), *Stenobates* (10), *Stenobatopsis* (1), *Telmatometroides* (1), *Thetibates* (2); Rhagadotarsinae – *Rheumatobates* (11)
2. Hebridae, a small family, has only 2 *Hebrus* species found in mangrove areas in Singapore.
3. Hermatobatidae, an exclusively marine monotypic family, has 8 or 9 known *Hermatobates* species inhabiting coral rubble or rocky intertidal shores.
4. Mesoveliidae, another small family, is represented by four genera, *Darwinivelia* (3), *Mesovelia* (4), *Nereivelia* (1) and *Speovelia* (2). Little is known about their ecology.
5. Veliidae, with ca. 880 described species, comprise at least 81 species in 9 genera and 4 subfamilies: Haloveliinae – *Halovelia* (33), *Haloveloides* (13), *Xenobates*(20); Microveliinae – *Husseyella* (3), *Microvelia* (4), *Xiphoveloidea* (1), *Mangrovelia* (1); Rhagoveliinae – *Trochopus* (5); Veliinae – *Paravelia* (1).The Australasian region has an especially rich diversity of marine water-striders. The ecology of representative species will be discussed.

Creophilus (Coleoptera: Staphylinidae): phylogeny & historical biogeography

DJ Clarke, MK Thayer, AF Newton
"Field Mus. Nat. Hist., 1400 S. Lake Shore Drive, Chicago IL 60605, USA; dclarke@fieldmuseum.org"

The genus *Creophilus* Leach (Coleoptera: Staphylinidae: Staphylininae) contains 12 species worldwide, divided into the *C. maxillosus* (5 species), and *C. erythrocephalus* (7 species) species groups. This division also characterizes a biogeographical split within the genus corresponding approximately to Wallace's line: The *C. maxillosus group* is widespread throughout Europe, Asia, North and South America, and Madagascar while the *C. erythrocephalus* group is entirely austral. However the two groups overlap in Indonesia. Identification of synonymy and investigation of potentially new species from oceanic islands has helped stabilize the taxonomy. With a sound taxonomic framework a phylogeny of *Creophilus* is presented to determine if the two groups are monophyletic, and to assess the biogeographical implications of the phylogeny. More than 40 characters have been discovered that support the monophyly of *Creophilus* and the two species groups, both of which also share distribution patterns exhibited by many disparate groups. The combined phylogenetic and biogeographic analysis will determine which group is basal within *Creophilus* and hence determine the biogeographic origins of the austral species (ancestral versus derived), and to what extent vicariance or dispersal are sufficient to explain observed distribution patterns. The biogeography of the New Zealand species is emphasized.

Bat-moth interactions: tiger moth calls & acoustic mimicry?

WE Conner, N Hristov, J Barber
Department of Biology, Wake Forest University, Winston-Salem, NC, USA 27109; conner@wfu.edu

The interactions of insectivorous bats and their insect prey can be thought of as an evolutionary arms race. Bats evolved sophisticated high-frequency sonar and insects countered with the evolution of sonar detection devices – ears – and the ability to answer the echolocation cries with cries of their own. But why do moths answer? Are they producing sounds to startle bats, to jam their sonar, or are they warning the bats that they are unpalatable? Using a learning approach we have been able to query naïve big brown bats (*Eptesicus fuscus*) about clicking tiger moths. Our results indicated that many arctiids are indeed warning the bats of their unpalatability. In our studies the sounds produced by tiger moths are only deterrent when combined with unpalatability. Using the same learning methods we are now poised to test whether the sounds produced by tiger moths form an acoustic mimicry ring that may include other members of the Lepidoptera and sound-producing insects of several orders.

Sperm structure of Mantophasmatodea

R Dallai
"Dpt. Evolutionary Biology, University of Siena, via A.Moro 2, I-53100, Siena, Italy; dallai@unisi.it"

According to morphological characters, Mantophasmatodea are similar to the two better known stick-insects and Mantodea taxa. Sperm ultrastructure has indicated that the group is related to Mantodea, with which it shares, among other features, the presence of three connecting bands in the sperm flagellum. On the contrary, sperm structure does not support a relationship with Phasmatodea, a group with several autapomorphies. The study of spermatozoa of different species (*Karoophasma biedouwensis* and *Namaquaphasma ookiepensis*) from other regions of South Africa, kindly sent by Mike Picker, confirms the general structures described for *Mantophasma zephyra*; it allows also to identify new features not present in the previous species dealing with the peculiar chromatin condensation. Moreover, as in the previous species examined, it was established that spermatoozoa in the genital ducts and seminal vesicles are clustered in conspicuous spermatodesms consisting of hundreds of sperm cells. In these sperm bundles, the ordered sperm heads are joined by *zonulae adhaerentes*; these junctions have been established by the presence of actin filaments revealed by the positive reaction with the confocal laser-microscope, after phalloidin-rhodamine treatment.

Mantophasmatodea: genitalic morphology, species diversity, and intra-ordinal phylogenetic relationships

J Damgaard, K-D Klass
Zoological Institute and Zoological Museum, University of Copenhagen, Universitetsparken 15, 2100 Copenhagen Ø, Denmark; jdamgaard@zi.ku.dk

Presently 13 extant (all African) and 1 fossil species (European) of Mantophasmatodea are known: South African *Austrophasma* (3 species), *Lobophasma* (1 species), *Hemilobophasma* (1 species), *Karoophasma* (2 species), and *Namaquaphasma* (1 species); Namibian *Sclerophasma*, *Mantophasma*, *Praedatophasma*, and *Tyrannophasma* (1 species each); Tanzanian *Tanzaniophasma* (1 species); Baltic amber *Raptophasma* (1 species). Species distinction is based on structure/shape of clasping cerci, vomeroid (sclerotized projection above genitalia), and genitalic sclerites and projections in males, shape of subgenital plate and spermathecal bulb in females, and mottled versus striped colouration of eyes. Body colouration varies strongly in most species. Cladistic analyses using 16SrDNA and COI (*Mantophasma*, *Praedatophasma*, *Tanzaniophasma* not included) combined with tentative placement of *Mantophasma*, *Tanzaniophasma*, and *Namaquaphasma* based on genitalic morphology results in [*Tanzaniophasma* + (*Tyrannophasma* + ((*Sclerophasma* + *Mantophasma*) + (*Austrophasma* + *Lobophasma* + *Hemilobophasma* + *Karoophasma* + *Namaquaphasma*))). Further yet undescribed species have been collected in South Africa in 2003, and are included in the phylogenetic analysis. Relationships among South African genera have remained insufficiently resolved. At least the South African species are highly endemic, rarely co-occurring in the same locality.

Phylogeny of the true water bugs (Nepomorpha) based on 16S and 28S rDNA & morphology

MB Hebsgaard, NM Andersen, J Damgaard
"Dept. of Evolutionary Biology, Biological Institute, University of Copenhagen, University of Copenhagen, Universitetsparken 15, DK-2100 Copenhagen Oe, Denmark; jdamgaard@zi.ku.dk"

Morphological characters and molecular sequence data are for the first time analysed separately and combined for the true water bugs (Hemiptera-Heteroptera, infraorder Nepomorpha). Data from 40 species representing all families are included together with 2 outgroup species representing the infraorders Gerromorpha and Leptopodomorpha. The morphological data matrix consists of 65 characters obtained from literature sources. Molecular data include approximately 960 bp from the mitochondrial gene 16S and the nuclear gene 28S rDNA. The morphological dataset was analysed using maximum parsimony and the combined morphological and molecular dataset was analysed using direct optimisation (POY). The preferred phylogeny supports the monophyly of all currently recognised families of Nepomorpha, and of the superfamilies Nepoidea (Nepidae + Belostomatidae), Corixoidea (Corixidae), Ochteroidea (Ochteridae + Gelastocoridae), Notonectoidea (Notonectidae), and Pleoidea (Pleidae + Helotrephidae), but not the monophyly of the Naucoroidea (Naucoridae + Aphelocheiridae + Potamocoridae). Our hypothesis concur with Mahner (1993) in the basal placement of the Corixidae as sister group to the remaining nepomorphan superfamilies except the Nepoidea, but differ in the placement of the Ochteroidea as sister group to the Notonectoidea + Pleoidea. Finally, our analysis strongly supports a sister group relationship between the families Aphelocheiridae and Potamocoridae.

Biology & diversity of the plant-mining family Opostegidae

DR Davis
"Smithsonian Institution, Washington, DC, USA, 20013-7012; davis.don@usnm.si.edu"

Although essentially cosmopolitan in distribution, the monotrysian family Opostegidae has been poorly surveyed and studied largely due to inherent difficulties in collecting both larvae and adults. Recent studies involving mostly the Oriental and Neotropical Regions over the past five years have nearly doubled the known species. Currently 7 genera and 193 species are recognized worldwide. Monophyly of the Nepticuloidea (Nepticulidae + Opostegidae) is well supported by 9 morphological synapomorphies. The Opostegidae comprise an isolated derivative of Nepticulidae as indicated by more than 18 larval and adult synapomorphies. Only 8 species in 4 opostegid genera have been reared, half of these within the endemic Hawaiian leaf-mining genus *Paralopostega*. Plant hosts of 5 additional species have been tentatively associated. All records demonstrate a broad range of host utilization involving possibly 8 plant families dispersed among 7 dicotyledonous orders. The univoltine life cycle for Opostegidae typically consists of: a) egg deposited on host leaf, b) a brief initial linear leaf-mining phase leading to c) an extended period of stem-mining followed eventually by d) pupation in a silken cocoon in the soil. Restricted leaf-mining, as observed in *Paralopostega*, represents a derivation from the norm.

On the origin of worldwide distributions in butterflies

R de Jong
National Museum of Natural History, PO Box 9517, 2300 RA Leiden, The Netherlands; jong@naturalis.nnm.nl

The emphasis laid on vicariance to explain disjunct distributions during the last 50 years, originating from an inductive way of reasoning, has led to unlikely scenarios including derivation from Pangea as a general explanation of (semi-)worldwide distributions. A deductive way of reasoning, testing alternative scenarios, seems a more productive approach. Only scenarios differing in time frame can be tested against each other. Because of the paucity of fossil butterflies the estimation of divergence times must be derived from the application of a molecular clock. Calibration of the molecular clock is crucial. Obviously if we want to test a vicariance scenario, the age of the geological vicariance event cannot be used to calibrate the clock. If a fossil can be used, it gives an indication of the minimum age of the taxon under study. Better calibration points, but obviously only applicable in particular instances are the age of oceanic islands and the age of foodplants. In both cases we get an estimate of the maximum age for the divergence (speciation event). Examples are given from Hesperiidae, Papilionidae, Lycaenidae and Nymphalidae. The impact on understanding early butterfly diversification is mentioned.

The phylogenetic analysis of complex mitochondrial gene rearrangement characters

M Dowton, LR Castro, AD Austin
Institutes for Biomolecular Sciences, and Conservation Biology, Wollongong University, Wollongong, NSW, 2522, Australia; mdowton@uow.edu.au

The discovery of complex gene rearrangements raises analytical issues. In particular, we and others have documented the situation wherein related taxa have one of a number of gene rearrangement variants. These have been variously and inconsistently interpreted as independent rearrangements, as a single, general rearrangement, or as a series of intermediates. No empirical data have yet been directed at assessing which of these approaches most closely mirrors biological reality. We assessed this issue amongst a group of braconid wasps at the cytochrome oxidase II/ATPase 8 gene junction, which ancestrally contains the tRNA genes for lysine and aspartate. Initial screening of this mitochondrial region revealed two variants of what appeared to be a compound rearrangement – some braconid wasps had the aspartate tRNA gene inverted, others had both the aspartate tRNA gene inverted and the histidine tRNA gene translocated to this gene junction. An independent analysis of phylogeny (16S, 28S, morphology) resolved each variant as belonging to discrete monophyletic groups, along with other braconids that retain the ancestral genome organization. This study indicates that the only analytical approach that would have resolved phylogeny consistent with the independent data is to treat these two variants as separate unordered characters.

Phylogeny of Chrysomelidae based on two molecular markers & morphological characters

CN Duckett, JJ Gillespie, CAM Reid, DP Duran, KM Kjer
"Smithsonian Institution, NHB MRC105, P.O. Box 37012, Washington, DC USA 20560-7012; duckett.catherine@nmnh.si.edu"

The Chrysomelidae are one of the largest families of beetles and although there are many published hypotheses for the relationships among the subfamilies, their relationships continue to be controversial. A phylogeny of Chrysomelidae using representative taxa from all subfamilies and based on 18S and 28S-D2 molecular markers and morphology is presented and discussed. Megalopodidae and Orsodacninidae are studied as outgroups. Phylogenetic analyses are performed using parsimony and maximum likelihood techniques. Support for the monophyly of well-recognized taxonomic groups is discussed and evaluated in light of recent literature. Phylogenies resulting from separate and combined analyses of each data set are presented; the 18S data set is not ideal for resolving the relationships among the subfamilies of Chrysomelidae. The hypothesis that the chrysomelid radiation was too rapid and too ancient to be effectively recovered using exclusively molecular data is explored. Support for differing hypotheses explaining the evolution of morphological characters such as, bifid setae, the kotopresse, and Maulik's organ (metafemoral apodeme) are explored. A reduced taxon data set involving a third molecular marker (cytochrome oxidase one) may be presented. This is the first analysis of the Chrysomelidae to use more than one molecular marker.

Phylogeny of the flea beetles (Chrysomelidae: Galerucinae: Alticini) based on three molecular markers

CN Duckett, KM Kjer
"Smithsonian Institution, NHB MRC105, P.O. Box 37012, Washington, DC USA 20560-7012; duckett.catherine@nmnh.si.edu"

The flea beetles (Galerucinae: Alticini) are notable in the lack of taxonomic consensus describing the relationships between the genera and their relationship to the traditional "galerucines". As the first part of a larger study of the phylogeny of the flea beetles, a phylogeny of the flea beetles using over 100 representative genera from all continents and based on fragments of large and small subunit nuclear ribosomal DNA (18S V7-9 and 28S-D2) and cytochrome oxidase I molecular markers is presented and discussed. Genera from the Galerucinae s.s. and 9 Chrysomelinae genera are also analyzed. Phylogenetic analyses are performed using parsimony and maximum likelihood techniques; the alignment was generated using secondary structural models. Support for the monophyly of the well-recognized taxonomic groups, Oedionychina, Monoplatina and Disonychina is discussed. Support for other groupings previously, recognized or not, is also discussed. Phylogenies resulting from separate and combined analyses of each data set will be presented; the 28S data set offers significant synapomorphies for some clades. Hypotheses describing the loss of Maulik's organ (the metafemoral apodeme) and evolution of endophagy in the Galerucinae s.l. will be presented and discussed.

The challenge of insect taxonomy in developing countries: A case study of the genus *Oribius* Marshall (Coleoptera: Curculionidae) in Papua New Guinea

MM Ero, G Monteith
"The National Agricultural Insect Collection, P.O. Box 1691, Boroko, NCD, Papua New Guinea;
narikila@global.net.pg"

Taxonomists of the developing tropical nations have a constant challenge of how to identify their diverse native faunas, without having to rely entirely on international colleagues. A study of *Oribius* Marshall (Curculionidae: Celeuthetini), a genus with agricultural importance endemic to New Guinea and Australia, is used as a case study to illustrate this issue. Objectives of the project were to provide working keys to pest species of *Oribius* for agricultural researchers, while at the same time developing a taxonomic synopsis of the remainder of the genus. The study was conducted in Papua New Guinea by National scientists, with collaborative support from Australia. Operational and taxonomic challenges included the limited availability of: national systematists, keys, type specimens, literature and operating funds. Ultimately the identifications of five out of seven pest species were confirmed: the remaining two pest species may be undescribed. Very limited advances could be made on the remaining 40+ non-pest species. This project demonstrates that development of local expertise is a better model than the historical one of simply sending specimens off for identification to international experts. However, it does highlight the enormous need for true collaboration between scientists from developing and developed countries.

Evolutionary trends in derelomine flower weevils: from associations to homology

NM Franz, R de Melo Valente
Department Of Entomology, Cornell University, Ithaca, NY 14853, USA; nmf2@cornell.edu

Derelomine flower weevils (Curculionidae: Derelomini) have longstanding, remarkably specialized associations with palms and other plants such as members of the Neotropical family Cyclanthaceae. Recent morphological phylogenetic analyses, particularly of taxa related to *Phyllotrox* Schoenherr and *Celetes* Schoenherr, are starting to provide a context within which these life histories can be analyzed and explained. The results send a mixed, though exciting message. Host plant associations - understood at an appropriately deep level - are often as informative phylogenetically as other traits. Yet the picture emerging from natural history studies is more complex. Certain lineages of weevils are not only restricted to a limited set of related host plants. They also display an array of morphological, ecological, and behavioral adaptations that are *correlated* with phylogenetic transformations in inflorescence morphology and phenology. A truly adequate language for these phenomena requires that we regard "host plant associations" merely as a starting point for evolutionary analyses. More in-depth studies of selected interactions should aim at making narrower homology statements, and view the plants as entities that have come up with their own responses to a range of beneficial or detrimental interactors. In the case of derelomine flower weevils, this approach will probably teach us more.

A phylogenomic approach to spider silk gene diversification

JE Garb, CY Hayashi
Department of Biology, University of California, Riverside, CA 92521 USA; jessicaga@ucr.edu

Spiders are unique in their ability to spin multiple types of task-specific silks. Each type of spider silk is composed of exceptionally long protein molecules (fibroins) that are synthesized in specialized silk glands. Several lines of evidence demonstrate that a large gene family encodes the different fibroins. To date, only a small fraction of the silk gene family has been characterized at the nucleotide level. Moreover, the silk genes sequenced thus far are sampled from a small number of species. In order to reconstruct the evolutionary history of the spider silk gene family, we are using a comparative approach to isolate novel silk gene sequences from a phylogenetically broad spectrum of spiders. Specifically, we have constructed and are screening cDNA libraries for novel silk transcripts from diverse taxa. We have also sequenced ESTs from these cDNA libraries in order to develop nuclear markers from which we are generating a spider species-tree. Using the species-tree in conjunction with the silk-gene tree, we will infer the number of duplications and losses of silk gene homologs.

Mitochondrial phylogenetics of UK Eurytomids

H Ghajarieh, M Bruford, HA Dawah
Tehran University, Aburayhan Faculty, Department of Plant Protection, PO Box 39754; 2
hghajarieh@yahoo.co.uk

The aim of this study was to investigate the taxonomic limits of species within four Eurytomid genera namely *Eurytoma* Illiger, *Tetramesa* Walker, *Ahtola* Claridge and *Sycophila* (Walker). In order to further clarify the taxonomic status of the genera: including *Tetramesa*, *Eurytoma*, *Ahtola* and *Sycophila*, mitochondrial DNA sequence analysis revealed differentiation between the above Eurytomidae genera. With the sequence data, the monophyletic status of three of these genera is well supported by all methods of phylogenetic reconstruction. Only *Tetramesa*, which is by far the most specious taxon studied here, seems polyphyletic, but even in this case, there are certain relationships within the group that are interesting from both a morphological and host preference point of view. For example, *T. petiolata* (Walker) and *T. airae* (von Schlechtendal), which are both herbivores of *Deschampsia cespitosa* (L.) (Beauv.) group together and two clusters contained all species that use *E. repens*, i.e. *T. linearis, T. hyalipenis* (Walker) and *T. cornuta* (Walker). Another result of this analysis supports the validity of *Ahtola* as a separate genus which was previously uncertain.

Molecular phylogeny of Micropterigidae (Lepidoptera)

GW Gibbs, Y Kobayashi, H Suzuki, S Hashimoto, DC Lees, M Sugimoto, T Saigusa
School of Biological Sciences, Victoria University, PO Box 600, Wellington, New Zealand; george.gibbs@vuw.ac.nz

Micropterigidae are tiny, sedentary, forest moths consisting of about 120 species in 10 genera. The family has been provisionally divided into two groups, the '*Micropterix*-group' (*Micropterix* only) and the '*Sabatinca*-group' (nine other genera), but their relationships remain obscure. Our study sequenced portions of the mitochondrial 16S rRNA gene of about 50 species in 12 genera including three unnamed generic taxa. Phylogenetic analyses revealed five major clades in this family. The analysis confirms the monophyly of *Micropterix* (100% support) in the Northern Hemisphere. However, the '*Sabatinca*-group' taxa comprise a complex of 4 clades of which the majority are Southern Hemisphere, with the exception of Asian genera (*Neomicropteryx*, *Palaeomicroides*, *Paramartyria*, and *Vietomartyria*) and North American *Epimartyria,* which formed a monophyletic group (bootstrap value 100%). The remaining southern taxa form 3 clades: *Sabatinca s. str*. (100% support) restricted to New Zealand and New Caledonia, a weakly connected group (53% support) containing "*Sabatinca" porphyrodes*, the S. American *Hypomartyria*, the S. African *Agrionympha*, two undescribed species from Madagascar and two Costa Rican unnamed genera, and finally a distinctive Australasian group with species in Eastern Australia, New Zealand and New Caledonia (100% support). Although the basal relationships among these clades remain unclear, it is suggested that divergence of some major lineages in Southern Hemisphere can be related to the breakup of Gondwana.

A preliminary phylogeny for the subfamily Chrysomelinae (Coleoptera: Chrysomelidae)

CAM Reid, E Grobbelaar
South African National Collection of Insects, Biosystematics Division, ARC - Plant Protection Research Institute, Private Bag X134, Pretoria, Queenswood 0121, South Africa; vreheg@plant5.agric.za

The morphological characters of insect immatures are often used in systematic analyses of insect relationships, but rarely given parity with adult morphological characters. One reason for this inequality is that immatures are often unknown; another is that adult characters are considered to carry greater phylogenetic weight. In Coleoptera, larvae provide considerable information in phylogenetic analyses of the Adephaga, but are little used elsewhere. The Chrysomelidae, subfamily Chrysomelinae, is a large group of phytophagous beetles with a classification that has changed little over the past 150 years. The known larvae are external plant feeders and easy to rear. Many species have been reared and many authors, including W. Hennig, have noted that larval morphology does not match the adult classification currently in use. Here we explore the use of larval morphology in chrysomelid systematics, using the Chrysomelinae as an exemplar taxon. The contrasting adult and larval morphological information is compared with phylogenetic signal provided by DNA sequence data.

Monophyly & phylogenetic relationships in basal Dermaptera

F Haas
"Staatliches Museum für Naturkunde Stuttgart, Rosenstein 1, D-70191 Stuttgart, Germany;
haas.smns@naturkundemuseum-bw.de"

The monophyly and phylogenetic relationships in Dermaptera are examined with new character systems and characters previously used for identification purposes. Dermapteran monophyly is difficult to assess because some basal taxa reduced character systems with compelling synapomorphies. Examples are highly modified hind wings, which are often reduced, and the ovipositor. The situation is further complicated through the Arixenina and Hemimerina, which live on bats (Sarawak) and hamster rats (sub-Saharan Africa). They are morphologically so strongly modified (wingless, cerci not forceps-shaped, viviparous) that at times they were ranked as separate ‚orders'. Recent research, however, indicates close relationships to Spongiphoridae and Apachyidae. Characters for monophyly, including Arixenina and Hemimerina, are lateral overlapping of abdominal tergites and sternites and holocentric chromosomes, both character states only occur in distantly related taxa. Many characters are not convincing as dermapteran autapomorphies as they also occur in potential sister groups of Dermaptera, while evidence from them is conflicting: single-annulus cerci (‚one segment'), maternal care, hind wing folding. For the first time the ovarian, spermathecal and tarsal structure of a number of basal taxa is examined and interpreted phylogenetically. These new character systems provide support for currently recognized ‚families' as monophyletic taxa.

On the fly: an interactive identification key to Australian fly families

JR Hamilton, DKYeates, A Hastings, DH Colless, DK McAlpine, D Bickel, PS Cranston, MA Schneider, G Daniels, S Marshall
CSIRO Entomology, PO Box 1700, Acton, ACT, 2601, Australia; Joanna.hamilton@csiro.au

There are 104 families of flies known from Australia and the only comprehensive identification guide to these groups is found in *The Insects of Australia* (CSIRO). This key is technically challenging and difficult for non-taxonomists to use. We are currently developing a computer-based interactive (polyclave) key to Australia's fly families using Lucid©, called "On-The-Fly". The key divides the families into four broad groupings (Lower Diptera, Lower Brachycera (including Lower Cyclorrhapha), Calyptrata and Acalyptrata). The family keys are accessed via a key to the four groupings, and a section to assist in distinguishing true flies from similar insects belonging to other orders. On-The-Fly is richly illustrated with images of character states, and live images of representative species. There will be a taxon information page on each family, including information on diversity, biology, ecology and pest status. The key is a complete educational tool with general information about fly biology, classification, collection, curation, links to literature and websites. The software package is greatly enhanced for education with the inclusion of an interactive glossary of fly anatomy for use in conjunction with the key. On-The-Fly is under development and a beta version will be demonstrated.

Comparison of life history traits including diapause regulation among four species of water striders, *Aquarius paludum*, *Gerris latiabdominis*, *G. nepalensis* & *G. gracilicornis* living at 33ºN

T Harada

Laboratory of Environmental Physiology, Faculty of Education, Kochi University, Kochi 780-8520, Japan; haratets@cc.kochi-u.ac.jp

The four species of Japanese common water striders, *Aquarius paludum, Gerris latiabdominis, G. nepalensis and G. gracilicornis* overwintered as adults which entered reproductive diapause. Even though populations of the four species were living in Kochi (33ºN) located in a critical area between warm temperate and subtropical zones, they showed very high variation in the duration of diapause period, from three (*G. nepalensis*) to nine or ten (*G. gracilicornis*) months. All of *G. gracilicornis* and majority of *G. latiabodominis* adopted obligatory diapause, although part of individuals in *G. latiabdominis* populations showed facultative diapause: long-days induce reproduction and short-days diapause. *Aquarius paludum* and *G. nepalensis* entered reproductive diapause, when they were grown under short days. *Gerris nepalensis* and *A. paludum* adopted facultative diapause, responding to photoperiod and temperature to make up bi- or trivoltinism in Kochi. Eggs and adults of *A. paludum* inhabiting temporary to permanent water surfaces had higher drought-hardiness than those of *G. nepalensis* which lived exclusively permanent habitat. The short active period shown by *G. latiabdominis* seems to be caused by short season of March to July when paddy fields as their main habitat filled with water. The four species showed a high variety of life history traits including diapause regulation.

A cortical conundrum: New Zealand's scribbler & the biogeography of Cecidosidae (Lepidoptera: Incurvarioidea)

RJB Hoare
Landcare Research, Private Bag 92170, Auckland, New Zealand; hoarer@landcareresearch.co.nz

The long bark-mines made by New Zealand's 'kamahi scribbler' on the trunks of several species of rainforest tree were first noticed in the 1950's, but the insect responsible was not reared through until 1990. It proved to be a moth belonging to the primitive (non-ditrysian) superfamily Incurvarioidea, and remains the only known member of this superfamily native to New Zealand. Study of larval, pupal and adult morphology revealed that it shared several synapomorphies with the Cecidosidae, a family otherwise only known from South Africa and South America, where the larvae form galls on Anacardiaceae. The New Zealand 'scribbler' (*Xanadoses nielseni* Hoare & Dugdale) has recently been described as a cecidosid, and in a tentative phylogeny is considered to represent the basal taxon in the family. Whilst the proposed phylogeny is congruent with the timing of the break-up of Gondwana, the apparent absence of Cecidosidae from the rich incurvarioid fauna of Australia remains to be explained.

Phylogeny & biogeography of Archostemata (Coleoptera), with special emphasis on the Australian monophyla

T Hörnschemeyer
Institute for Zoology and Anthropology, Dept. Morphology and Systematics, Berliner Str.28 D-37073 Göttingen, Germany; thoerns@gwdg.de

With 40 extant species the Archostemata are the smallest suborder of Coleoptera. Nevertheless, these species are important for the study of the evolution of Coleoptera because they seem to have hardly changed morphologically during the last 200 Mio. years. The oldest known fossil beetles in many respects are very similar to the extant Archostemata. By studying this taxon we can expect to significantly increase our knowledge about the original morphology of Coleoptera. Another aim of this investigation was to reconstruct the species level phylogeny of the Archostemata. For this purpose, an investigation of their morphology was done, including high-resolution X-ray tomographic studies of a number of species. This method was used to gain as much information as possible from the few available specimens of these rare species. A main result is the identification of an Australian monophylum. This evolutionary young taxon includes *Distocupes*, *Ascioplaga* and *Adinolepis*, which are endemic for Australia and New Caledonia. Their most closely related group are the *Tenomerga*-species from Asia and South-East Asia. The evolutionary history of these groups goes back to the late Cretaceous. Nevertheless, at least some of the extant species might have had their origin at the end of the last ice

Successes & snags of continental island arthropod inventories: case studies in New Caledonia, Madagascar, & Fiji

EI Schlinger, ME Irwin, NL Evenhuis
"Spider Parasitoid Laboratory, PO Box 1421, Santa Ynez, CA 93460. 1101 USA. newacrofly@earthlink.net."

Continental island bioinventories can provide a wealth of information about the evolution of entire groups of poor dispersing organisms that arose before or during the Jurassic by relating evolutionary radiation and extinction events to the separation and attachment of drifting continents from or to other land masses. Inventorying arthropods has been an ongoing activity of ours. Over the past 15 years, much of our efforts have focused on flies (Diptera) of islands confirmed or believed to be continental in origin. We have conducted bioinventories on three island chains, New Caledonia in the 1990s, Madagascar in the late 1990s (still ongoing), and Fiji in 2003 (just getting underway). As bioinventories have transitioned from one island to another, we have gained considerable knowledge of how to conduct them and how to increase the probabilities of collecting not just greater quantities of material, but encountering those species that seem rare. We will share this knowledge and inform the audience of the difficulties in properly coordinating specimen storage, sorting, curation, and identification tasks. Beyond that we provide evidence of the importance of these inventories to global concepts in the evolution and biogeography of specific groups of flies.

Preliminary investigations on the evolution of true land bugs (Hemiptera: Heteroptera)

M Javahery
c/o Lyman Entomological Mus. & Research Lab., PO Box 140, Macdonald Campus of McGill University, 21111 Lakeshore, QC H9X 3V9 Canada; javahery@allstream.net

The reproductive morphology, embryogenesis and characteristic of eggs in two infraorders of the hemipteran suborder Heteroptera were studied in representatives of five families in Cimicomorpha and 11 families of Pentamomorpha. All together, 65 species from 45 genera belonging to the families Miridae, Nabidae, Phymatidae, Reduviidae, Tingidae, (Cimicomorpha); as well as Acanthosomatidae, Alydidae, Aradidae, Pyrrhocoridae, Rhopalidae, Scutelleridae, and Thyrecoridae (Pentamomorpha) were investigated. The bugs were collected in the Nearctic and Palearctic regions, mainly in Canada, England and Iran. A comparative study of male and female reproductive systems, male aedeagus and female ovipositor, development of eggs, egg burster, and characteristics of egg shells have been studied. The results indicated the two infraorders are probably sister groups, and various shaped eggs in these groups have evolved independently, and along different path ways from an ovoid ancestral egg. The collected data is a valuable resource for tracing the evolution and phylogeny of the above two heteropteran infraorders.

Australasian Aulacidae (Hymenoptera: Evanioidea), endoparasitoids of wood-boring beetles & wasps

JT Jennings, AD Austin, NB Stevens
"Centre For Evolutionary Biology & Biodiversity, School Of Agriculture & Wine, Waite Campus, The University Of Adelaide, Po Box 1, Glen Osmond, SA 5064, Australia; john.jennings@adelaide.edu.au"

The Aulacidae is a family of parasitic wasps that are endoparasitoids of wood-boring sawflies (Xiphyiidae) and beetles (Cerambycidae and Buprestidae). Until recently, the Australian fauna comprised 34 described species (18 *Aulacus* and 16 *Pristaulacus*), primarily from the wetter forested areas of the east coast of Australia. Just one species from New Guinea was described and they were unknown from New Caledonia, New Zealand and the other island groups of the south-west Pacific. However, based on specimens in museum and other collections, the aulacid fauna of the region is likely to exceed 100 species. The distribution of the group has been substantially expanded with new species known from south-west Western Australia, the arid interior of Australia, and from New Caledonia. This paper presents data on the distribution of these wasps in the Australasian region and discusses a range of characters and character states to be used in a phylogenetic analysis. Characters investigated include those associated with sculpturing, wing venation, and the ovipositor guide.

Phylogeny of the Gelechioidea: evolution of larval food substrate use

L Kaila
Zoological Museum, Finnish Museum of Natural History, P.O. Box 17, FI-00014 University of Helsinki, Finland; lauri.kaila@helsinki.fi

The phylogeny of the lepidopteran superfamily Gelechioidea was estimated using 193 characters derived from larval, pupal and adult morphology and larval ecology. 143 species represented the diversity of the putative Gelechioidea in the analysis, and further 13 species representing three monotrysian and eight other ditrysian families were included to test the monophyly of the Gelechioidea. The Gelechioidea was nested within Apoditrysia instead of being its sister group as previously suggested. The well-resolved cladogram suggested a largely different concept of interrelationships of constituent gelechioid families as compared to other studies. The Gelechioidea was basally divided into two main lineages, herbivory as the ancestral larval feeding strategy of one, and, depending on character optimization, either saprophagy or herbivory of the other. Therefore it is not possible to unambiguously determine which of these traits is the ancestral one in the Gelechioidea. It is also sometimes questionable whether such a classification of the food substrate can be applied, .e.g. if the larva uses dry seeds and other dry vegetable matter. Detritivory/fungivory may have evolved only twice within Gelechioidea, though the evolution of larval food substrate use has been quite dynamic with frequent reversals.

Basal phylogenetic relationships in Dictyoptera

K-D Klass, N Lo, R Meier
Staatliche Naturhistorische Sammlungen Dresden, Museum für Tierkunde, Königsbrücker Landstrasse 159, 01109 Dresden, Germany; klaus.klass@snsd.smwk.sachsen.de

Monophyly of Dictyoptera is supported through (1) perforation in tentorium; (2) female subgenital plate by coxosternum 7, bearing a dorsal vestibular sclerite; (3) packing of eggs in an ootheca built by accessory glands of abdomen 9; (4) paratergal insertion of abdominal spiracle dilators. For reconstructing dictyopteran phylogeny male and female genitalia (mostly reduced in Isoptera) and the proventricle are most informative. Cladistic analysis of morphological and life-history characters strongly supports Isoptera as the sister group of Cryptocercidae, hence as nested within Blattaria. Cladistic analyses using 107 characters of the exoskeleton and musculature of male genitalia suggest [Blattidae + (Tryonicidae + ((Cryptocercidae + (Lamproblattidae + Polyphagidae)) + (Anaplectidae + (paraphyletic Plectopterinae + (Blattellinae + Nyctiborinae + Ectobiinae + Blaberidae)))))] for Blattaria, and [Mantoididae + (Chaeteessidae + (Metallyticidae + remaining Mantodea))] for Mantodea; however, the taxon sample (currently 25 taxa) will have to be extended. Sequences from 12S, 16S, and 18SrDNA and COII also suggest Isoptera to be sister to Cryptocercidae, and sequences from *Blattabacterium* fat-body endosymbionts confirm this; however, the Cryptocercidae-Isoptera clade appears as sister to Blattidae.

Mantophasmatodea: important aspects of the skeleto-muscular system and internal organs

K-D Klass, G Pass

Staatliche Naturhistorische Sammlungen Dresden, Museum für Tierkunde, Königsbrücker Landstrasse 159, 01109 Dresden, Germany;
klaus.klass@snsd.smwk.sachsen.de

Mantophasmatodea are Pterygota due to the absence of a non-cuticular endoskeleton and lateral parts of abdominal tergum 11, and Neoptera due to the presence of typical abdominal spiracle muscles and apodemes. Morphological peculiarities (autapomorphies) are: (1) specialized antenna structure: basiflagellomeres without constrictions between them, only with coarse setation, the distal ones showing a secondary subdivision; 7 distiflagellomeres, 1st very long, 2nd very short, all separated by constrictions and with fine setation; (2) strongly angled course of subgenal sulcus, depending on a dorsal shift of the origins of the anterior tentorial arms; (3) medioventral projection on male subgenital plate (for umming); (4) conspicuously blunt tip of gonapophyses 8 in ovipositor; (5) small dorsal projection in membrane beyond 3rd tarsomere. Proventricle resembling that in Notoptera. Circulatory organs: no lateral arteries in abdomen; antennal circulatory organs consisting of non-pulsatile ampullae and vessels with a characteristic double-layered wall (inner epithelium strongly resembling the transport epithelium so far reported only from antennal vessels of Dictyoptera); female cerci without distinct circulatory organ.

Early embryonic development of basal Lepidoptera

Y Kobayashi, EH Ando
Department of Natural History, Graduate School of Science, Tokyo Metropolitan University, Minami-Ohsawa 1-1, Hachioji-shi, Tokyo 192-0397, Japan; kobayashi-yukimasa@c.metro-u.ac.jp

Lepidoptera are generally regarded as the insect group whose embryogenesis is well known. From the phylogenetic standpoint, however, the materials have been concentrated on the highest group or Ditrysia, and no embryological work appeared on the lower non-ditrysian Lepidoptera until about 25 years ago when we started to wok on the embryogenesis of the basal Lepidoptera. Since then much information has been accumulated on the embryogenesis of such non-ditrysians as *Neomicropteryx* (Micropterigidae), *Eriocrania* (Eriocraniidae), *Endoclita* (Hepialidae), *Mnesarchaea* (Mnesarchaeidae), *Stigmella* (Nepticulidae), and *Nemophora* (Adelidae). Then large differences have been found especially in the early developmental processes among these and ditrysian Lepidoptera and these embryological data are also expected to afford significant means for tracing the phylogenetic relationships among major lepidopteran lineages. We will discuss some major differences and their phylogenetic implications: (1) The thickness of the blastoderm, very thin in *Neomicropteryx*, relatively thick in *Eriocrania*, *Stigmella*, and *Nemophora*, but very thick in *Endoclita* and *Mnesarchaea*. (2) The shape and size of the germ disk. (3) The mode of formation of the germ rudiment and embryonic membranes, the invaginate type in *Neomicropteryx*, *Endoclita*, and *Mnesarchaea*, the amnio-serosal fold type in *Eriocrania*, and the fault type in *Stigmella* and *Nemophora*.

Morphology of insect tagmata and phylogenetic implications

M Koch
Free University of Berlin, Institute of Biology, Königin-Luise-Str. 1-3, 14195 Berlin, Germany;
mkoch@zoosyst-berlin.de

The distinctive body division into three tagmata (head, three-segmented thorax, eleven-segmented abdomen) still represents the main argument for the monophyly of the Hexapoda. Recent molecular studies, however, challenged the view that the corresponding tagmatization of the trunk is an apomorphy. Presently competing hypotheses either assume that hexapods are derived from an already tagmatized ancestor or suggest paraphyly of Hexapoda. According to the latter, the hexapod tagmosis evolved convergently in at least Collembola and the "true insects" (i.e. Ectognatha). In order to test these hypotheses, the morphological evidence is revised. Special attention is awn on the skeleto-muscular system of primarily wingless insects, on which new data are presented. Comparisons with the state in Protura and Diplura permit to reconsider their relationship to the remaining hexapods. Insights obtained are discussed with respect to current assumptions that Remipedia or Malacostraca within the previous Crustacea may form the insects' closest relatives.

A phylogenetic study of the ant- and bee-loving soft scale insects of the world (Hemiptera: Coccoidea: Coccidae)

T Kondo, ML Williams
Department of Entomology, University of California, One Shields Avenue, Davis, CA 95616, USA; tkondo@ucdavis.edu

In the Coccidae, the subfamily Myzolecaniinae is composed of soft scales that exhibit a strong bond with ants. These coccids are one of the most derived groups in the Coccidae, having morphological features that have evolved in such a way that these scale insects can no longer survive without attendance by their ant symbionts. The subfamily Myzolecaniinae (*sensu* Hodgson, 1994) contains the following genera: *Akermes*, *Alecanium*, *Alecanopsis*, *Cribrolecanium*, *Cryptostigma*, *Cyclolecanium*, *Halococcus*, *Houardia*, *Megasaissetia*, *Myzolecanium*, *Neolecanium*, *Paractenochiton*, *Pseudophilippia*, *Richardiella*, *Toumeyella* and *Xenolecanium*. The Myzolecaniinae have a worldwide distribution and are thought to be composed of several non-related genera which share common characters such as: the reduction in size of legs, antennae and anal tube; the increase in size of spiracles; lack of eyespots; and other shared characters that could be a result of parallel evolution. The objectives of the present study were: 1) to resolve classification conflicts within the subfamily Myzolecaniinae; and 2) to identify monophyletic groups and lineages within the subfamily. A total of 100 morphological characters from adult females and first instar nymphs were used. One new subfamily, the Toumeyellinae, and the *Alecanopsis*-group are proposed.

Some key events in the structural evolution of basal heteroneuran Lepidoptera

NP Kristensen
Natural History Museum of Denmark, Copenhagen University, Universitetsparken 15, DK-2100 Copenhagen Ø, Denmark; npkristensen@zmuc.ku.dk

While the phylogeny of the homoneurous-grade moth superfamilies has been at least preliminarily resolved, much uncertainty remains about the interrelationships of the non-ditrysian and basal ditrysian Heteroneura. For some notable character transformations plesiomorphic and apomorphic states are known to occur, respectively, among the homoneurans and the advanced ditrysians, and multiple discrete steps may be recognizable in the transformation series. Establishing the occurrence of the apomorphic state(s) in basal heteroneurans is, then, of considerable interest for phylogeny reconstruction. Cases discussed include (1) the proboscis base and its extrinsic musculature, which in basal glossatans differ but little from the generalized endopterygote type ascribed to the lepidopteran ground plan, but which are highly modified in 'typical' (ditrysian) Lepidoptera; (2) the ocellus with its diversity in 'vitreous body' and cornea morphology; (3) the testicular sperm with the complex 'lacinate appendages' in 'typical' ditrysians.

The basal splitting event recognizable in extant winged insects: the morphological evidence

NP Kristensen
Natural History Museum of Denmark, Copenhagen University, Universitetsparken 15, DK-2100 Copenhagen Ø, Denmark; npkristensen@zmuc.ku.dk

Morphological evidence bearing on the question of the relations between the conventionally recognized extant basal pterygote assemblages (mayflies, dragonflies and Neoptera) will be summarized; it has been awn from a suite of character sets in both immatures and adults. The bulk of the morphological evidence so far considered supports the monophyly of the taxon 'Metapterygota' (agonflies + Neoptera). Morphological evidence supporting the principal alternative hypothesis of a monophyletic 'Palaeoptera' (mayflies + dragonflies, retrieved in recent rDNA analyses) is more ambiguous, and that supporting a monophyletic 'Chiastomyaria' (mayflies + Neoptera) even more so. While neopteran monophyly has been accepted by most insect systematists, it has been questioned for some time by Rasnitsyn and his coworkers, and indeed it deserves more scrutiny.

The origin & early history of leaf mining

CC Labandeira
"Smithsonian Institution, National Museum of Natural History, Paleobiology, P.O. Box 37012, Washington, DC, 20013-7012, USA; labandec@nmnh.si.edu"

Leaf mining is the only major insect functional feeding group whose earliest occurrence is documented in the Mesozoic, rather than the Paleozoic. Currently dominant on angiosperms, the earliest demonstrable fossil leaf mines are present on a variety of gymnospermous seed-plant clades, including the ginkgophytes *Paraginkgo* and *Sphenobaiera*, the probable bennettitalean *Dejerysea*, the herbaceous broad-leaved conifer *Heidiphyllum*, the ubiquitous peltasperm seed-fern *Dicroidium*, and a fern. These mines occur in the Late Triassic Molteno Formation in South Africa, dated at approximately 225 Ma and precede the earliest angiosperms by 90 million years. Culprits are probably coleopterans. With the exception of two other Gondwanan Triassic occurrences, a leaf-mining hiatus persists until the Jurassic-Cretaceous boundary, from which sinusoidal mines are found on another peltasperm seed-fern, *Pachypteris*, from the Battle Camp Formation of northern Queensland, Australia. The Dakota Formation of the United States, redated as latest Early Cretaceous, has yielded 10 leaf-mine types, representing the lepidopteran families Nepticulidae and Gracillariidae. They colonized basal dicotyledonous clades, including the Platanaceae, and taxa best assigned to the Chloranthaceae and Lauraceae. These data indicate that leaf mining first originated in Gondwana, opportunistically invading several gymnosperm and fern clades, and later underwent a radiation on basal dicotyledonous angiosperms in Laurasia.

Rewards & challenges of global, collaborative taxonomy: the paradigm shift offered by PEET

CL Lambkin, ME Irwin, GE Kampmeier, DK Yeates, BM Wiegmann
"CSIRO Entomology, GPO Box 1700, Canberra ACT, 2601, Australia; chris.lambkin@csiro.au"

The history of taxonomy is dominated by single author contributions, ranging in scope from single species descriptions to monographs. The NSF PEET program offers taxonomists the opportunity to explore a paradigm common in other sciences: multi-nodal, multi-authored collaborations. A major challenge for the 10-year therevid PEET project was coordinating global collaborative taxonomies of this medium-sized fly family (4,000 species). An international team including principal investigators, postdocs, 7 PhD and 4 Masters Degree students have monographed taxonomic "parcels", in a largely bottom-up approach. To date, over 47 papers on systematics, biology, biogeography, and morphology of therevids have been published through this global PEET collaboration, and a world catalog of Therevidae is planned. Tension developed between the necessity for students to work on manageable groups and the need for a family-level overview. The phylogenies for the family were developed through an iterative process, from both molecular and morphological datasets, with feedback between top-down and bottom-up approaches. Collaborative efforts, efficient communication, and continual innovation contributed to the development of the Mandala databases that manage taxonomic nomenclature, literature, illustrations, and over 122,000 specimens resulting from extensive worldwide expeditions and loans from over 200 collections. Yet concerns persist over ensuring data quality and addressing the long term maintenance of the data and database structure when the project terminates. This new collaborative paradigm is the future if we are to address taxonomic challenges posed by large, widespread groups in reasonable timeframes.

Digitized insect specimen access: new digitization tools

K-H Lampe
Zoologisches Forschungsinstitut & Museum Alexander Koenig (Zfmk), Adenauerallee 160, 53113 Bonn, Germany; k.lampe.zfmk@uni-bonn.de

In practise the overall efficiency of databasing the inventory of traditional entomological collections depends on two factors: suitable software and management measures to ensure the highest possible data quality already in the input process. Lessons learned from the development of the specimen-based database BIODAT, from the DORSA- (Digitized Orthoptera Specimen Access) project and preliminary results of the DIG-(Digitization of key Insect groups at ZFMK) project, which is especially designed to develop a 'good practise', recommend: (1) a lockstep programme for data-basing, (2) split record function, (3) visualisation of geo-referenced locations/sites during data entry, (4) semi-automatic/automatic data transformation from original format into alternative ones, (5) semiautomatic data transfer of taxo- and geo-referenced information units. Current activities deal with the introduction of semantic feedback mechanisms into the practise of data-basing entomological collections.

Three extraordinary genera of Dermestidae (Coleoptera) & their phylogenetic significance

JF Lawrence, SA Slipinski
130 Hartwig Rd., Gympie, QLD 4570, Australia; beetle@spiderweb.com.au

Three new genera of Dermestidae are described. One, the second known member of the subfamily Orphilinae, is represented by three species in eastern and southern Australia, two of which are associated with a conglobate and probably myrmecophilous type of larva. Another, from extreme northwestern Australia, is a member of the Dermestinae and shares features with both *Dermestes* and the Marioutini. The third genus from Malaysia and Indonesia appears to be intermediate between *Thyloias* and the Trinodinae. A cladistic analysis is performed on a data set including 19 genera of Dermestidae, representing all subfamilies and tribes, plus outgroups from Eucinetidae, Derodontidae, Nosodenidae, Endecatomidae and Bostrichidae, and about 100 characters, a third of which are based on immatures. The resulting cladograms are compared with recent studies on dermestid phylogeny.
